Policing 802.11 MAC Misbehaviours

Paul Patras*, Member, IEEE, Hessan Feghhi*, David Malone, and Douglas J. Leith, Senior Member, IEEE

Abstract—With the increasing availability of flexible wireless 802.11 devices, the potential exists for users to selfishly manipulate their channel access parameters and gain a performance advantage. Such practices can have a severe negative impact on compliant stations. To enable access points to counteract these selfish behaviours and preserve fairness in wireless networks, in this paper we propose a policing mechanism that drives misbehaving users into compliant operation without requiring any cooperation from clients. This approach is demonstrably effective against a broad class of misbehaviours, soundly-based, i.e. provably hard to circumvent and amenable to practical implementation on existing commodity hardware.

Index Terms—Wireless LAN, 802.11, misbehaviour, policing, prototyping

1 INTRODUCTION

Computers equipped with Wi-Fi devices that follow the popular IEEE 802.11 specification [1] employ a decentralised Medium Access Control (MAC) protocol to coordinate their transmissions on the channel. By design, this mechanism ensures compliant users connecting to a wireless network receive equal opportunity of access to the medium and in this sense share resources in a fair manner. Each client station, however, operates independently and thus could act more aggressively in order to gain performance benefits, if changes can be made to the protocol behaviour. This already occurs in practice when network interface cards are not designed correctly, as reported in [2]. More critically, it can happen when users selfishly manipulate their channel access parameters to gain a performance advantage (see e.g. [3]). This can cause significant unfairness, with the performance of the users that obey the standard being severely degraded [4], [5]. For example, consider a real network with two backlogged stations, one of them compliant and the other using a minimum contention window (\(CW_{\text{min}}\)) half that recommended by the 802.11 standard. If the network operates with a regular access point (AP), the misbehaving user will transmit on average nearly twice as many frames as the compliant station. We illustrate this scenario in Fig. 1 with light bars. Also plotted with dark bars is the performance of each client when the AP runs the policing scheme introduced in this paper, demonstrating its effectiveness in penalising misbehaving clients and equalising attempt rates, thereby restoring fairness.

Such MAC misbehaviours are increasingly of concern as open-source device drivers (e.g. MadWifi [6], compatible wireless [7], etc.) are becoming prevalent and permit users to modify the protocol rules either from the command line or with basic programming knowledge. Looking ahead, the trend is towards introducing still further flexibility, such as versatile architectures that allow changing the MAC operation of commodity hardware, by reprogramming the protocol state machine with the help of simple visual tools [8].

In this paper we introduce an AP-based policing scheme for 802.11 Wireless LANs that is (i) demonstrably effective against a broad class of misbehaviours, (ii) soundly-
based, i.e. provably hard to circumvent, and importantly, (iii) amenable to practical implementation, as we demonstrate via prototyping on existing commodity hardware. With this policing scheme, the AP controls the transmission attempt rate of misbehaving stations by acknowledging their frames with a probability that depends on the deviation of the stations’ transmission attempt rate from the fair value. Decreasing the probability of acknowledgement causes a client station to backoff its contention window, thereby reducing its transmit rate and restoring fairness. An important feature of this approach is that it only requires measuring the transmit rate of each client station, which is straightforward as all traffic passes through the AP in the infrastructure operational mode, and does not require identification of the specific type of misbehaviour being performed (e.g. shorter backoff, frame bursting, etc.). This features make the proposed scheme particularly suitable for nomadic Wi-Fi hot spots set up using smart phones or pocket 3G routers, as well as mobile broadband network services on the move, e.g. in-flight Wi-Fi, wireless access on public transportation (buses, underground railway, etc.), and even hot air balloons that provide Internet connectivity to remote areas.\(^2\)

We provide a mathematical analysis of the proposed policing algorithm’s convergence properties and prove its robustness in the presence of users that can detect APs that penalise misbehaviour. More precisely, we show that any strategy that seeks to game our policing algorithm, deviating from the fair operation, necessarily leads to lesser goodput for a misbehaving station in the long run.

To establish the feasibility of our proposal, we present a prototype implementation of the policing algorithm on off-the-shelf hardware. We validate the performance of our implementation by conducting extensive testbed experiments over a wide range of misbehaviour scenarios. The results obtained demonstrate that our solution effectively penalises misbehaviour irrespective of the network size, number of selfish users and the parameters manipulated, without impacting negatively the operation of compliant stations. We also show that our algorithm does not mistakenly penalise compliant stations, even in complex situations where compliant stations generate different volumes of traffic and so some clients consume the air time underutilised by others. Further, we show that our proposal not only tackles MAC misbehaviour, but has no negative impact on state-of-the-art PHY rate control algorithms, while it successfully alleviates fairness issues that arise in practical deployments due to PHY/MAC interactions.

To the best of our knowledge, our proposal is the first AP-based MAC misbehaviour counteracting solution with theoretical performance guarantees and a fully functioning prototype implementation that has been extensively evaluated by way of experiments in a real Wi-Fi network. We summarise the key contributions of our work below.

1. We design a novel algorithm that, unlike previous proposals, not only addresses MAC misbehaviour
2. We specify a scheme that controls stations’ transmission attempt rates and is robust to adaptive misbehaving strategies that seek to game its operation;
3. We provide detailed proof of this robustness and rigorous analytical evidence of the algorithm’s convergence;
4. We detail a functional implementation of the designed system on real 802.11 hardware;
5. We give a sound methodology for estimating the maximum achievable attempt rate, without injecting traffic in the network or requiring changes to compliant stations;
6. We further validate the algorithm’s convergence properties with real experiments;
7. We provide a comprehensive performance evaluation of our scheme, running on commodity devices in a real deployment, covering a broad range of circumstances.

The rest of the paper is organised as follows. In Sec. 2 we review related work. In Sec. 3 we present the proposed policing algorithm and in Sec. 4 we analyse its convergence properties and its robustness to misbehaviour strategies that seek to game its operation. In Sec. 5 we detail the prototype we implemented on commodity hardware and in Sec. 6 we report the results of the experimental evaluation conducted under different network scenarios. In Sec. 7 we investigate the operation of our solution under more problematic channel effects. Finally, Sec. 8 concludes the paper.

2 Related Work

Misbehaviour detection has received much attention from the research community (see e.g. [3], [4], [9], [10], [11], [12], [13], [14], [15]). Existing work, however, largely focuses on how undesired behaviour can be achieved with current cards and on engineering solutions that assist the AP in identifying disobedient users, as well as the nature of their misbehaviour [4], [12], [13]. Only a limited number of proposals address counteracting greedy actions, and these suffer from significant practical drawbacks. For instance, [9] requires a reputation management system to prevent MAC layer misbehaviour, while a cross-layer interaction is assumed in [10] to enable higher layers to restrict the traffic that non-compliant clients generate.

In contrast to prior work, in this paper we introduce an effective policing scheme for 802.11 Wireless LANs (WLANs) that overcomes the above limitations, as it does not require modification of the protocol stack and is amenable to practical implementation. By design, a key benefit of our policing algorithm is that it does not require any information about the number of active stations or the nature of their misbehaviour.

The underlying principle behind our approach is to control the attempt rate of misbehaving clients by censoring the generation of MAC layer acknowledgements (ACKs). ACK skipping has been suggested as a means to allocate bandwidth for traffic prioritisation in a network of well-behaved stations [16], [17], [18], but to the best of our knowledge has not been implemented to date with real
devices, as this fundamental operation is handled at the firmware level.

The solution we propose leverages our previous design [19], but differs in that here: (I) we aim to control the transmission attempt rate instead of throughput, thus seeking to equalise stations’ air time [20]. By driving the channel access probabilities of all clients to the same value, regardless of the contention parameters they employ, we effectively preserve short-term fairness. (II) We allow carrying forward penalties, thus also achieve long-term fairness. Finally, (III) we guarantee that the mechanism cannot be gamed by greedy users that detect its operation.

3 POLICING ALGORITHM

In this section we first explain the class of misbehaviours our proposal tackles and then we detail the operation of the policing algorithm. We consider WLANs with a single-AP (or, alternatively a group of co-operating APs) operating in infrastructure mode, i.e. all packets are transmitted through the AP, as this is the default and most widespread operational mode of today’s Wi-Fi deployments.

3.1 Class of Misbehaviours

Our focus is on 802.11 MAC protocol misbehaviours. We do not consider lower layer PHY attacks, e.g. ACK jamming, or higher layer selfish behaviour, e.g. TCP acknowledgement manipulation or station association attacks. We also confine consideration to behaviours that seek to obtain performance benefits, rather than simply to disrupt the network operation through e.g. signal jamming [21], or exploiting security vulnerabilities [22].

Our interest in this class of greedy MAC behaviours arises from the observation that they can be realised with currently available open-source drivers that allow manipulation of the MAC layer parameters (CW\text{min}, CW\text{max}, AIFS and TXOP [1]), sometimes simply by issuing a single command on the system console (see e.g. iwpriv for Atheros-based cards). Note that, despite the possibility of broadcasting precise EDCA configurations by means of beacon frames from the AP, selfish clients are free to ignore any of the contention parameter values assigned through this (advisory) mechanism and the prevalence of such open drivers provides them sufficient incentives to do so.\(^3\) We assume WLANs implement an authentication mechanism such as Wi-Fi Protected Access (WPA2) [25], that prevents short and repeatedly aggressive sessions facilitated by MAC address spoofing techniques. Note also that the IEEE 802.11i standard ensures replay protection through several mechanisms, of which the use of CCMP (Counter Mode Cipher Block Chaining Message Authentication Code Protocol, Counter Mode CBC-MAC Protocol) or TKIP (Temporal Key Integrity Protocol) procedures are particularly relevant to our scheme. Thus, a selfish user will be unable to impersonate fair clients and jeopardise their reputation. Our work can be adapted also to open-access networks, by augmenting it with a signal-strength based MAC layer spoofing detector [26] or a passive device fingerprinting tool [27].

\(^3\) Consequently, earlier TXOP-based allocation approaches (e.g. [23], [24]) do not provide effective policing when stations are misbehaving. The resilience of our proposal to more sophisticated security attacks can be further strengthened if used in combination with fine-grained PHY layer information [28].

3.2 Controller Operation

To tackle this class of misbehaviours, we propose that the AP exploits the fundamental nature of the acknowledgements within the ARQ mechanism of 802.11. Specifically, we use the fact that stations will increase their contention window and re-attempt to deliver a frame that was not acknowledged before sending the next packet. By appropriately suppressing ACK generation for cheating users, the AP can therefore reduce their transmission rate and drive them to fair operation.

We consider WLANs that operate in a commercial setting where the service provider seeks to monetize connectivity and thus a naïve solution that simply disassociates users with marginal, possibly accidental misbehaviour (see e.g. [2]), would be operationally unacceptable. Instead, our goal is to effectively correct such behaviours. It is possible though that a misbehaving station does not increase its contention window despite not receiving ACKs. For such blatantly and deliberately misbehaving stations, it is not possible to use ACK suppression to drive the station to fair operation and instead the policing algorithm adapts to drop all ACKs and associated data packets, reducing the goodput of such misbehaving stations to zero and eventually disassociating them from the network.

The key to the performance of this algorithm is the manner in which we adjust the penalty \(p_i(t)\) associated to a misbehaving user \(i\) and the corresponding ACK suppression rate \(P_{\text{ACK}}(i)(t)\) at each time step \(t\) of its execution. The underlying principle is to compute a penalty \(p\) that is proportional to a station’s deviation from the expected fair behaviour, and apply that penalty in the next step or, in case of gross deviations, across multiple iterations. The ACK suppression rate is the probability with which a received frame is acknowledged, i.e. \(\min\{p_i, 1\}\), and is directly responsible for regulating a station’s transmission rate in the next interval. Algorithm 1 details the operation of the proposed approach.

For each station, the algorithm works as follows. At each execution step \(t\), it compares the measured station’s transmission attempt rate \(x_i(t)\) against the fair value \(\bar{x}(t)\). When the attempt rate\(^4\) is above the fair value, the rate of ACK suppression is increased, and vice-versa when the attempt rate is below the fair value. Thus at a fixed point we have \(x_i(t)/\bar{x}(t) = k\) and consequently the station’s attempt rate is driven to the fair value.\(^5\)

The algorithm requires an estimate of the maximum fair transmission attempt rate. That is, the transmit rate that would be achieved by a client station employing the standard recommended 802.11 MAC configuration. In Sec. 5.2 we discuss in detail how to estimate this quantity and show that the AP can perform this operation on commodity 4. We use the term “attempt rate” to refer to the stationary probability that a station transmits a frame in a randomly chosen slot time. Note that this does not refer to the PHY layer bit rate achievable with various modulation and coding schemes (MCS).

5. Note that, to streamline notation, we will often drop the \(i\) subscript from now on, provided there is no scope for confusion.
Algorithm 1 Determining the rate of ACK suppression.

Estimate the maximum fair transmission attempt rate \( \bar{x}(t) \), given the current network conditions;

for each associated client station \( i \) do

Measure transmission attempt rate \( x_i(t) \) of the station;

Update the penalty:

\[
p_i(t + 1) = \max \left( 0, p_i(t) + \alpha \left( \frac{x_i(t)}{\bar{x}(t)} - 1 \right) \right),
\]

where \( 0 < \alpha < 1 \) is a parameter that determines the speed of reaction to deviations from the fair behaviour;

\[P_{NACK,i}(t + 1) = \min\{p_i(t + 1), 1\};\]

\( t \leftarrow t + 1;\)

end for

end loop

4 Mathematical Analysis

In this section, we first establish the convergence properties of Algorithm 1. Second, we study the robustness of the proposed solution under misbehaviour strategies that seek to game its operation with the goal of achieving long-term performance benefits. Our mathematical analysis does not focus exclusively on saturation scenarios (i.e. whereby stations always have packets to transmit), though we do use saturation to upper bound the attempt rate of compliant stations. In the experimental evaluation we report in Sec. 6, however, we also investigate the performance of the proposed scheme with on/off and real-time (i.e. non-saturated) traffic, showing that our algorithm adapts quickly to traffic changes and does not penalise compliant stations with higher demands.

4.1 Convergence

We begin by establishing general conditions under which Algorithm 1 converges to a fixed point. For well-behaved stations that follow the 802.11 DCF specification, using a model such as [31] we can verify that \( 3c, 0 < c < 1 \), such that \( x(t)/\bar{x}(t) \leq 1 - cP_{NACK}(t), \forall t > 0 \). Specifically, the attempt rate of a fair station will be proportional to the transmission probability, which we can calculate as a function of \( P_{NACK} \), the failure probability \( f \) seen by the station due to collisions, and other (fixed) MAC parameters. Fig. 3 shows that for a range of collision probabilities,
these can be bounded with \(c \leq 0.4\). Thus for well-behaved stations we have the following important result.

**Theorem 1 (Well-behaved stations).** For stations satisfying 
\[ x(t)/\bar{x}(t) \leq 1 - cP_{NACK}(t), \quad 0 < c < 1, \forall t > 0, \]
Algorithm 1 ensures \( \lim_{t \to \infty} p(t) = 0 \). That is, for well-behaved stations the policing algorithm does not drop any ACKs.

**Proof:** First note \( p(t) \geq 0 \) and if \( p(t) = 0 \), then subsequent terms \( p(t + k), k > 0 \), are zero. If the sequence does not become constant at zero, then the max with zero is not active in Algorithm 1, and we consider two cases:

1) if \( 0 < p(t) \leq 1 \), then
\[ p(t + 1) = p(t) + \alpha \left( \frac{x(t)}{\bar{x}(t)} - 1 \right) \leq p(t) - \alpha cp(t); \]
2) if \( p(t) > 1 \), then
\[ p(t + 1) = p(t) - \alpha. \]

So, at each step, \( p(t) \) decreases by at least \( \alpha \min(p(t), 1) \). Thus \( p(t) \) is non-increasing and bounded below, and so convergent. As \( p(t) - p(t + 1) \to 0 \), we see \( \alpha \min(p(t), 1) \to 0 \), and thus \( p(t) \to 0 \).

We now show that in situations with misbehaving stations Algorithm 1 also converges. Firstly, for misbehaving stations whose transmit attempt rates remain sensitive to ACK suppression, we have the following.

**Theorem 2 (Moderately misbehaving stations).** Suppose the transmit rate of a station satisfies the following conditions:

1) \( x(t)/\bar{x}(t) > 1 \) when \( P_{NACK}(t) = 0 \),
2) \( x(t)/\bar{x}(t) < 1 \) when \( P_{NACK}(t) = 1 \), and
3) \( x(t)/\bar{x}(t) \) is strictly decreasing with \( P_{NACK,t} \) and Lipschitz with a constant smaller that \( 2/\alpha \).

Then Algorithm 1 converges to a point where \( x(t) = \bar{x}(t) \).

**Proof:** Since \( x(t)/\bar{x}(t) \) is strictly decreasing, there exists a unique value of \( P_{NACK}(t) \) where \( x(t)/\bar{x}(t) = 1 \). We call this value \( P \). Let \( V(t) = (p(t) - P)^2 \). Note that \( V(t) \) is positive definite and radially unbounded [32] in \( p(t) \) and
\[ V(t + 1) = (p(t + 1) - P)^2 \leq \left( p(t) - P + \alpha \left( \frac{x(t)}{\bar{x}(t)} - 1 \right) \right)^2. \]

Expanding, we find
\[ V(t + 1) \leq V(t) + \alpha \left( \frac{x(t)}{\bar{x}(t)} - 1 \right) (p(t) - P) \left( 2 - \alpha \frac{x(t)}{\bar{x}(t)} \right). \]

Note that \( \alpha > 0 \) and \( (x(t)/\bar{x}(t) - 1)(p(t) - P) \) is strictly negative except when \( p(t) = P \), so if
\[ 2 > \alpha \frac{x(t)}{\bar{x}(t)}, \]
then we can ensure that \( V(t) \) converges asymptotically to zero as \( t \to \infty \). However, this condition is ensured by

4.2 Robustness

Next we consider a scenario where a misbehaving client becomes aware of the policing algorithm running at the AP and attempts to game its operation, with the goal of achieving a long-term benefit in terms of throughput. We demonstrate that our scheme is robust to such sophisticated misbehaviour strategies by showing that, by design, the algorithm will penalise any strategy that deviates from the fair behaviour.

Suppose that the selfish station seeks to maximise its goodput and remember the algorithm can carry forward the penalty. The mean goodput over the interval \([0, T]\) is given by
\[ S(T) := \frac{1}{T} \sum_{t=1}^{T} x(t) (1 - p(t)) = \frac{\bar{x}}{T} T \left( (1 + y(t))(1 - p(t)), \right) \]
where \( y(t) = x(t)/\bar{x} - 1 \). We can rewrite the policing update as
\[ p(t + 1) = \max \left( 0, p(t) + \alpha y(t) \right), \]
and if we iterate this backwards to the previous time \( t^* \) where \( p(t) \) was zero, we see
\[ p(t + 1) = \max \left( 0, \alpha \sum_{k=t^*}^{t} y(k) \right). \]

Suppose there is a time \( T^* > 0 \) with \( p(T^*) = 0 \) but \( p(t) > 0 \) for \( 1 \leq t < T^* \). Then, we see \( \sum_{k=0}^{t-1} y(k) \leq 0 \), so the average attempt rate of the station up to time \( T^* \) is less than that of a fair station. As \( p(T^*) = 0 \), we may remove this interval from our consideration and consider just the times from \( T^* \) onwards. By repeating this argument, we see that we only need to consider the potential unfair behaviour of stations where \( p(0) = 0 \) and \( p(t) = \alpha \sum_{k=0}^{t-1} y(k) > 0 \) for \( 1 \leq t < T \). We have the following result.

**Theorem 4.** For policing Algorithm 1, suppose that \( \alpha \sum_{k=0}^{t-1} y(k) \geq 0 \) for \( 1 \leq t < T \). Let \( Y \) be an upper

6. Note that \( p(t) \) will be zero at least at \( t^* = 0 \).
bound for \( y(j) \) and let \( \Delta > 1/\alpha + Y \) be a positive integer. Then, if \( T > \Delta \) and we consider the values of \( S(T) \) as we vary \( y(1), \ldots, y(T - \Delta) \), and hold the other \( y(j) \) fixed, \( S(T) \) is maximised by choosing \( y(1) = \ldots = y(T - \Delta) = 0 \).

Proof: With policing update (3) we have
\[
p(t + 1) = \alpha \sum_{k=1}^{t} y(t),
\]
and we consider terms in \( S(T) \) as follows.
\[
S(T) = \bar{x} + \frac{\bar{x}}{T} \sum_{t=1}^{T} y(t) - \frac{\bar{x}}{T} \sum_{t=1}^{T} (1 + y(t)) p(t). \quad (4)
\]
Now,
\[
\sum_{t=1}^{T} (1 + y(t)) p(t) = \sum_{t=1}^{T} (1 + y(t)) \alpha \sum_{k=1}^{t-1} y(t) = \sum_{t=1}^{T} y(t) \alpha \sum_{k=t+1}^{T} (1 + y(k)).
\]
So, the net relative gain is bounded by
\[
\sum_{t=1}^{T} y(t) - \sum_{t=1}^{T} y(t) \alpha \sum_{k=t+1}^{T} (1 + y(k))
= \sum_{t=1}^{T} y(t)(1 - \alpha(T - t)) - \alpha \sum_{t=1}^{T} \sum_{k=t+1}^{T} y(t) y(k).
\]
Taking the derivative with respect to \( y(j) \) we get
\[
(1 - \alpha(T - j)) - \alpha \sum_{t\neq j} y(j)
= \alpha \left( \frac{1}{\alpha} - T + j - \sum_{t=j}^{T-1} y(t) + y(j) \right),
\]
which is negative when \( j \leq T - \Delta < T - 1/\alpha - Y \), as the sum is non-negative and \( y(j) \leq Y \). Thus, to maximise the gain, we choose the smallest possible values of \( y(j) \) subject to the constraint on the partial sums being non-negative. Thus \( y(1) = \ldots = y(T - \Delta) = 0 \).

This results confirms that no benefit can be obtained by deviating from the fair behaviour over \( T - \Delta \) steps. Note however that a non-compliant client could potentially attempt to use a more aggressive transmit rate over the last \( \Delta \) iterations before leaving the network, seeking to gain a small throughput benefit. But the fact that we allow for the penalty to carry forward to future times and consider networks that employ authentication makes such misbehaviours costly.

5 Implementation

To demonstrate that deploying the policing algorithm is feasible with off-the-shelf hardware, in this section we present a Linux-based prototype implementation that we developed and discuss a non-intrusive technique for estimating the fair transmission attempt rate.

![Fig. 4: Schematic view of the policing algorithm implementation. The policing update and fair rate estimation are implemented in the driver, per-station information is stored in the shared memory and ACK suppression is performed in FW.](Image)
based on the frame count, associated station and performs the following operations:

rate) and the current at configurable discrete time intervals, when the driver

items point to per-station information elements storing the

ulations more quickly. The computation of the transmit rates

allocated for policing.

Fig. 5: Memory structure storing policing data. The hash map

ACK dropping probability associated to a station, as well as

IEEE TRANSACTIONS ON MOBILE COMPUTING, VOL. XX, NO. XX, XXXX 7

impacts the chance that some other station transmits in

slot, the interaction of a (virtual) station with the net-

work can be summarised in a succinct way through the

expected collision probability this experiences. Note that

this method does not require precise knowledge of the
current network conditions, in terms of number of clients
and the contention parameter these employ. Instead we

may use a two-dimensional Markov chain model [29] to
determine the attempt rate for a saturated station with this

collision probability. In our implementation, the firmware
code inspects the IFS STATUS and IFS IDLE COUNTER

registers\(^7\) to count the number of busy and respectively idle

slots, and writes these values periodically into the shared

memory. At the end of an observation period, the driver

retrieves these measurements and uses them to compute

the expected collision probability, and the corresponding

attempt rate. In what follows, we give a formal analysis of

this approach and investigate its accuracy.

Suppose we have a network of \(n\) stations transmitting

with probabilities \(x_1, \ldots, x_n\). Further, suppose that a station

is saturated, for instance station 1. Assume for now that this

station is fair. We can write the failure probability due to

collisions for this station as

\[
 f_1 = 1 - (1 - x_2) \ldots (1 - x_n).
\]

As the station is fair,

\[
 x_1 = g(f_1),
\]

where \(g\) is a function mapping the failure probability to the

transmission probability and is given in (5) above [29].

In the above, we denote \(W = CW_{\text{min}}, m\) is the maximum

backoff stage and \(R\) denotes the retry limit.

Consider now that the AP runs a saturated virtual MAC

instance. We can similarly express the failure probability \(f_v\)

this observes, as follows:

\[
 f_v = 1 - (1 - x_1)(1 - x_2) \ldots (1 - x_n)
 = 1 - (1 - x_1)(1 - f_1) = 1 - (1 - g(f_1))(1 - f_1),
\]

where \(g\) is the fair backoff function given by (5). Note that if

we know \(f_v\), we can solve the above for \(f_1\). We note that the
difference between the two is relatively small and reduces

as the contention rate increases.

Since there is a one-to-one mapping from \(f_v\) to \(f_1\), we

could invert this to obtain an exact value for the failure

probability of a fair saturated station and apply (5) to

compute the maximum achievable rate \(\bar{x}\) of a fair station.

Another approach is to compute the virtual attempt rate,

\(g(f_v)\), and scale this up by 14\%, as numerical calculations of

both the virtual and actual maximum achievable attempt

rate show this is a good estimate of their gap, over a broad

range of network conditions.

The remaining question is how long should the channel

observation period be, to ensure an accurate estimate of \(f_v\).
To answer this, we regard the virtual transmission attempt as a Bernoulli trial, whereby assuming independent trials, a failure is observed with probability $f_v$ and a success with probability $1 - f_v$. By the central limit theorem, if the number of observations $N$ is large, the distribution of $\hat{f}_v$ is approximately normal with mean $f_v$ and variance $\sigma^2 = f_v(1 - f_v)/N$.

Say we want to compute the number of samples $N$ that gives us 95% confidence that the estimated mean has precision $\epsilon$, i.e. $P(|\hat{f}_v - f_v| > \epsilon) < 0.05$. The confidence interval is $f_v \pm z\sigma$, where $z = 1.96$ is the $z$-score required for 95% confidence. Since $\sigma$ is unknown and $f_v(1 - f_v) \leq 0.5$, using this conservative upper bound [36], $N$ must satisfy

$$\frac{z}{2\sqrt{N}} = \epsilon.$$ 

Thus the number of observations required to ensure a good estimate of the fair attempt rate is

$$N = \left(\frac{z}{2\epsilon}\right)^2.$$ 

To translate this into an observation period required for a good estimate of fair performance before an update of the $P_{NACK}$ probabilities, consider the average slot duration in a network with saturated stations

$$E[T_{\text{slot}}] = P_e \sigma + P_s T_s + P_c T_c,$$

where $P_e$, $P_s$ and $P_c$ are the probabilities that a slot is empty, contains a success and respectively a collision, and $\sigma$, $T_s$ and $T_c$ are the corresponding slot durations (see [31] for detailed calculations). Thus we compute the observation interval that gives an accurate estimation of the mean as

$$T_{\text{update}} = N \cdot E[T_{\text{slot}}].$$

To indicate the values $T_{\text{update}}$ would take in practice for $\epsilon = 0.01$, in Fig. 6 we plot the necessary channel observation time for obtaining an estimate according to the above requirements for different network conditions in terms of number of saturated stations and assuming stations send packets with 1,000-byte payload at 11 Mb/s (IEEE 802.11 HR/DSSS). We conclude, that an observation interval above 5 seconds will ensure a good estimate of the fair performance in many scenarios. In our experiments we conservatively use a $T_{\text{update}} = 10$s for all tests.

Note that alternatively the AP can rely on existing downlink traffic to estimate the maximum fair attempt rate. This only requires small modifications to the AP’s device driver to record the collision probability experienced by packets leaving its MAC queue. This measurement may then be used with (5) above to determine the fair attempt rate, as required for policing. To demonstrate its feasibility, we use this approach in the experiments we report in Sec. 6.5.

In what follows, we evaluate the performance of our prototype in a real testbed and demonstrate its effectiveness under different types of misbehaviour.

### 6 Experimental Evaluation

Having described the design and implementation of our proposal, we now evaluate the performance of the policing algorithm in a real 802.11 testbed and prove its effectiveness under different types of misbehaviours and a wide range of network conditions. Our deployment consists of nine Soekris net4801 embedded PCs, one acting as AP and the other eight as stations. The AP is equipped with a Broadcom BCM4318 wireless card and is capable of running our prototype. The clients use Atheros AR5212 chipset adapters and the ath5k driver, which we modified to allow manipulating the MAC parameters by simple commands from the system console. All clients employ the 802.11 HR/DSSS physical layer (802.11b) and, if not otherwise specified, do not perform rate adaptation.

Unless stated otherwise, we consider all stations are backlogged and send unidirectional UDP traffic to the AP. In all cases, we measure the performance of the stations when the network is operating with a standard AP and an AP running the proposed policing algorithm configured with the following settings: speed of reaction factor $\alpha = 0.1$ (see (1)) and update period $T_{\text{update}} = 10$s.

#### 6.1 Controller Validation

First we study the impact of four types of misbehaviour that can be easily implemented with current hardware, whereby aggressive MAC settings are used. Specifically, we investigate the scenarios where a user seeks to obtain performance benefits by employing selfish configurations as follows: (i) contending with a $CW_{\text{min}}$ parameter half the default value (“$CW_{\text{min}}$ Halved”), (ii) disabling the Binary Exponential Backoff (BEB) mechanisms while keeping a smaller $CW_{\text{min}}$ setting (“$CW_{\text{min}}$=CW$_{\text{max}}$”), (iii) using a shorter interframe space post-backoff (“$AIFS = SIFS$”), and (iv) retaining the access to the medium for 6.413ms by violating the TXOP$_{\text{limit}}$ parameter (“Large TXOP”), thus being able to send multiple frames upon a single transmission.

In these scenarios we consider a simple network topology with one misbehaving station sharing the medium with

---

8. Note that $E[T_{\text{slot}}]$ is upper bounded by the length of a successful transmission $T_s$, which is readily obtainable from the “duration” field of correctly received frames. Thus, one could avoid the complexity of computing $T_{\text{slot}}$ and use $T_s$ instead, to simplify implementation.
9. Note that compliant devices employ $CW_{\text{max}} > CW_{\text{min}}$ settings to reduce failure probability upon subsequent attempts, thus being less aggressive.
10. $AIFS \geq 2\sigma + SIFS$ is the amount of time a station is required to sense the channel idle before entering the backoff procedure. SIFS=10μs is the short interframe space. $\sigma$ is the duration of an idle slot.
With Policing

Without Policing

short post-backoff interframe space, e.g. the greedy station
behaves aggressively (“CW\(_{\text{max}}\) = CW\(_{\text{min}}\)”, light bars). When we activate the policing algorithm (dark bars), this behaviour becomes more aggressive (“CW\(_{\text{max}}\) = CW\(_{\text{min}}\)”, light bars), e.g. the cheater employs a fixed contention window
and thus does not backoff upon failures, in fact the policing algorithm rapidly increases the ACK dropping probability corresponding to that client to 1, thereby disassociating this from the AP. This is reflected in both the attempt rate and throughput performance, which are effectively zero when policing is applied (dark bars).

A more subtle misbehaviour strategy could employ a short post-backoff interframe space, e.g. the greedy station
only waits SIFS before a new attempt, which is the minimum time separating two consecutive frames. Although less significant (since the selfish station sometimes randomly selects a large backoff counter and waits more than the other contenders that wait DIFS plus a short backoff value), the non-compliant client still achieves performance gains to the detriment of the fair stations present in the network (“AIFS=SIFS”, light bars). Once again, if we execute the policing algorithm at the AP, the transmission attempt rates are equalised and fairness is restored (dark bars).

Let us now take a closer look at the behaviour of the controller implemented by our scheme. Specifically, we are interested in validating the convergence of the algorithm under different types of misbehaviour. For this purpose, we pick two of the four scenarios discussed above and examine the time evolution of the network performance.

More precisely, in Figs. 8 and 9 we show the time evolution of the throughput and attempt rate for the non-compliant user and a fair station, as well as the penalty applied by our algorithm, in the cases when the selfish client uses a CW\(_{\text{min}}\) half the default value, and respectively a large TXOP setting , e.g. TXOP = 6.413ms.

In both cases, observe that the policing algorithm successfully brings the attempt rate of the misbehaving station down to that of a fair client (middle graph), while their
throughput is reduced (top graph). What is important to remark is that the algorithm is close to convergence after a few steps, with the convergence time being shorter for more aggressive behaviour (i.e. with manipulated TXOP). Note also that the convergence time can be further reduced by choosing a larger $\alpha$ parameter.

Further, we verify that our algorithm does not unnecessarily penalise fair stations, i.e. does not trigger false alarms, due to the channel access randomness inherent in 802.11 DCF. To this end we examine the time evolution of a station’s attempt rate, the maximum achievable attempt rate estimated by our algorithm, and the penalty applied to each client. We investigate these with the same network settings (three backlogged stations) in two scenarios, namely all stations fair and respectively one of them misbehaving with a $CW_{\text{min}}$ half the default value. As we show in Fig. 10, our estimate closely follows the actual performance attainable by a fair client, and consequently the penalty applied to these exhibits only small variations above zero. To put things in perspective, we plot a 0.02 penalty threshold and confirm that the percentage of times the penalty applied to fair clients exceeds this value is zero in all scenarios.

### 6.2 Impact of Network Size

Next, we investigate whether a misbehaving client could hide in the crowd as the number of network users increases. For this purpose, we consider a network with one selfish station employing a small $CW_{\text{min}}$ based misbehaviour and we vary the number of fair stations, while we examine the performance of both. In each case, all clients are backlogged and send 1,000-byte packets for a total duration of 3 minutes. We repeat each experiment 10 times and compute the average with 95% confidence intervals of the attempt rate and throughput attained by each station.

In Fig. 11 we show the attempt rate and throughput of the selfish station and that of one fair client, with a standard AP as well as with an AP executing our algorithm. Observe that the performance of the selfish user decreases as the network size increases, but is constantly significantly above that of a fair client if no action is taken to counteract the greedy behaviour. In contrast, when the AP runs our policing algorithm, the attempt rate of the misbehaving user never exceeds that of a fair client (observe the overlapping dark lines in the top sub-figure), while their throughput performance falls below that of fair clients in all circumstances.

We conclude that the network size does not impact the performance of our algorithm, which effectively penalises misbehaving clients even in denser topologies.

### 6.3 Multiple Misbehaving Clients

In what follows, we study the performance of the proposed policing algorithm when multiple misbehaving clients are present in the WLAN. Here, we aim to understand whether the presence of a large number of selfish users could influence the penalty update of our algorithm. We demonstrate that, despite its prevalence, such behaviour will not be regarded as fair by the policing scheme. We use the same methodology as in the previous subsection, running 3-minute tests for each network scenario and conducting 10 independent experiments for each case. We measure the average performance of both fair and misbehaving stations in terms of attempt rate and throughput.

First let us consider the case where only one station is fair and increase the number of selfish clients present
the network. The results of these experiments are depicted in Fig. 12, where we plot the attempt rate and throughput of the fair station and that of one non-compliant station, with and without the policing algorithm running at the AP. We observe that also in these scenarios, the policing algorithm equalises the attempt rate of all stations while the throughput performance of non-compliant users is effectively reduced.

In addition, we examine a network with a fixed number of clients \((n = 8)\) and vary the proportion of fair/misbehaving stations. The attempt rate and throughput of one client within each category is shown in Fig. 13 when the AP operates with and without the proposed policing scheme. Also shown in the figure is the maximum achievable fair attempt rate as computed by our algorithm, which is largely the same irrespective of the number of selfish clients in the WLAN. These results further confirm the effectiveness of our scheme in the presence of several misbehaving stations.

### 6.4 Dynamic Network Conditions

We consider next a scenario with network dynamics where fair and misbehaving clients join and leave the WLAN at different times. Our goal here is twofold: \((i)\) we verify that our proposal adapts quickly to changes in the network topology, and \((ii)\) we demonstrate the algorithm carries forward the penalty of selfish users when those leave the network. To this end, we conduct an experiment with the AP running our policing scheme and four backlogged client stations, as follows. Two fair stations connect to the WLAN and start transmitting to the AP at \(t = 0s\). After 100s, a misbehaving station \((S3)\) joins the network, contending with a \(CW_{\text{min}}\) parameter half the default value. At \(t = 200s\) another standard compliant station \((S4)\) connects to the WLAN. Finally, \(S3\) leaves the network after transmitting for 200s and \(S4\) disassociates 100s later.

The result of this experiment is depicted in Fig. 14 where we plot the time evolution of the attempt rate, throughput and penalty corresponding to each client. We can see clearly that our algorithm quickly detects and starts penalising the misbehaving station, equalising the attempt rates in a few iterations. As the fourth client joins, our solution re-estimates the maximum achievable attempt rate and continues penalising the selfish user, without affecting the performance of the new station. Lastly, as the cheater leaves the network, the penalty is preserved and carried forward to be applied when this client will reconnect. Thus we confirm that the performance of our algorithm is not affected by network dynamics and penalties are successfully carried forward. We also note that the number of false alarms is zero, since the penalty applied to compliant stations remains below 0.02.

In the experiments presented so far, all the contenders, whether compliant or selfish, transmitted saturated traffic. Indeed misbehaviour becomes problematic under heavy network loads, since the performance of compliant users suffers as a result of the gains achieved by the selfish clients. However, it is also useful to verify that our algorithm can detect misbehaving clients that transmit on/off (bursty) traffic, since intuitively the average attempt rate of these might...
The second station establishes finite size TCP connections, alternates periodically between silent and active periods of activity, during which a 2-Mbyte file is transferred, and silent periods exponentially distributed with mean $\lambda^{-1} = 60s$ [37]. The third station streams a MPEG-4 encoded version of “Resident Evil: Apocalypse” at 1 Mb/s using the VLC media player [38]. To emulate the activity of the fourth station, we use a backlogged iperf downstream session from the AP to the client. In this scenario, as the AP is always fair, we use the downstream flow to estimate the fair throughput. We run the experiment for a total duration of 1 hour, measuring for each flow the attempt rate, throughput and penalty applied.

In Fig. 15 we plot a 30-minute snapshot of the network operation in this experiment, showing the time evolution of the aforementioned performance metrics for each client station. First, we observe that the penalty stays at zero most of the time for all stations, only with infrequent and small variations above zero (the percentage of times the penalty exceeds the 0.02 threshold is 8.89%, while the average penalty applied at each iteration for the uplink flow is 0.011, which is negligible). Second, the medium-quality video flow sees its bandwidth demand satisfied most of the time. Third, the bandwidth demanding upload and download flows equally share the remaining available air time. Lastly, the spurious web traffic experiences similar performance to that of other flows whenever they compete.

We conclude that indeed the proposed policing algorithm does not penalise stations that generate more traffic than their competitors as long as they comply with the MAC configuration defined by the 802.11 standard. This

6.5 Real Traffic

Next, we investigate the performance of the policing algorithm in a more realistic scenario with heterogeneous traffic. We will show that the policing algorithm does not unnecessarily penalise fair clients that have increased demands and attain higher transmission rates simply due to the reduced activity of the other contenders.

Towards this end, we consider a network with $n = 4$ clients, the first one uploading a large file, the second generating web traffic, the third streaming a video file and the last performing a system update. To emulate the file upload, we generate saturated traffic using iperf on the first client. The second station establishes finite size TCP connections, alternating between periods of activity, during which a 2-Mbyte file is transferred, and silent periods exponentially distributed with mean $\lambda^{-1} = 60s$ [37]. The third station streams a MPEG-4 encoded version of “Resident Evil: Apocalypse” at 1 Mb/s using the VLC media player [38]. To emulate the activity of the fourth station, we use a backlogged iperf downstream session from the AP to the client. In this scenario, as the AP is always fair, we use the downstream flow to estimate the fair throughput. We run the experiment for a total duration of 1 hour, measuring for each flow the attempt rate, throughput and penalty applied.

In Fig. 15 we plot a 30-minute snapshot of the network operation in this experiment, showing the time evolution of the aforementioned performance metrics for each client station. First, we observe that the penalty stays at zero most of the time for all stations, only with infrequent and small variations above zero (the percentage of times the penalty exceeds the 0.02 threshold is 8.89%, while the average penalty applied at each iteration for the uplink flow is 0.011, which is negligible). Second, the medium-quality video flow sees its bandwidth demand satisfied most of the time. Third, the bandwidth demanding upload and download flows equally share the remaining available air time. Lastly, the spurious web traffic experiences similar performance to that of other flows whenever they compete.

We conclude that indeed the proposed policing algorithm does not penalise stations that generate more traffic than their competitors as long as they comply with the MAC configuration defined by the 802.11 standard. This
We study the behaviour of a rate control algorithm executed at a greedy client that manipulates their MAC configuration and is being penalised by our policing algorithm to counteract their misbehaviour. Our goal here is to verify that rate control (RC) algorithms will not wrongly interpret suppressed ACKs as losses caused by poor channel conditions and thus will not trigger downgrades of the PHY rate. This is particularly important, since unnecessarily selecting a lower modulation scheme can be wasteful of channel time and significantly impact on the overall network utility [39].

To this end, we consider again a simple scenario with two fair clients and one misbehaving station that uses a $\text{CW}_{\text{min}}$ parameter half the standard recommended value. In this experiment, the selfish client runs the Minstrel rate control algorithm, which is the default mechanism implemented by mac80211 drivers on Linux systems since kernel version 2.6.29 (March 2009 to date), and the AP executes the proposed policing scheme. Note that Minstrel [40], SampleRate [41] and other commonly used rate control schemes work by sampling the mean transmission time at different PHY rates. Since our ACK dropping scheme impacts on all PHY rates in the same way, it will inflate the transmission times for all rates in the same way, and consequently we expect the rate control scheme will still pick the rate with shortest transmission time. Similarly, schemes that make decisions based on SNR or related indicators will not be mislead by ACK dropping [42].

We examine the time evolution of the penalty applied by our algorithm to the cheater, as well as the rate selected by Minstrel during the operation of our scheme. As shown in Fig. 16, increasing the penalty does not influence the rate selection decisions taken by the rate control algorithm, since packets are transmitted almost always at the maximum rate (11 Mb/s) and lower rates are only periodically sampled (approx. every 30s), with only a couple of frames.

To verify that indeed the network utility is not affected when policing is applied to selfish stations, we also plot at the bottom of Fig. 16 this metric for the same experiment, as well as for the case when the misbehaving client does not perform rate adaptation and all stations transmit at a single rate, e.g. 11Mb/s. Note that we compute the network utility as in [43], i.e. the sum of the natural logarithms of the individual throughputs, which is considered a good measure of proportional fairness [20]. From the results in Fig. 16 we conclude that our policing algorithm does not tamper with the operation of current rate control mechanisms and thus has no negative impact on the network utility when penalties are applied to non-compliant client stations.

## 7 Non-ideal Channel Effects

We also investigate the performance of our implementation under several challenging situations that occur frequently in practice. Specifically, we verify that the proposed algorithm has no negative impact on rate switching decisions taken by state-of-the-art rate control algorithms and demonstrate the potential of our scheme to alleviate unfairness issues that arise due to the PHY/MAC interactions occurring in the presence of the capture effect.

11 Traffic differentiation based on transport protocol is infeasible when clients use IPsec, e.g. by setting up a virtual private network.
users into compliant operation, regardless of the type of misbehaviour employed, and does not penalise compliant clients that consume more air time than lightly loaded stations. In addition, we showed that our solution has a negative impact on current rate control algorithms and can alleviate unfairness incurred by PHY layer capture effect.
