Interleukin-4 is a cytokine widely known for its role in CD4<sup>+</sup> T-cell polarization and its ability to alternatively activate macrophage populations. In contrast, the impact of IL-4 on the activation and function of dendritic cells (DCs) is poorly understood. We report here that DCs respond to IL-4 both in vitro and in vivo by expression of multiple alternative activation markers with a different expression pattern to that of macrophages. We further demonstrate a central role for DC IL-4Rα expression in the optimal induction of IFNγ responses in vivo in both Th1 and Th2 settings, through a feedback loop in which IL-4 promotes DC secretion of IL-12, which in turn, we reveal a central role for RELMα during T-cell priming, establishing that its expression by DCs is critical for optimal IL-10 and IL-13 promotion in vitro and in vivo. Together, these data highlight the significant impact that IL-4 and RELMα can have on DC activation and function in the context of either bacterial or helminth pathogens.

In helminth infection and tissue remodeling, and are capable of suppressing T-cell responses (8–10). MΦs are thought to play vital roles in helminth infection and tissue remodeling, and are capable of suppressing T-cell responses (8–10). However, only a limited number of studies have addressed whether DCs express markers associated with aaMΦ (11–14), and it remains unclear how expression of IL-4–induced molecules may influence DC function in Th2 settings. Somewhat surprisingly, previous work has indicated that IL-4 can enhance production of IL-12p70 by DCs stimulated with bacterial LPS in vitro via inhibition of IL-10 (15–18). This suggests that IL-4 may facilitate DC priming of Th1 responses in ongoing, counterregulatory, Th2 settings (15, 16, 19).

We set out to delineate the role of IL-4 in influencing DC activation and function, both in vitro and in vivo. We show that treatment of DCs with IL-4 in vitro resulted in robust expression of a wide range of alternative activation markers at both the transcript and protein level, with a more selective expression of alternative activation markers RELMα and Ym1 in vivo.

We further demonstrate a key role for DC-derived RELMα in promotion of optimal Th2 responses that contrasts with the previously suggested regulatory function of this alternative activation product (20–22). Together, these data reveal that the ability to respond to IL-4 is critical for optimal Th1 or Th2 priming by DCs through modulation of IL-12/IL-10 or RELMα production, respectively.

Results

IL-4 Induces DC Expression of RELMα in Vivo. The phenotypes of aaMΦ populations, isolated from a variety of tissues in Th2 inflammatory settings, have been well characterized, with one hallmark being the abundant expression of markers RELMα and Ym1 (6). RELMα has also previously been identified in cells other than aaMΦs, including eosinophils and epithelial cells (10, 20, 22).

To investigate whether DCs respond to Th2 environments in a manner similar to MΦs, mice were injected i.p. with rIL-4 complexed with anti–IL-4 mAb (IL-4c), which ensures slow release of cytokine for 2–3 d (23). Peritoneal exudate cells (PEC) were isolated 4 d after mice received a single dose of IL-4c or PBS. For flow-cytometric analysis, granulocytes, monocytes, and B cells were excluded (based on cell size, G1, and CD19 staining). MΦs were defined as F4/80<sup>+</sup>FSC<sub>lo/int</sub>MHC-II<sup>+</sup> and DCs as F4/80<sup>+</sup>FSC<sub>hi</sub>MHC-II<sup>+</sup> (Fig. 1A). IL-4 did not significantly affect the number of DCs in the PEC but, as recently reported (23), significantly increased accumulation of MΦs (P < 0.05; Fig. 1A), suggesting that, in contrast to MΦs, DCs do not proliferate in response to IL-4c injection.

To assess whether IL-4 administration caused alternative activation of these populations, we performed intracellular staining for RELMα and Ym1/2. As expected, MΦs injected with IL-4c–injected mice displayed striking levels of RELMα and Ym1/2 expression compared with MΦs isolated from PBS control animals (Fig. 1B).

Furthermore, the expression of these proteins was not uniform, with RELMα<sup>+</sup>Ym1/2<sup>+</sup>, RELMα<sup>+</sup>Ym1/2<sup>+</sup>, and RELMα Ym1/2<sup>+</sup> MΦ populations all being identified. In contrast to the effect on MΦs, predominantly single positive RELMα–expressing DCs were observed at a low dose of IL-4c (0.6 μg) with little change in Ym1/2 evident. However, at a higher dose of IL-4c (4 μg), a significant proportion of RELMα-positive DCs expressed Ym1/2. In addition, the ability to respond to IL-4 in vivo was not restricted to peri-

Antigen-presenting cells | T lymphocytes | innate immunity | adaptive immunity
toneal cavity DCs, as splenic MHCII^hi^CD11c^hi^ DCs also significantly up-regulated RELMα and Ym1/2 expression following IL-4 injection (Fig. S1).

To determine the general capacity of DCs to alternatively activate in vivo in response to stimuli other than IL-4, we assessed RELMα and Ym1/2 production by DCs from mice infected with *Litomosoides sigmodontis* or *Schistosoma mansoni* (Fig. S2), parasitic helminths that promote strong Th2 responses. Pleural cavity (Fig. S2A) or splenic (Fig. S2B) MHCII^hi^CD11c^hi^ DCs from infected mice displayed significantly increased expression of RELMα in comparison with naive control animals. Ym1/2 expression was less dramatically influenced by infection (Fig. S2). Thus, DCs from diverse tissue sites can express markers associated with aMΦs in vivo, in response to injection with IL-4 or in the more complex setting of helminth infection.

**IL-4 Up-Regulates DC Expression of Multiple Markers of Alternative Activation.** To carefully dissect the influence of IL-4 on a well-characterized population of cells, we generated DCs from murine bone marrow (BM) using GM-CSF, then exposed the DCs to recombinant IL-4 in vitro. As shown previously, DCs expressed IL-4Rα (Fig. 2A) (18), and IL-4 did not substantially alter MHC-II or the costimulatory molecules CD40, CD80 and CD86 (Fig. S3). However, IL-4 significantly increased DC mRNA levels and protein secretion of both RELMα (*Retnla*) and Ym1/2 (*Chi3l3*) (Fig. 2B and C). Intracellular staining showed that production of these
proteins was not limited to a single population, with both RELMα and Ym1/2 single and double-positive DCs clearly distinguishable (Fig. 2D: WT). Verifying that DC up-regulation of RELMα and Ym1/2 was a consequence of IL-4 responsiveness, Il4ra−/− DCs did not up-regulate RELMα and Ym1/2 in response to IL-4 (Fig. 2D: Il4ra−/−). In addition, in WT DCs, IL-4 increased transcripts for Dectin-1 (Clec7a), Mir1 (MR) and Ccl24 (Fig. 2E), markers previously associated with aαM0s (6, 7). However, Arginase-1, another signature molecule of aαM0s (6), was not significantly increased in terms of either transcription or enzymatic activity in IL-4–treated DCs (Fig. 2F). Increased transcript expression of Retnla, Clec7a, and Ccl24 was also seen following in vitro exposure of FACS-purified splenic cDCs from naive mice to IL-4 (Fig. S4). Together, these data reveal that murine DCs can respond to IL-4 in a manner similar to that previously described for aαM0s by significantly up-regulating RELMα and Ym1/2 and other aαM0 markers, with the notable exception of Arginase-1.

**Signaling to DCs via IL-4Rα Alters Their Response to Inflammatory Stimuli and Is Important for Their Ability to Induce IFNγ and IL-17.** Previous studies have shown that IL-4 can boost DC proinflammatory cytokine production upon engagement of specific pattern recognition receptors, and suggested that this may represent a mechanism to enable DC induction of adaptive Th1 responses in IL-4-rich environments (15, 19). We assessed the influence of IL-4 on DCs exposed to IL-4 concurrently with complex Ag from pathogens and individual Toll-like receptor (TLR) ligands. We found that DC exposure to ligands of TLR4 (LPS), TLR9 (CpG), or a heat-killed preparation of the Gram-positive bacterium Propionibacterium acnes (Pa) boosted IL-12p70 secretion, and inhibited production of IL-10, RELMα, and Ym1/2, in response to IL-4 (Fig. S5 A–D). Production of proinflammatory cytokines IL-1β and IL-6 was not significantly altered by IL-4 treatment (Fig. S5E). In contrast to Pa and TLR ligands, DCs exposed to soluble extracts from the egg stage of S. mansoni [soluble egg Ag (SEA)] in the presence or absence of IL-4 did not alter secretion of either RELMα or Ym1/2, indicating that SEA has no potential to drive or block alternative activation of DCs (Fig. S5 C and D). Similarly, unlike Pa- and TLR-pulsed DCs, IL-4 treatment did not alter production of proinflammatory or regulatory cytokines by SEA-exposed DCs. Thus, the influence of IL-4 over DC activation is context dependent: IL-4 can enhance TLR-driven IL-12p70 production, but engagement of these pattern recognition receptors by defined TLR ligands or bacteria can also dramatically inhibit alternative activation markers ordinarily induced by IL-4. In contrast, the helminth Ag SEA did not impede this process. Having demonstrated that DCs can express molecules associated with aαM0s in an IL-4Rα-dependent manner, and that IL-4 can boost TLR-mediated proinflammatory cytokine production, we next addressed the relevance of DC responsiveness to IL-4 for T cell priming, one major characteristic used to distinguish DCs from M0s. We have previously shown that Pa-activated DCs generate a strong mixed Th1/Th17 response following transfer into naive recipient mice (24). In contrast, we have established that DCs pulsed with SEA are capable inducers of Th2 responses both in vitro and in vivo, despite failing to up-regulate traditional markers of activation (5). Although it has been debated recently whether DCs are needed to prime Th2 responses (4), we have definitively shown that Th2 priming to schistosome Ag depends on CD11c+ DCs (25).

To investigate whether DC responsiveness to IL-4 alters priming of naive T cells, we generated WT or Il4ra−/− DCs, exposed them to Pa or SEA in vitro, then adoptively transferred them into WT naive recipient mice, and compared Ag-specific immune responses in the draining LN (dLN). Transfer of Pa pulsed Il4ra−/− DCs resulted in significantly lower amounts of Ag-specific IL-17 and IFNγ in recipient mice, in comparison with WT PA DCs (Fig. 34). This demonstrates that DC IL-4Rα signaling is required to promote optimal T-cell responses even in a Th1/Th17 polarizing environment with low levels of available Th2 cytokine. The deficiency in IL-17 priming is unlikely to be due to alteration in DC production of Th17-promoting cytokines IL-1β and IL-6, as IL-4 did not significantly influence secretion of either of these cytokines by DCs responding to Pa in vitro (Fig. S5E).

In the context of helminth- rather than bacterial Ag-conditioned DCs, Il4ra−/− SEA DCs induced similar levels of Ag-specific IL-4 and IL-13, but significantly lower amounts of IL-10 and IFNγ in comparison with WT SEA DCs (Fig. 3B). This indicates that DC expression of IL-4Rα is not an absolute requirement for Th2 priming, but is needed for the induction of IFNγ and IL-10 responses against SEA. In keeping with previous work (26), the level of IL-17 induced by SEA-activated C57BL/6 DCs was negligible, and was not influenced by the presence or absence of IL-4Rα on the transferred DCs. The reduced ability of Il4ra−/− DCs to promote Pa-specific IL-17 and IFNγ, and SEA-specific IL-10 and IFNγ, was not due to a fundamental defect in Ag uptake, processing, or presentation by these cells. Il4ra−/− DCs capably took up Ag in the form of FITC-labeled dextran (Fig. S6), and displayed enhanced ability to stimulate proliferation of OVT TCR Tg T cells in vitro, following exposure to ovalbumin (OVA) peptide or protein, compared with WT DCs (Fig. S7).

**IL-4 Alters the Response of DCs to CD40 Ligation.** CD40 expressed by DCs binds CD154 on the surface of activated T cells, this interaction enhancing DC activation and cytokine production which is often crucial for their ability to prime Th1, Th2 and Th17 responses (24, 27). To address whether the IL-4-induced alteration in the balance of IL-12, IL-10, RELMα, and Ym1/2 production by DCs might be influenced by interaction with T cells we examined the impact of CD40 ligation on DC cytokine production following IL-4 exposure. To mimic DC–T-cell interaction in vitro, we analyzed cytokine secretion by DCs that had previously been exposed to Pa or SEA in the presence of absence of IL-4, after stimulation with agonistic αCD40 mAb. IL-4 treatment of Pa-pulsed DCs significantly enhanced pro-

---

**Fig. 3.** Il4ra−/− DCs are less able to induce IFNγ and IL-17 responses. WT or Il4ra−/− BMDCs were cultured overnight in medium alone (M), with Pa (A) or SEA (B), harvested, and injected s.c. into WT mice. Seven days later, the draining pLN were harvested, cells were restimulated for 72 h with Pa (A) or SEA (B), and cytokine secretion was assessed by ELISA. Data are representative of five experiments. Error bars indicate SEM of three to five mice per group.
duction of IL-12p40, IL-6, and IL-12p70, and reduced secretion of IL-10, following addition of αCD40 mAb (Fig. S8A). However, in keeping with previously published data (28), control (medium) DCs or SEA DCs did not produce significant amounts of IL-12p70 or IL-10 following stimulation with anti-CD40, and this was not influenced by IL-4 exposure (Fig. S8A). Therefore, the influence of IL-4 on cytokine secretion by DCs responding to bacterial stimulation was not transient, and extended to secondary activation via CD40 ligation.

Previous studies have suggested that RELMα and Ym1/2 may have a role in regulating or promoting T-cell responses, respectively (14, 21, 22), and it is conceivable that during T-cell priming, CD154 expressed by T cells could engage DC CD40 and influence secretion of these molecules. However, IL-4–treated DCs stimulated with αCD40 mAb produced similar levels of RELMα and Ym1/2 compared with isotype controls (Fig. S8B), indicating that CD40 stimulation does not regulate IL-4–driven expression of these alternative activation products either in control or SEA DCs. Furthermore, in the case of Pa stimulated DCs, bacterial inhibition of RELMα and Ym1/2 was maintained throughout culture, and was not overcome by CD40 ligation (Fig. S8B). These CD40 ligation experiments also illustrate that DCs previously exposed to IL-4 still produced substantial amounts of RELMα and Ym1/2 up to 36 h after initial cytokine treatment (Fig. S8B). Thus, production of RELMα and Ym1/2 by DCs is not transient and requires neither the continued presence of IL-4 nor subsequent CD40 ligation.

**DC Secretion of RELMα During Th2 Priming Regulates IFNγ and Promotes Th2 Responses.** Although our data demonstrate that DC sensitivity to IL-4 plays an important role in priming of T-cell IL-10, IL-17, and IFNγ (Fig. 3 A and B), it is not clear whether this is a consequence of alternative activation marker expression or some other facet of the diverse influence of IL-4 on DCs (Fig. 2 and Fig. S5). To specifically address the role of a defined alternative activation product in T-cell priming, we generated DCs from Retnla−/− mice (20), which were similar to WT in terms of numbers and phenotype. We adoptively transferred SEA- or Pa-pulsed WT or Retnla−/− DCs into WT naïve recipient mice and assessed the resulting Ag-specific immune response.

Retnla−/− Pa DCs induced similar IFNγ and IL-17 responses to WT DCs in the draining LN following transfer (Fig. 4A), demonstrating that DC-derived RELMα neither promotes nor regulates T-cell differentiation in a bacterial Th1/Th17 setting. Thus, impaired priming by IL4α−/− DCs exposed to bacteria (Fig. 3A) is RELMα independent. The lack of a major role for RELMα in Th1/Th17 priming also fits with the observed inhibition of IL-4–induced RELMα expression by DCs following bacterial or TLR ligand exposure (Fig. S5).

To directly assess the importance of DC RELMα secretion in a Th2 setting, we transferred Retnla−/− DCs pulsed with SEA into naïve recipients. In repeated experiments, both WT and Retnla−/− SEA DCs stimulated similar levels of Ag-specific IL-4, but mice that received Retnla−/− DCs displayed significantly reduced levels of IL-10 and IL-13 compared with WT SEA DCs (Fig. 4B). Furthermore, Retnla−/− SEA DCs induced significantly greater amounts of IFNγ compared with WT SEA DCs (Fig. 4B). This suggests that DC production of RELMα is required for optimal Th2 cell priming by helminth-activated DCs, promoting some components of the Th2 response while regulating the level of the Th1 response.

To further dissect requirements for DC RELMα production in promoting optimal T-cell Th2 cytokine secretion, we examined the ability of WT or Retnla−/− DCs to induce CD4+ T-cell IL-4, IL-10, and IL-13 in vitro. In this assay, the addition of exogenous IL-4 to WT DCs cocultured with CD4+ IL-10GFP− T cells primed from Kn2 mice in vitro (29), or CD4+ T cells from Kn2 mice in which IL-4–producing cells express huCD2 (30), resulted in induction of T-cell expression of eGFP or huCD2, and secretion of IL-10 and IL-13 (Fig. 4C and D). In keeping with the lack of a significant impact of RELMα deficiency on IL-4 induction in vivo (Fig. 4B), Retnla−/− DCs capably provoked huCD2 expression on responding Kn2 T cells in vitro (Fig. 4C). However, Retnla−/− DCs were incapable of promoting T-cell expression of IL-10 mRNA as detected by GFP expression (Fig. 4C). Furthermore, analysis of secreted cytokine by ELISA showed that cultures of CD4+ T cells and WT DCs produced more IL-10 and IL-13 protein in the presence of IL-4 compared with cocultures with Retnla−/− DCs (Fig. 4D). Interestingly, T cells cultured with WT DCs secreted lower levels of IFNγ protein than their Retnla−/− counterparts, supporting observations following in vivo DC transfer of SEA activated DCs (Fig. 4B).

**Fig. 4.** DC expression of RELMα during Th2 priming regulates IFNγ and promotes Th2 responses. A, IL-17, IL-4, and IL-13 expression by DCs following bacterial stimulation was quantified by ELISA (A) or by ELISA and flow cytometry (B). WT or Retnla−/− BMDCs were cultured in medium alone (M), Pa (A), or SEA (B) and injected s.c. into WT mice. Next, 5–7d later, pLN were harvested, cells were restimulated for 72 h with Pa (A) or SEA (B), and cytokine secretion was assessed by ELISA. CD4+ cells sorted from Kn2 IL-4 reporter mice, or IL-10GFP−CD4− cells, were cultured for 4 d with WT or Retnla−/− BMDCs and anti-CD3 mAb with or without IL-4 and assessed for IL-4 protein production or IL-10 mRNA expression by flow cytometry (C) and cytokine secretion by ELISA (D). Data are representative of two (A and C) or four (B and D) experiments. Error bars indicate SEM of three to five mice (A and B) or four to five replicate wells (C and D) per group.

9980 | www.pnas.org/cgi/doi/10.1073/pnas.1121231109

Cook et al.
Mechanistically, the altered ability of Retnla−/− DCs to polarize SEA-specific cytokine responses was not due to defective Ag uptake, processing, or presentation by these cells. Similar to Il4ra−/− DCs, Retnla−/− DCs competitively took up Ag (Fig. S6), and showed evidence of the altered ability to mount proliferative OTI TCR Tg T cells in vitro (Fig. S7), with either OVA peptide or protein. This increased proliferation is consistent with expectation, given the reduced IL-10 production evident following transfer of Retnla−/− DCs in vivo (Fig. 4B) or coculture of Retnla−/− DCs with T cells in vitro (Fig. 4 C and D).

These data strongly suggest that DC production of RELMα is an important process both for directing priming of Th2 responses and for control of Th1 responses, and provide mechanistic insight into the function of RELMα during the early stages of T-cell activation.

Discussion

A substantial body of literature documents the ability of IL-4 to generate aaMΦs in multiple settings. However, comparatively few studies have addressed how DCs respond to IL-4, whether they can express markers associated with aaMΦs (11–14), and what the functional relevance of this expression may be. The data that we present here reveal that murine DCs can respond to IL-4 both in vitro and in vivo in a manner similar to that previously described for aaMΦs, by significantly up-regulating RELMα, Ym1/2, and other aaMΦ makers, with the notable exception of Arginase-1. Furthermore, we have identified that DC expression of RELMα plays a critical role in their instruction of T cells to produce IL-10 and IL-13. This demonstrates a previously undescribed role for RELMα, and reveals that DC responsiveness to IL-4 is vital for priming optimal Th2 responses.

Exposure of DCs to IL-4 triggered expression of numerous markers associated with aaMΦs, but one notable difference was the lack of Arginase-1 up-regulation at both the mRNA and protein activity level. Arginase-1 competes with iNOS for L-arginine, impairing proliferation of T cells in the lesion (31). Furthermore, MΦ-derived Arginase-1 is required to suppress T-cell proliferation during Th2 infection, where it limits pathology (8). The function of DCs is instead mainly to prime naïve T cells in the early phase of immune response development. In this context, a high level of Arginase-1 expression by immunogenic DCs that could deplete L-arginine, impairing proliferation of T cells in the lesion, is deleterious (31). In peripheral environments, DCs migrate away from the site of CD40 ligation of a wide range of alternative activation-related molecules in DCs, which are mainly found in fungal cell walls, initiates proinflammatory responses in DCs even in the absence of TLR ligation (33). Our finding that IL-4 increases DC expression of both these C-type lectin receptors suggests that they will have an enhanced ability to internalize and respond to a wide range of glycosylated pathogen motifs that could further modulate their activation and function. Increased DC expression of CCL24 could also influence this process, as this chemokine can enhance recruitment of CCR3-expressing cells such as eosinophils and basophils, as has been reported for CCL24-producing aaMΦs in the lung (34). These recruited granulocytes could, in turn, assist Th2 priming in certain situations through provision of cytokines such as IL-4.

As well as identifying that DCs can display hallmarks of alternative activation following IL-4 exposure in vitro and in vivo, we have revealed DC expression of alternative activation markers in the context of chronic helminth infection, a subject that has so far barely been addressed in the literature (11). There was some heterogeneity in the levels of specific markers expressed when comparing in vitro and in vivo settings, in particular with Ym1/2. This could reflect basic differences between BMDCs and their in vivo counterparts, or differential regulation of aspects of DC alternative activation in vivo, in line with the well-documented diversity of aaMΦs (6).

Our results also support and extend previously published work addressing how IL-4 might alter the IL-12/IL-10 balance (15, 19), but are unique in showing the impact of IL-4 on T-cell polarization by DCs in vivo. Our data highlight an important feedback loop in DC-mediated priming in vivo, where sources of IL-4/IL-13 will not only promote Th2 responses (4), but will down-regulate DC-mediated priming of Th1 responses through enhancement of IL-12p70 and inhibition of IL-10 production by DCs. Extending our understanding of the cross-talk between microbes, DCs, and their environment, we have demonstrated the ability of defined TLR ligands and heat-killed bacteria to inhibit the ability of IL-4 to prompt RELMα and Ym1/2 production by DCs. In light of our identification of a pro-Th2 role for DC-derived RELMα, inhibition of such by bacteria or their products may be important in some settings to allow optimal Th1/Th17 immunity to develop.

In peripheral environments, DCs might migrate from the site of Ag exposure toward draining LNs (35). In order for RELMα and Ym1/2 to play a relevant role in T-cell priming in the draining LNs, DC expression of such molecules would have to be prolonged, or responsive to subsequent interaction with T cells. We have shown that production of RELMα and Ym1/2 by DCs is not transient and requires neither the continued presence of IL-4 nor subsequent CD40 ligation. Furthermore, by adoptive transfer of Retnla−/− DCs in vivo, we have identified a previously unreported requirement for DC production of RELMα in the initiation of Th2 responses in the LN draining the site of DC introduction. All non-promoting role for IL-13 correlated with the down-regulatory role that has previously been described using global Retnla−/− mice, which identified RELMα as a negative regulator of ongoing Th2 inflammation against helminth Ag, with Retnla−/− mice displaying elevated Th2 responses and greater pathology (21, 22). These reports would suggest that the ultimate role for RELMα produced by multiple cellular sources in vivo (including eosinophils, epithelial cells, and MΦs) is to regulate chronic Th2 pathology by influencing T-cell differentiation and cellular recruitment while regulating wound repair. In the present study, we focused on the early events in Th2 priming by DCs responding to IL-4 in vivo. By restricting RELMα deficiency to DCs alone, our results extend our fundamental understanding of the cellular, temporal, and spatial diversity of RELMα function, demonstrating an alternative function of DC expression of this molecule early in immune response development. Our identification of a critical role for DC-derived RELMα in promotion of T-cell production of IL-10 reveals a mechanism that may, in part, explain the dysregulated immune pathology previously observed in Th2 infection models using global Retnla−/− mice (21, 22).

It is clear from our results that RELMα production does not solely account for Th2 induction by DCs, but helps promote specific facets of this response (IL-10 and IL-13). Because we have shown that IL-4 stimulates production or expression of a wide range of alternative activation-related molecules in DCs, and that Il4ra−/− and Retnla−/− DCs do not display identical functional ability, it is likely that a combination of IL-4–induced products will work together and in balance to ultimately dictate the character of the resultant Th2 response. For example, as Ym1/2 has previously been suggested to promote some Th2 cytokines, at least in vitro, its production by DCs responding to IL-4 may act in concert with RELMα and other alternative activation products to generate optimal Th2 immunity.

In summary, we have shown that the canonical Th2 cytokine IL-4 can have a profound impact on DC activation and function, triggering both in vivo and in vitro expression of a range of
molecules ordinarily associated with aMφs, altering responsiveness to challenge with bacteria and TLR ligands, and dramatically influencing T-cell response induction and polarization. Although the cumulative impact of IL-4 on DC activation and function is complex, in the context of pathogenic stimulation, the over-riding effect of IL-4 appears to be to enable IFNγ induction through enhanced DC IL-12p70 production. Furthermore, DC production of the IL-4 induced protein, RELMγ, is important in priming of T-cell IL-10 and IL-13. Together these findings indicate that IL-4 has a more influential and diverse role in directly regulating DC-mediated T-cell priming than has been previously appreciated.

**Materials and Methods**

**Mice and IL-4 injections.** C57BL/6, BALB/c, Retnla−/−, IL-10eGFP×DOG, KN2 (C57BL/6), Il4ra−/−, and OTI mice (20, 23, 25, 28, 30) were maintained under specific pathogen-free conditions at the University of Edinburgh. Experiments were conducted under a Project License granted by the Home Office (United Kingdom) in accordance with local guidelines. IL-4ant/ant-IL-4 mAb complexes (IL-4c) were prepared as described previously (23). Mice were injected i.p. with 50 μL PBS or 0.625–10 μg IL-4 complexed to 11B11, and peritoneal exudate cells (PEC) and spleens harvested 4 days later.

**Cell Culture and DC Transfer.** BM-derived DCs were generated with GM-CSF as previously described (36). Following 10 d of culture, BMDCs were harvested and replated at 2 × 10^3/mL for 18 h in the presence or absence of rIL-4 (20 ng/mL; Peprotech). In coculture experiments, CD4+ T cells were sorted from IL-10eGFP×DOG or KN286xB6 mice using BD FACs Aria-II and cultured with WT or Retnla−/− DCs. For DC transfer, WT, Il4ra−/−, or Retnla−/− BMDCs were cultured as above, with SEA, Pa, or medium alone. BMDCs were injected s.c. into recipient WT mice (2.5 × 10^6 per foot) and 5–7 d later the draining popliteal LNs and restimulated as previously described (24, 36).

**RNA Isolation and Quantitative PCR.** RNA was recovered from cells using Trizol (Invitrogen), cDNA was generated using SuperScript-III (Invitrogen). Relative quantification of the gene of interest was performed by quantitative PCR. Primer details are given in **SI Materials and Methods**.

**Statistical Analysis.** Statistical analyses were carried out using GraphPad Prism 5. The Student’s t test or one-way analysis of variance was used to determine significant differences between sample groups (in figures, *P < 0.05 **P < 0.01 ***P < 0.001 ****P < 0.0001).

**ACKNOWLEDGMENTS.** We thank Rob Thompson for preparation of bone marrow samples, Martin Waterfall for cell sorting and assistance with flow cytometry, and David Gray and Markus Mohrs for provision of IL-10eGFP and KN2 mice. We also thank Rachel Lundie, Alex Phythian-Adams, Lauren Webb, Dominik Rückerl, and Elia Talt for support with experiments and critique of the manuscript. Schistosomes used to generate soluble egg Ag for this research were supplied by the National Institute of Allergy and Infectious Diseases (NIAID) Schistosomiasis Resource Center at the Biomedical Research Institute (Rockville, MD) through Contract N01-AI-30026. This work was supported by Medical Research Council UK G0701437 (to A.S.M.) and G0600818 (to J.E.A.) and by the Wellcome Trust (L.H.J.).
