Received 26 October 2010/Accepted 17 January 2011

Massively parallel sequencing of transposon-flanking regions assigned the genotype and fitness score to 91% of *Escherichia coli* O157:H7 mutants previously screened in cattle by signature-tagged mutagenesis (STM). The method obviates the limitations of STM and markedly extended the functional annotation of the prototype *E. coli* O157:H7 genome without further animal use.

Enterohemorrhagic *Escherichia coli* (EHEC) strains comprise a subset of Shiga toxin-producing *E. coli* strains that cause acute enteritis in humans (2). Infections may be complicated by severe sequelae and are frequently acquired via contact with ruminant feces. The molecular mechanisms underlying colonization of the ruminant intestines by EHEC are incompletely understood. Previously, we screened a library of 1,900 EHEC O157:H7 mutants for their ability to colonize bovine intestines by signature-tagged mutagenesis (STM) (6). STM relies on a panel of transposons harboring unique oligonucleotide tags. The tags can be detected by amplification and hybridization, enabling the composition of complex pools to be analyzed before and after inoculation of animals. Mutants that are negatively selected in vivo relative to the inoculum are inferred to lack a gene required for colonization or survival, which can be identified by isolation and sequencing of transposon-flanking regions (16).

Our analysis focused on the prototype *E. coli* O157:H7 strain EDL933, for which the chromosome and plasmid sequences are known (1, 18). Of the 1,900 signature-tagged mutants screened, 101 were underrepresented in pools recovered from feces 5 days postinoculation of calves (6). The transposon insertion site could be mapped in 79 such mutants, identifying 59 different genes influencing colonization (6). Thirteen attenuating mutations were mapped to the locus of enterocyte effacement (LEE), which encodes a type III secretion system (T3SS) required for the formation of “attaching and effacing” lesions. The role of T3SS components in intestinal colonization was subsequently confirmed with defined mutants (6, 17) and by screening of 480 signature-tagged mutants of EHEC O26:H− from calves (27). STM also detected attenuating mutations in genes encoding secreted substrates of the T3SS (espD, map, and rleD) (6).

Though STM has provided valuable insights into the genetic basis of virulence of microbes, it is limited by the number of unique tags and the effort required to construct libraries and map attenuating mutations. Moreover, only negatively selected mutants tend to be investigated and subjective judgments are required to compare signal intensities relative to the input and coscreened mutants. Functional annotation of the *E. coli* O157:H7 genome in reservoir hosts is further hindered by the cost of using large animals at a high level of disease containment. Recently, several protocols have been described that permit the simultaneous assignment of the genotype and fitness score for mutants screened in pools. Transposon-directed insertion-site sequencing (TraDIS) exploits Illumina sequencing to obtain the sequence flanking each transposon insertion (11). The massively parallel nature of such sequencing permits comparison of the number of specific reads derived from inocula and output pools recovered from animals, providing a numerical measure of the extent to which mutants were selected in vivo. TraDIS obviates the need to construct and array uniquely tagged mutants and to subclone and sequence attenuating mutations, yielding substantial time and cost savings. TraDIS-like methods have defined the essential gene complement of *Salmonella enterica* serovar Typhi (11) and *Streptococcus pneumoniae* (28) and have identified genes influencing *Haemophilus influenzae* pathogenesis (7) and survival of the gut symbiont *Bacteroides thetaiotaomicron* (8).

We retrospectively applied TraDIS to assign the genotype and fitness score of EDL933 mutants previously screened in calves. This required the massively parallel sequencing of transposon-flanking regions in the input and output pools of

EDL933 mini-Tn5Km2 mutants obtained by Dziva et al. (6), as schematically shown in Fig. 1. Adequate genomic DNA was retrieved for 19 of the mutant pools screened, comprising a total of 1,805 mutants. Genomic DNA from each input and output sample was quantified with a Nanodrop ND-1000 spectrophotometer (Thermo Fisher, Loughborough, United Kingdom). Equal amounts (1 μg) from all input and all output samples were pooled, and input and output pools were separately fragmented by ultrasonication with a Covaris adaptive focused acoustics instrument, to an average of 200 bp (19). Fragment libraries were prepared with the Illumina paired-end DNA sample preparation kit (PE-102-1001; Illumina, Little Chesterford, United Kingdom), according to the manufacturer’s instructions, and quantified on an Agilent DNA1000 chip (Agilent, South Queensferry, United Kingdom). To form double-strand adapters, oligonucleotides Ind_Ad_T (5’-ACACTCTTTCCCTACACGACGCTCTTCCGATC*T-3’ [where the asterisk represents phosphorothioate] and Ind_Ad_B (5’-pGATCGGAAGAGCGGTTCAGCAGGAATGCCGAGACGTCCTTCCGATCT-3’) were annealed. The input and output DNA was ligated to the double-strand adapters and then quantified by quantitative PCR (qPCR) using the primers Ad_T_qPCR1 (5’-CTTTCCTACACGACGCTCTTCCGATC*T-3’) and Ad_B_qPCR2 (5’-ATTCCCTGCTACACCGGCTCTTCCGATCT-3’) and SYBR green (Applied Biosystems, Warrington, United Kingdom). Two hundred nanograms of adaptor-ligated fragments was used to specifically amplify transposon insertion sites. Twenty-four cycles of PCR were performed with transposon-specific forward primer MiniTn5-P5-3pr-3 (5’-AATGATACGGCGACCACCAGATCTACACCTAGGCTGCGGCTGCTGTGTA-3’), which contains the Illumina P5 end for attachment to the flow cell, and reverse primer RInV3.3 (5’-CAACGAGAAGACCCATTACGAGACCGGTACACTCTTTCCCTACACCGGCTCTTCCGATCT-3’), containing the Illumina P7 end. PCR products were size separated on an agarose gel, and fragments of 350 to 450 bp were excised and recovered with QiaExII gel extraction columns (Qiagen, Crawley, United Kingdom) following the manufacturer’s instructions, but without heating (19). DNA was eluted in 30 μl of elution buffer, and quantified by qPCR with standards of known concentration, using primers Syb_FP5 (5’-AATGATACGGCGACCACCAGATCTACACCTAGGCTGCGGCTGCTGTGTA-3’) and Syb_RP7 (5’-CAACGAGAAGACCCATTACGAGACCGGTACACTCTTTCCCTACACCGGCTCTTCCGATCT-3’) (19).

The DNA fragment libraries were sequenced for 37 cycles according to the manufacturer’s instructions on single end flow cells by an Illumina GAII sequencer, using the custom sequencing primer MiniTn5-3pr-seq3 (5’-TAGGCTGCGGCTGCACCTGTTGTA-3’), which binds 10 bp from the transposon end. There were 12.6 and 13.3 million reads obtained for the input and output pools, respectively (European Nucleotide Archive accession no. ERP000368). Totals of 12.1 million (96.3%) of the input reads and 12.4 million (93.7%) of the output reads contained perfect matches to the 3’ end of mini-Tn5Km2 (3), and these reads were included in downstream analyses. Transposon-derived sequence was removed from each read with a custom Perl script available from the authors. The remainder of each sequence read was mapped to the

**FIG. 1.** (A) Schematic representation of the screening of signature-tagged mutants of EDL933 from cattle. Uniquely tagged mini-Tn5Km2 mutants were arrayed in 96-well microtiter plates (1 well in each plate was left empty), and a total of 19 plates were separately screened by oral inoculation of a single calf (6). Genomic DNA was prepared from the pool of 95 mutants in the inoculum (input) and bacteria recovered from the feces of each infected calf (output). All 19 input samples and all 19 output samples were pooled into massively parallel sequencing of transposon-flanking regions, as schematically shown in panel B. Separately, genomic DNA from the input and output pools was fragmented, and Illumina paired-end adapters were ligated to the ends. This produces a mixture of fragments, some of which contain the transposon and the adjacent bacterial genome sequence. A 24-cycle PCR was performed with a transposon-specific primer and an adapter-specific primer, and products of the appropriate sizes were selected on an agarose gel. Amplicons were sequenced with a nested transposon-specific primer that anneals 10 nucleotides short of the end of the transposon.
EDL933 chromosome and pO157 with NovoAlign (Novocraft Technologies Sdn Bhd, Selangor, Malaysia). Totals of 9.9 million input reads (78.4%) and 10.7 million output reads (80.6%) were mapped to unique positions in the EDL933 genome. Subsequent analyses were performed with R, version 2.8.0 (R Foundation for Statistical Computing, Vienna, Austria).

To quantify changes in the number of reads arising from specific insertions between the input and output, we adopted an approach suggested for RNA-Seq data analysis (15). The number of reads at each insertion location ($x$) was treated as a proportion of the total number of mapped reads ($n$), and a variance-stabilizing arcsine-root transformation was applied, converting each value of $x$ to $\sqrt{n}/n$. The transformed output values were divided by the equivalent input values to determine the fold change. To avoid infinite values derived from taking the log of 0, sequence counts of 0 were replaced with an arbitrary value of 0.5. $\log_2$ fold change values were calculated to represent the difference in abundance of each mutant in the output pools relative to the input and provide a measure of fitness. In our experience, TraDIS may overpredict the number of insertion sites due to a low-level background signal derived from incorrectly mapped or chimeric reads. To distinguish genuine inserts from this background signal, predicted insertion sites with fewer than 25 (i.e., chimeric reads) were considered exhauster at the time, TraDIS identified 54 insertions during the library screen. Table S1 in the supplemental material lists the insertion site and $\log_2$ fold change relative to input for each mutation.

Figure S1 in the supplemental material shows a histogram of $\log_2$ fold change values obtained for all the mutants. This distribution was modeled by fitting a bimodal normal distribution using the R package mixdist (13) (Fig. S2). This model represents the mutants as a mixture of two distinct populations. Most of the mutants show no attenuation, with no clear change in abundance relative to the input pool and a normal distribution of $\log_2$ fold change values with a mean close to 0. Attenuated mutants show lower $\log_2$ fold change values, with a mean of approximately $-3$. The model suggests that a $\log_2$ fold change of $-1$ (equivalent to a 2-fold decrease in the abundance of the mutant in the output pool relative to the input) is a suitable cutoff value to identify most of the attenuated mutants while restricting the number of false positives to an acceptable level.

Seventy-two insertions were detected by both STM and TraDIS, 86.1% of which were negatively selected, except those with insertions in rofI or the region between ler and espG (Fig. 3). Insertions in the LEE-flanking regions were not attenuating. Mutations in predicted T3SS structural components were strongly negatively selected, with the exception of a single insertion in a gene of unknown function (rorf8). Several LEE genes were disrupted many times, producing comparable fitness scores. Variance in the scores for a given gene may reflect differences in competition dynamics in the pools in which the mutants were screened. TraDIS found 5 attenuating mutations in eae, encoding intimin and 3 mutations in tir, encoding the translocated intimin receptor. These were missed by STM, even though intimin and Tir play key roles in intestinal colonization of cattle by E. coli O157:H7 (22, 29). TraDIS also identified mutations in 29 of the 39 type III secreted effectors of E. coli O157:H7 verified by Tobe et al. (26) (see Table S2 in the supplemental material). Mutants with insertions in several LEE-encoded effectors (EspF, EspB, Tir, Map, EspH, and EspZ) were all negatively selected, consistent with the role of such effectors in intestinal persistence of Citrobacter rodentium in mice (4) and E. coli O157:H7 in rabbits (20). Of the non-LEE-encoded effectors, several appeared to play little or no role (e.g., NleG, NleH, EspY1, and EspY4) (Table S2), whereas mutations in the genes coding for the others were attenuating. Among the latter was z1829, encoding EspK, an effector missed by STM but which influences persistence of EHEC in calves (27, 30). Though several effector phenotypes have been independently verified, we caution that some attenuating mutations identified by STM could not be reproduced when mutants were tested in isolation (e.g., map) (6) or by coinfection with the parent strain (e.g., nleD) (14), possibly due to the distinct selection pressure exerted by combining 95 mutants during the library screen.

Analysis of signature-tagged mutants of EHEC O26:H\textsuperscript{+} in calves indicated that the cytotoxins EspP and enterohemolysin may promote intestinal colonization (27). Though mutants with defects in these genes were not detected in the EDL933 STM screen (6), TraDIS revealed that several such mutants were represented in the library and were generally negatively selected in calves. Three of four EDL933 espP mutants were attenuated by TraDIS (see Table S1 in the supplemental material), consistent with the modest attenuation of a defined espP mutant in calves (5). Nine of 11 mutants with defects in the enterohemolysin (EHEC-hly) operon were negatively selected by TraDIS, supporting the attenuation of an ehxA mutant of EHEC O26:H\textsuperscript{+} in calves (27). EhxA appears not to play a significant role in rectal colonization in steers (22); however, the latter study involved rectal application of the mutant to ruminant steers, without passage through the intestines. Eight insertions were detected in l7031/tagA, which encodes a zinc metalloprotease that cleaves Cl-esterase inhibitor (StcE) (12), promotes adherence (9), and modulates neutrophil function (25). StcE mutants were generally underrepresented in calves, as were mutants with insertions in the EtpCD type II secretion system required for StcE secretion, consistent with the role of this system in colonization of rabbits (10). Seventeen mutations were detected in the gene encoding the large clostridial toxin homolog L7095/ToxB, though only 7 were negatively selected by greater than $-1$ $\log_2$ fold change.
FIG. 2. Circular diagrams of the *E. coli* O157:H7 strain EDL933 chromosome and pO157 plasmid showing the locations of transposon insertions. For the chromosome, from the outside in, circle 1 indicates the positions of all the coding sequencer (CDS) transcribed in a clockwise and anticlockwise direction, respectively (light blue); circle 2 indicates the attenuating transposon insertions mapped by STM (6) (red); circle 3 indicates all transposon insertions mapped by TraDIS analysis of 1,805 of the same mutants screened by STM (dark blue); circle 4 indicates insertions mapped by TraDIS that were negatively selected by at least $-1 \log_2$ fold change (light blue); and circle 5 shows GC bias $[(G-C)/(G+C)]$. Khaki indicates values that are $>1$, and purple indicates values that are $<1$. Circle 6 shows the percentage of G+C content (black); regions with a high percentage of A+T content showing overrepresentation of insertions are highlighted in orange, including the LEE. a, duplicated O islands where transposon insertions cannot be mapped by TraDIS; b, region containing essential genes encoding ribosomal components, (e.g., *rps*, *rpl*, and *rpm*). Numbers indicate megabase pairs along the genome. For the plasmid, the outer circle represents all CDS; circle 2 represents all transposon insertions mapped by TraDIS, circle 3 represents insertions mapped by TraDIS that were negatively selected by at least $-1 \log_2$ fold change, circle 4 represents GC bias $[(G-C)/(G+C)]$. Khaki indicates values that are $>1$, and purple indicates values that are $<1$. Circle 5 represents the percentage of G+C content (black). Numbers indicate thousands of base pairs.
This relatively weak phenotype is consistent with the phenotype of a defined \textit{E. coli} O157:H7 \textit{toxB} mutant in calves (24). Other genes carried by pO157 that were missed by STM but putatively linked to colonization by TraDIS include \textit{katP} (catalase-peroxidase), \textit{l7029/msbB} (lipid A myristoyl transferase), and a gene of the linked \textit{ecf} operon (\textit{l7026}).

TraDIS faithfully reproduced the fitness defect of mutants detected by STM that are impaired in O-antigen biosynthesis (e.g., \textit{manC}, \textit{per}, \textit{wbdP}, and \textit{wzy}), consistent with the phenotype of an \textit{E. coli} O157:H7 perosamine synthetase (\textit{per}) mutant in steers (23). It also identified other attenuating mutations missed by STM that affect this process, as well as other pathways implicated in bacterial survival \textit{in vivo}, such as aromatic amino acid biosynthesis (\textit{aroA}) and iron storage (\textit{fin}). Of further interest, TraDIS identified an attenuating mutation in the catalytic subunit of Shiga toxin 1 (\textit{stx1A}). Previously, STM identified an attenuating mutation downstream of the toxin genes in prophage CP-933V but upstream of those involved in bacterial lysis. The attenuation of the \textit{stx1A} mutant supports the finding that Stxl promotes intestinal colonization of mice by \textit{E. coli} O157:H7 (21).

In conclusion, TraDIS validated and substantially extended our analysis of signature-tagged \textit{E. coli} O157:H7 mutants in cattle. It described the genotype and fitness score for 91.1% of mutants screened, unlocking hundreds of novel phenotypes with no further animal use. It represents a significant advance toward the principles of reduction, refinement, and replacement of animals in research and is relatively inexpensive to apply \textit{de novo} or retrospectively. The procedures described herein relate to transposons that have been extensively used in other microbes (reviewed in reference 16) and can therefore be widely applied to derive quantitative data for functional annotation of microbial genomes.
