**Abstract**

Parallel patterns (e.g., map, reduce) have gained traction as an abstraction for targeting parallel accelerators and are a promising answer to the performance portability problem. However, compiling high-level programs into efficient low-level parallel code is challenging. Current approaches start from a high-level parallel IR and proceed to emit GPU code directly in one big step. Fixed strategies are used to optimize and map parallelism exploiting properties of a particular GPU generation leading to performance portability issues.

We introduce the LIFT IR, a new data-parallel IR which encodes OpenCL-specific constructs as functional patterns. Our prior work has shown that this functional nature simplifies the exploration of optimizations and mapping of parallelism from portable high-level programs using rewrite-rules.

This paper describes how LIFT IR programs are compiled into efficient OpenCL code. This is non-trivial as many performance sensitive details such as memory allocation, array accesses or synchronization are not explicitly represented in the LIFT IR. We present techniques which overcome this challenge by exploiting the pattern’s high-level semantics. Our evaluation shows that the LIFT IR is flexible enough to express GPU programs with complex optimizations achieving performance on par with manually optimized code.

1. Introduction

GPUs (Graphics Processing Units) and other parallel accelerators are now commonplace in computing systems. Their performance is orders of magnitude higher than traditional CPUs making them attractive for many application domains. However, achieving their full performance potential is extremely hard, even for experienced programmers. This requires ultra-specialized kernels written in low-level languages such as OpenCL. This inevitably leads to code that is not performance portable across different hardware.

High-level languages such as Lift [18], Accelerate [15], Delite [19], StreamIt [20] or Halide [16] have been proposed to ease programming of GPUs. These approaches are all based on parallel patterns, a concept developed in the late 80’s [7]. Parallel patterns are deeply rooted in functional programming concepts such as function composition and nesting, and absence of side-effects. When using parallel patterns, programs are expressed without committing to a particular implementation which is the key for achieving performance portability across parallel architectures.

From the compiler point of view, the semantic information associated with parallel patterns offers a unique opportunity for optimization. These abstractions make it easier to reason about parallelism and apply optimizations without the need for complex analysis. However, designing an IR (Internal Representation) that preserves this semantic information throughout the compilation pipeline is difficult. Most existing approaches either lower the parallel primitives into loop-based code, loosing high-level semantic information, or directly produce GPU code using fixed optimization strategies. This inevitably results in missed opportunities for optimizations or performance portability issues.

In this paper, we advocate the use of a functional data-parallel IR which expresses OpenCL-specific constructs. Our functional IR is built on top of lambda-calculus and can express a whole computational kernel as a series of nested and composed function calls. It is equipped with a dependent type system that reasons about array sizes and value ranges for variables, preserving important semantic information from the high-level patterns. The information available in the types is used at multiple stages such as when performing array allocation, index calculation, and even synchronization and control flow simplification.

One downside of a functional IR is that all operations are represented as functions which produce intermediate results. This issue is addressed by fusing chains of composed or nested functions which only affect the data layout (e.g., zip or gather). This involves recording information about the accessed data in a view structure which is then used to emit the appropriate array access expression. These indexing expressions are then simplified using a symbolic algebraic simplifier that relies on type information (e.g., array length and value ranges). This leads to the generation of highly efficient GPU code competitive with hand-tuned kernels.

To summarize, we make the following contributions:

- We present a new data-parallel functional IR that targets the OpenCL programming model;
- We show how semantic information embedded in the IR is used in various phases such as memory allocation, array access generation and optimizations, synchronization minimization and control-flow simplification;
• We demonstrate that the generated GPU code performance is on par with manually optimized OpenCL code.

The rest of the paper is organized as follows: Section 2 reviews related work and motivates our approach. Sections 3 and 4 discuss our Lift pattern based function abstraction of OpenCL and its internal representation. Section 5 discusses the compiler implementation and optimizations for high-performance code generation. Sections 6 and 7 present experimental setup and evaluation before section 8 concludes.

2. Related Work and Motivation

The problem of producing efficient GPU code has been well studied over the years. Figure 1 gives an overview of the different approaches related to this paper. Loop-based auto-parallelization techniques have been extensively studied for languages like C. Recent work on polyhedral compilation [1] for instance has pushed the boundaries of such techniques for GPU code generation. However, these techniques only operate on loops and requires certain property such as affine indices to work effectively.

In the last decade, there have been a shift towards algorithmic skeletons [7] and DSLs (Domain Specific Languages). These approaches offer the advantage of exploiting high-level and domain-specific information. The simplest approaches are based on parametric library implementation of skeletons such as Thrust [2] and SkelCL [17]. However, these approaches are not portable and more importantly, cannot perform optimizations across library calls.

A different approach consists of lowering the applications to a functional representation which is then compiled to GPU code. This process involves mapping of parallelism, performing optimizations such as fusion of operations and finally code generation. This approach is used by a many systems such as Copperhead [5], Delite [3], Accelerate [6, 15], LiquidMetal [9], HiDP [21], Halide [16] and NOVA [8].

The drawback of such approaches is that the mechanism to map parallelism and optimize code is performed within the code generator and in general uses a fixed strategy. This means that it might be difficult to achieve performance portability due to the large gap to fill between the functional IR and the GPU code that will eventually be produced. In contrast, we advocate the use of a low-level IR which encodes OpenCL-specific constructs as we will see in the next section. The decision of how to optimize code and map parallelism are taken during the conversion from the generic functional IR and the OpenCL-specific Lift IR. This clearly separates the concerns of optimization and parallelism mapping from the actual process of code generation.

The Lift IR introduced in this paper is capable of expressing many different OpenCL mappings and optimizations in a pattern-based and functional style. This complements prior work which studied the problem of deciding how to find optimal mapping using analysis-driven heuristics [12] or semantic preserving rewrite-rules as in our own prior work [18].

The main contribution of this paper is to explain how the Lift compiler produces efficient OpenCL code once the original program has been lowered and mapped into the Lift IL. As we will see, generating high performance OpenCL code relies on using the parallel patterns’ semantic information encoded in the IR.

3. The Lift Intermediate Language

This section presents Lift, a functional data-parallel intermediate language designed as a target for high-level languages based on parallel patterns. It is similar in spirit to prior published work on data-parallel representation [4, 10, 11, 14] and complements our prior work [18]. The Lift IL (Intermediate Language) specifically targets OpenCL, although many concepts presented are more widely applicable.

3.1 Design Principles

High-level languages based on parallel patterns capture rich information about the algorithmic structure of programs. Take the computation of the dot product as an example:

\[
\text{dot}(x, y) = \text{reduce}(+, 0, \text{map}(\times, \text{zip}(x, y)))
\]

Here the zip pattern captures that arrays x and y are accessed pairwise. Furthermore, the map pattern allows the compiler to perform the multiplication in parallel, as well as the final summation, expressed using the reduce pattern.

Our most important design goal is to preserve algorithmic information for as long as possible in the compiler. The Lift intermediate language achieves this by expressing the OpenCL programming model functionally. One of the key advantages of the Lift approach is that it is possible to decouple the problem of mapping and exploiting parallelism, which has been covered in our prior work [18], from the code generation process, which is what this paper is about.

3.2 Intermediate Language

The Lift IL expresses program as compositions and nesting of functions which operate on arrays. The foundation of the Lift IL is lambda calculus which formalizes the reasoning about functions, their composition, nesting and application.
In the following section we introduce the predefined patterns used as building blocks to express programs. Besides these patterns, the Lrift IL also supports user functions written in C operating on scalar values, which implement the application specific computations.

**Algorithmic Patterns** The Lrift IL supports four algorithmic patterns corresponding to sequential implementations of the well known map and reduce patterns, the identity and the iterate primitive. The iterate pattern applies a function \( f \) \( m \) times by re-injecting the output of each iteration as the input of the next. The length of the output array is inferred as a function \( h \) of the number of iterations \( m \), the input array length \( n \) and the change of the array length by a single iteration captured by the function \( g \). We will discuss in section 5 how we automatically infer the length of the output array.

\[
\begin{align*}
\text{mapSeq}(f, x_1, x_2, \ldots, x_n) &= f(x_1) \cdot f(x_2) \cdot \cdots \cdot f(x_n) \\
\text{reduceSeq}(z, f, x_1, x_2, \ldots, x_n) &= f(f(z, x_1), x_2, \ldots, f(x_{n-1}, x_n)) \\
\text{id}(x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n \\
\text{iterate}^m(f, x_1, x_2, \ldots, x_n) &= f(f(f(x_1, x_2, \ldots, x_n), f(x_1, x_2, \ldots, x_n), \ldots, f(x_1, x_2, \ldots, x_n)), \ldots, f(x_1, x_2, \ldots, x_n) ) \\
\end{align*}
\]

**Data Layout Patterns** The Lrift IL defines a set of patterns that do not perform any computation but simply reorganize the data layout. The first two patterns, \( \text{split} \) and \( \text{join} \), add or remove a dimension from the input array.

\[
\begin{align*}
\text{split}^m(x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n \\
\text{join}^m(x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n, x_1, x_2, \ldots, x_n, \ldots \\
\end{align*}
\]

The \( \text{gather} \) and \( \text{scatter} \) patterns apply a permutation function \( f \) which remaps indices when reading from or writing to arrays respectively. Combined with \( \text{split} \) and \( \text{join} \), for instance, these primitives can express matrix transposition: \( \text{split}^\text{mrows} \circ \text{scatter}(i \rightarrow \text{mod} n\text{cols}) \times \text{nrows} + i / n\text{cols} \circ \text{join} \).

\[
\begin{align*}
\text{gather}(f, x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n \\
\text{scatter}(f, x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n \\
\end{align*}
\]

The \( \text{zip} \) pattern is used to combine two arrays of elements into a single array of pairs while the \( \text{get} \) primitive projects a component of a tuple.

\[
\begin{align*}
\text{zip}(x_1, x_2, \ldots, x_n, y_1, y_2, \ldots, y_n) &= (x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n) \\
\text{get}_i((x_1, x_2, \ldots, x_n)) &= x_i \\
\end{align*}
\]

Finally, \( \text{slide} \) applies a moving window to the input data and is used to express stencil computations. For instance, \( \text{mapSeq}(\text{reduceSeq}(0, +)) \circ \text{slide}(3, 1, \text{input}) \) expresses a simple 3-point stencil. Multi-dimensional stencils are also expressible by composing several \( \text{slide} \) functions interleaved with transpositions (not shown for space constraint).

\[
\text{slide}(\text{size}, \text{step}, x_1, x_2, \ldots, x_n) = (x_1, x_2, \ldots, x_n)
\]

**Parallel Patterns** OpenCL provides a hierarchical organization of parallelism where threads are grouped into work groups of local threads or a flat organization where threads are simply global. This hierarchy is represented with three patterns, where a mapLcl must be nested inside of mapWrg:

\[
\begin{align*}
\text{mapGlb}^{[0,1,2]} & \rightarrow \text{mapWrg}^{[0,1,2]} & \rightarrow \text{mapLcl}^{[0,1,2]} \\
\end{align*}
\]

OpenCL supports up to three thread dimensions, represented by the superscripts \( 0, 1, 2 \). The semantic of these patterns is identical to mapSeq, except that \( f \) is applied in parallel.

**Address Space Patterns** OpenCL distinguishes between global, local and private address spaces. The Lrift IL offers three corresponding primitives which wrap a function and influence the address space used to store the output:

\[
\begin{align*}
\text{toGlobal} & \rightarrow \text{toLocal} \rightarrow \text{toPrivate} \\
\end{align*}
\]

For example, a sequential copy of an array \( x \) into local memory is expressed as: \( \text{toLocal}(\text{mapSeq}(\text{id}))(x) \). This design decouples the decision of where to store data (i.e., the address space) from the decision of how the data is produced (i.e., sequentially or in parallel).

**Vectorize Pattern** The Lrift IL supports two primitives that transforms data between scalar and vector types, and one pattern which applies a function to a vector.

\[
\begin{align*}
\text{asVector}(x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n, \text{ where } x_i \text{ is scalar} \\
\text{asScalar}(x_1, x_2, \ldots, x_n) &= x_1, x_2, \ldots, x_n \\
\text{mapVec}(f, x_1, x_2, \ldots, x_n) &= f(x_1), f(x_2), \ldots, f(x_n) \\
\end{align*}
\]

During code generation, the function \( f \) is transformed into a vectorized form. This transformation is straightforward for functions based on simple arithmetic operations since OpenCL already defines vectorized forms for these operation. In the other more complicated cases, the code generator simply applies \( f \) to each scalar in the vector.
We focus on this OpenCL kernel and omit a second kernel.

All programs expressible in the LIFT intermediate language (LIFT IR) can be represented by the LIFT IR. One of the key features of the LIFT IR is that it preserves a functional representation of the program all the way through.

3.3 Example: Dot Product in the LIFT IL

Listing 1 shows one possible implementation of dot product expressed in the LIFT IL. The program is represented using a functional style, therefore, the program is read from right to left instead of the familiar left to right common in imperative programming. Furthermore, to simplify the notation we use the $\circ$ symbol to denote sequential function composition, i.e., $(f \circ g)(x) = f(g(x))$.

In the program of Listing 1 the input arrays $x$ and $y$ are combined using the zip pattern in line 10. The zipped array is then split into chunks of size 128 (line 10). A work group processes a single chunk using the mapWrg pattern (line 2) before combining the computed chunks using the join pattern (line 2). Inside of a work group we perform three steps to process a chunk of 128 elements: 1) we split the chunk further into pairs of two zipped elements, which we multiply and add up before copying the computed result into local memory (lines 8 and 9); 2) we iteratively reduce two elements at a time in local memory (lines 5 and 7); 3) we copy the computed result back into global memory (line 3).

Note that the code shown here corresponds to a single OpenCL kernel which only computes a partial dot product. We focus on this OpenCL kernel and omit a second kernel which sums up all intermediate results, because the vast majority of the runtime is spent in the first kernel.

3.4 Summary

In this section we have discussed the design of the LIFT functional data-parallel intermediate language. It is similar in style to prior work [4, 14, 18] and is OpenCL specific. The LIFT IL expresses very precisely how programs are mapped to the OpenCL programming model, as we have seen for the dot product example. The following section describes how this language is represented in our compiler. Section 5 will then describe how efficient OpenCL code is produced.

4. The LIFT Intermediate Representation

This section introduces the LIFT Intermediate Representation. All programs expressible in the LIFT intermediate language can be represented by the LIFT IR. One of the key features of the LIFT IR is that it preserves a functional representation of the program all the way through.

4.1 Organization of Classes

Programs are represented as graphs where nodes are implemented as objects. The use of a graph-based representation avoids the problem of performing extensive renaming when transforming functional programs [13]. The class diagram of the LIFT IR in Figure 2 shows two main classes: expressions (Expr) and function declarations (FunDecl).

Expressions represent values and have a type associated with. Expressions are either literals, parameters or function calls. Literals represent compile time known constants such as 3.4f, arrays or tuples. Parameters are used inside functions and their values are the arguments of a function call. Finally, function calls connect a function to be called (a FunDecl) with its arguments (Exprs).

Function Declarations correspond to either a lambda, a predefined pattern or a user function. Lambdas are anonymous function declarations with parameters and a body which is evaluated when the lambda is called. A pattern is a built-in function such as map or reduce. The UserFun corresponds to user-defined functions expressed in a subset of the C language operating on non-array data types.

4.2 LIFT IR Example

Figure 3 shows the LIFT IR of the dot-product program from Listing 1. The plain arrows show how object reference each other. The top left node labeled Lambda2 is the root node of the graph taking two parameters and its body implements dot-product as a sequence of function calls. The dashed arrows visualizes the way the data flows through the IR. The inputs $x$ and $y$ are first used as an input to the zip function which is then fed into a call to split(128). Then the the results of the split is fed into the mapWrg function. The function which is applied to each chunk of 128
the \texttt{Iterate} node. To understand what the lambda does, we can look back at Listing 1, lines 4–7 copied here:

\begin{verbatim}
iterate^6( \text{ join } \circ \text{ mapLcl}^0( \ldots ) \circ \text{ split}^2 )
\end{verbatim}

This notation is only syntactic sugar for:

\begin{verbatim}
iterate^6( \lambda p. \text{ join}(\text{mapLcl}^0(\ldots \circ \text{split}^2(p))) )
\end{verbatim}

The lambda ($\lambda$) makes the data flow explicit, i.e. the \texttt{iterate} pattern passing its input via the parameter $p$ first to \texttt{split} which then passes it to \texttt{mapLcl} and \texttt{join}.

5. **Compilation Flow**

Figure 4 shows the stages involved in compiling the \texttt{Lift IR} into efficient OpenCL code. The compilation starts by analyzing type information which is key for high-performance code generation. This information is used heavily in the subsequent memory allocation and array accesses generation passes. The barrier elimination stage minimizes the number of synchronizations required for correct parallel code. Finally, the OpenCL code generation performs a last final optimizations to simplify control flow.

5.1 **Type System and Analysis**

The \texttt{Lift} compiler implements a \textit{dependent type system} which keeps track of the length and shapes of nested arrays. Besides \textit{array types}, the type system supports \textit{scalar types} (e.g., \texttt{int}, \texttt{float}), \textit{vector types}, and \textit{tuple types}. While vector types correspond to OpenCL vector data types (e.g., \texttt{int2}, \texttt{float4}) tuples are represented as \texttt{struct}s. Array types can be nested to represent multi-dimensional arrays. In addition, arrays carry information about the length of each dimension in their type. These length information are arithmetic expressions of operations on natural numbers larger than zero and named variables which are unknown at compiler time. For example, given an array $x$ of length $n$ where the type of the elements is \texttt{float} we write the type of $x$ as $\texttt{[float]}_n$. Applying the array $x$ to the \texttt{split} $m$ pattern results in the type $\texttt{[float]}_{n/m}$.

The types of function bodies are automatically inferred from the parameter types by traversing the graph following the data flow, as indicated by the dotted arrows in Figure 3.

5.2 **Memory Allocation**

A straightforward memory allocator would allocate a new output buffer for every single \texttt{FunCall} node. However, this would be very inefficient as data layout patterns, such as \texttt{split}, only change the way memory is accessed but do not modify the actual data. Memory allocation is, therefore, only performed for functions actually modifying data. These are \texttt{FunCall} nodes where the called function contains a \texttt{UserFun} node, such as the \texttt{UserFun(add)} node in Figure 3.

Figure 4. Overview of the \texttt{Lift} compilation stages.

used to emit the final index to the memory of input MemoryView(x). Finally, we reach a memory view which is
information to decide which view should be visited next: the
access. The ZipView pops from the tuple stack and uses this
mensional index using the split factor, linearizing the array
indices from the stack and combines them into a one di-
index variable (\(l_id\)) on the stack. The SplitView pops two

one dimension. Another ArrayAccessView pushes another
tuple, \(0\), onto the tuple stack. Then an ArrayAccessView
pops a new variable (\(i\)) on the stack indexing the array in
one dimension. Another ArrayAccessView pushes another
index variable (\(l_id\)) on the stack. The SplitView pops two
indices from the stack and combines them into a one di-
imensional index using the split factor, linearizing the array
access. The ZipView pops from the tuple stack and uses this
information to decide which view should be visited next: the
MemoryView(x). Finally, we reach a memory view which is
used to emit the final index to the memory of input \(x\).

Simplifying Array Accesses If we follow the approach
described above we will obtain correct array indices, however,
this can lead to long and complex expressions. We illustrate
this issue using matrix transposition, expressed in LIRF as:

\[
1 ([([wg_id\times M + l_id]) / M] + ([([wg_id\times M + l_id]) \mod M]) \times N)) / N + ([([wg_id\times M + l_id]) / M] + ([([wg_id\times M + l_id]) \mod M]) \times N)) \mod N
\]

\[
2 (\text{wg_id} + \ l_id \times N) / N + (\text{wg_id} + \ l_id \times N) \mod N
\]

\[
3 \ l_id \times N + \text{wg_id}
\]

Figure 6. Simplification process of automatically generated array indices.

Figure 5. Views constructed for the generation of the first memory access of dot product (on the left) and consumption of views to generate an array index (on the right).

View Consumption Once the view structure is constructed,
all information required for generating accesses is available. An array index expression is calculated by consuming this information in the opposite order of construction, i.e., top-to-bottom. This process is illustrated on the right hand side of Figure 5 with the resulting array access at the bottom. The constructed view is shown on left hand side. The Tuple Stack on the right side contains information about tuple access which determine which array is being accessed. The Array Stack in the middle records information about which element of the array is being accessed.

Starting from the top with two empty stacks, we process the TupleAccessView(0) pushing the first component of a tuple, i.e., 0, onto the tuple stack. Then an ArrayAccessView pushes a new variable (\(i\)) on the stack indexing the array in one dimension. Another ArrayAccessView pushes another index variable (\(l_id\)) on the stack. The SplitView pops two indices from the stack and combines them into a one dimensional index using the split factor, linearizing the array access. The ZipView pops from the tuple stack and uses this information to decide which view should be visited next: the MemoryView(x). Finally, we reach a memory view which is used to emit the final index to the memory of input \(x\).

\[
1 \text{matrixTranspose}(x; \{[\text{float}]_M\}) = \\
2 (\text{map}\_\text{rg}^{\delta}(\text{map}\_\text{cl}^{\delta}(id)) \circ \\
3 \text{split}^N \circ \text{gather}(i(i \rightarrow i / M + (i \mod M) \times N) \circ \text{join})(x)
\]

Here the join, gather and split patterns flatten the two-dimensional matrix, rearrange the indices with a stride before splitting the array in two dimensions. When generating the read accesses for the \(id\) function, following the methodology introduced above, we obtain the array index shown in Figure 6 line 1. While this array index expression is correct it is also quite long compared to the index a human could write for performing a matrix transposition, shown in line 3.

However, a standard compiler would be unable to simplify this expression since important information about value ranges is missing. In contrast, the LIRF compiler is able to derive the simplified form using a symbolic simplification mechanism exploiting domain knowledge. The simplification process follows a set of algebraic rules exploiting properties of arithmetic operators supported in the compiler (additions, multiplications, integer divisions, fractions, powers and logarithms). A small subset of the rules supported is shown below:

\[
\begin{align*}
  x/y &= 0, \quad \text{if } x < y \text{ and } y \neq 0 \\
  (x \times y + z)/y &= x + z/y, \quad \text{if } y \neq 0 \\
  x \mod y &= x, \quad \text{if } x < y \text{ and } y \neq 0 \\
  (x/y) \times y + x \mod y &= x, \quad \text{if } y \neq 0 \\
  (x \times y) \mod y &= 0, \quad \text{if } y \neq 0 \\
  (x + y) \mod z &= (x \mod z + y \mod z) \mod z, \quad \text{if } z \neq 0
\end{align*}
\]

The type system exploits domain specific knowledge by inferring range information for every variable. For example, the \(wg_id\) variable corresponding to the map\_rg, ranges from 0 to \(M\), which is the row length of the input matrix. Similarly, the \(l_id\) variable corresponding to the map\_cl, has values between 0 and \(N\) since it indexes an array split in chunks of \(N\). The expression \((wg_id \times M + l_id) \mod M\) can, therefore, be simplified to \(l_id\) using rule 6 to distribute the modulo followed by rules 3 and 5 to simplify the remaining modulo operations. A traditional OpenCL compiler is not able to simplify this code, as it is missing the information that \(wg_id\) is positive and smaller than \(M\). Lines 2 and 3 in Figure 5 show the expression after a few simplification steps. This results in the same compact array index a human would write.

In one case, disabling the simplification let to the generation of several MB of OpenCL code. By applying arithmetic simplification we generate concise indices which reduce code size and speed up execution as costly operations such as modulo can often be simplified away. We will investigate the performance benefits in section 7.
5.4 Barrier Elimination

When different threads access the same memory location they must synchronize to ensure memory consistency. When compiling the Lift IR, this corresponds to generating an appropriate synchronization primitive after each occurrence of a parallel map pattern. A return is emitted after the mapGlb and mapWrg patterns, since OpenCL does not support synchronization across work groups. For mapLcl a barrier is emitted synchronizing all threads in the work group.

Sometimes these barriers are not required, for example, when there is no sharing because all threads continue operating on the same memory locations. We take an approach of safety first, were a barrier is emitted by default and is only removed if we can infer from the context that it is not required. The key insight for this barrier elimination process is the fact that the Lift IL only allows sharing of data by using the split, join, gather or scatter patterns. Therefore, we look for sequences of mapLcl calls which have no split, join, gather, or scatter between them and mark them specially. These marked mapLcl function calls will not emit a barrier in the OpenCL code generation stage. We also eliminate one barrier when two mapLcl appear inside of a zip since the two branches of a zip can be executed completely independently.

5.5 OpenCL Code Generation

The final stage in the Lift compilation pipeline is the OpenCL code generation where low-level optimizations are performed to precisely control the generated code. To generate the OpenCL code, the Lift IR graph is traversed following the data flow and a matching OpenCL code snippets is generated for every pattern. The generated kernel for the dot product example is shown in Figure 7 with only minor cosmetic changes made by hand for presentation purpose (renamed variables, removed comments, removed extra parenthesis).

No OpenCL code is generated for patterns such as split and toLocal since their effect have been recorded in the views. For the different map patterns, for loops are generated, which for the parallel variations will be executed in parallel by multiple work groups or threads, such as the loop in line 7. For the reduceSeq pattern, a loop with an accumulation variable (e.g., in line 10) is generated calling its function in every iteration. The code generated for iterate spans lines 17 to 29 with double buffering initializing two pointers in line 18 and swapping the pointers after each iteration in lines 27 and 28.

Control Flow Simplification  The Lift compiler performs control flow simplification using the extra semantic information available in patterns and types. A straightforward implementation would emit a for loop for every map, reduce and iterate pattern. Fortunately, the Lift compiler often statically infers if the number of threads for a map is larger, equal or lower than the number of elements to process. This is the case in lines 20 and 30 which correspond to the mapLcl in line 5 and 3 in the original Listing 1. This is possible because get_local_id(0) returns a positive number. If we infer that the loop executes exactly once by every thread we eliminate the loop completely, which is the case in line 9 which corresponds to the mapLcl in line 8 in Listing 1.

Performing control flow simplification is beneficial in two ways: first, execution time is improved as additional instructions from the loop are avoided; and, secondly, in general fewer registers are required when loops are avoided.

5.6 Summary

In this section we have seen how Lift IR is compiled to OpenCL. We used the dot product computation from Listing 1 as a running example to discuss how types are inferred, memory is allocated, concise array accesses are generated, barriers are eliminated, and, finally, the OpenCL kernel with simplified control flow shown in Figure 7 is generated. The next section investigates the overall performance as well as the impact of the optimizations discussed in this section.

6. Experimental Setup

Two GPUs are used for the evaluation: an AMD Radeon R9 295X2 with AMD APP SDK 2.9.214.1 and driver 1598.5, as well as an Nvidia GTX Titan Black with CUDA 8.0.0 and driver 367.35. All experiments are performed using single precision floats. We report the median runtime of 10 executions for each kernel measured using the OpenCL profiling API. We focus on the quality of the kernel code and, therefore, ignore data transfer times. For benchmarks with multiple kernels, we sum up the kernel runtimes.

Figure 7. Compiler-generated OpenCL kernel for the dot product example shown in Listing 1.
7. Experimental Evaluation

This section evaluates the quality of the \texttt{Lift} compiler using 12 OpenCL hand-optimized kernels collected from various sources shown in Table 1. These represent GPU programs from different fields such as physics simulations (N-Body, MD), statistics and machine learning (KMeans, NN), imaging (MRI-Q), stencil (Convolution), and universally useful linear algebra primitives (ATAX, GEMV, GESUMMV, MM). The characteristics of the reference implementations are described in Table 1. Local and private memory denotes their usage for storing data that is reused. The vectorization of memory or compute operations is indicated as well as global memory coalescing. Iteration space shows the thread organization dimensionality when running the kernel.

7.1 Code Size

Table 1 also shows the code size in lines of code for each benchmark. For \texttt{Lift} we distinguish between the low-level \texttt{Lift} IL which is the input for the \texttt{Lift} compiler discussed in this paper and the high-level \texttt{Lift} IL which is a portable representation introduced in our prior paper [18] which presents an automated process based on rewrite-rules to automatically map the high-level to the low-level \texttt{Lift} IL.

The numbers show that writing high-performance OpenCL kernels is extremely challenging with 768 lines required for an optimized matrix multiplication kernel. The benchmarks in the \texttt{Lift} IL are up to \(45\times\) shorter, especially the portable high-level programs. The low-level \texttt{Lift} programs are slightly longer as they encode optimization choices explicitly.

7.2 Expressing OpenCL Optimizations in the \texttt{Lift} IR

The benchmarks OpenCL implementations encode GPU specific optimizations. Each implementation is represented in the \texttt{Lift} IR by mimicking the OpenCL reference code. We are interested in testing the ability to represent differently optimized programs using the \texttt{Lift} patterns presented in section 3. This section gives a brief overview of different patterns of computation and communication are encoded.

The \textit{N-Body} implementation from the NVIDIA SDK makes use of local memory to store particle locations accessed by multiple threads. In \texttt{Lift} we represent this by copying the particle locations using \texttt{map(id)} nested inside the \texttt{toLocal} pattern. By selecting one of the \texttt{mapSeq}, \texttt{mapLcl}, and \texttt{mapGlb} patterns, we control how the data is copied in the local memory. The AMD implementation does not use local memory but vectorizes the operations expressed using a combination of \texttt{mapVec} and \texttt{asVector}.

The \textit{Convolution} benchmark applies tiling to improve performance by exploiting locality. Overlapping tiles, required by stencil applications, are created using the \texttt{slide} pattern. Two-dimensional tiles are achieved by a clever composition of \texttt{slide} with \texttt{map} and matrix transposition, which itself is expressed using \texttt{split}, \texttt{join}, and \texttt{gather}. These 2D tiles are then cooperatively copied into the local memory using the \texttt{toLocal(mapLcl(id))} pattern composition.

The CLBlast implementation of matrix-vector multiplication (SGEMV) carefully loads elements from the global memory using coalesced memory accesses. In the \texttt{Lift} IR the \texttt{gather} pattern is used to influence which thread loads which element from memory and by choosing the right permutation accesses to the global memory are coalesced.

The \textit{MM} implementations from CLBlast apply slightly different optimizations for both GPUs. For NVIDIA CLBlast uses a combination of \texttt{tiling} in local memory, \texttt{register blocking}, and \texttt{vectorization} of global and local memory operations. For AMD it also uses register blocking and vectorization but not tiling in local memory. In the \texttt{Lift} IR, tiling and register blocking are represented by compositions of the \texttt{split} and \texttt{map} patterns together with a matrix transposition, which is itself expressed as combination of \texttt{split}, \texttt{scatter|gather} and \texttt{join} as seen in section 3.2. The \texttt{Lift} IR vectorize patterns are used for vectorization.

The \texttt{Lift} IR has proven to be powerful and flexible enough to represent our set of benchmarks and their versatile GPU optimizations. The next section investigates the performance obtained when generating OpenCL code from the \texttt{Lift} IR.

Table 1. Overview, Characteristics, and Code size of the benchmarks
Surprisingly, the barrier elimination and control-flow simplification seems to have little effect on performance on both machines. The largest impact is for the AMD version of N-Body where the simplification of control plays an important role since this AMD implementation does not use local memory. The control simplification is able to produce a kernel with a single loop (the reduction) which corresponds to the human-written implementation. On the other hand, without the simplification of control-flow enabled, three loops are produced which results in a 20% slowdown.

7.5 Summary

The experimental evaluation has shown that the optimizations presented in this paper have a significant impact on the performance of more complex applications with a performance improvement of over 20 times. This results in generated code matching the performance of manually tuned OpenCL code.

8. Conclusion

This paper has presented \texttt{Lift}, a functional data-parallel intermediate representation for OpenCL. The \texttt{Lift} IR abstracts away many of the OpenCL concepts and optimizations patterns typically found in hand-written code. The functional nature of \texttt{Lift} makes it an ideal target for existing high-level approaches based on parallel patterns.

By design, \texttt{Lift} preserves high-level semantic information which can be exploited by the \texttt{Lift} compiler to generate efficient OpenCL code. However, as seen in this paper, generating efficient code is far from trivial and requires the careful application of optimizations such as array access simplification. Our evaluation shows that these optimizations are crucial to achieve high performance and produce code on par with hand-tuned kernels.

Acknowledgments

The authors would like to thank Thibaut Lutz, Adam Harries, and Bastian Hagedorn for their work on the \texttt{Lift} implementation. This work was partially supported by Google.
References

A. Artifact Description

A.1 Abstract
The artifact contains the implementation of the Lift compiler described in the CGO 2017 paper Lift: A Functional Data-Parallel IR for High-Performance GPU Code Generation. Furthermore, this artifact contains the scripts and reference implementations required to reproduce the performance results presented in the paper. To validate the results build Lift and the reference implementations with the provided scripts, run the benchmarks and, finally, the plotting script to reproduce the results from Figure 8 in the paper.

A.2 Description

A.2.1 Check-List (Artifact Meta Information)
- **Program**: The Lift compiler implemented in Scala; Benchmark programs implemented in C/C++ using OpenCL.
- **Compilation**: With provided scripts via gcc/g++ and sbt.
- **Data set**: Provided with the corresponding benchmarks.
- **Run-time environment**: Linux with OpenCL
- **Hardware**: Any OpenCL enabled GPU
- **Output**: Runtime in CSV files and plot as PDF
- **Experiment workflow**: Git clone; (docker build and run); run build scripts; run test scripts; run plotting script; observe performance results
- **Publicly available?**: Yes

A.2.2 How Delivered
The artifact is hosted on gitlab at:
https://gitlab.com/michel-steuwer/cgo_2017_artifact
The artifact and its instructions are publicly available.

A.2.3 Hardware Dependencies
An OpenCL enabled GPU is required. In the paper a Nvidia GTX Titan Black and an AMD Radeon R9 295X2 were used.

A.2.4 Software Dependencies
Lift requires Java 8, OpenCL, and a working C++ compiler as its main dependencies. Detailed software dependencies are described on the gitlab page. A Dockerfile is provided which encapsulates all software dependencies.

A.3 Installation
After cloning the repository, build scripts are provided for Lift and the reference benchmark implementations.
Detailed installation descriptions are given on gitlab.

A.4 Experiment Workflow
After building Lift and the reference implementations, provided scripts should be used for running all benchmarks and plotting the results.
Detailed descriptions for the experiment workflow are provided on the gitlab page.

A.5 Evaluation and Expected Result
The main results of the artifact evaluation is to reproduce the performance comparison given in Figure 8 of the paper. Depending on the precise GPU used for evaluation we expect the results to show a similar performance trend as reported in the paper between the Lift generated OpenCL kernels compared to the reference implementations.
The reviewers are invited to investigate the implementation of the Lift compiler and evaluate it against the description given in the paper.

A.6 Submission and Reviewing Methodology
This artifact was successfully evaluated during the artifact evaluation of CGO 2017. The authors would like to thank the reviewers. Their feedback helped to significantly improve this artifact. Especially, the public discussions proved to be valuable for quickly addressing issues.
The methodology used for evaluating this artifact is described on the following webpage:
http://cTuning.org/ae/submission-20161020.html.
