**Abstract**

African trypanosomes cause disease in humans and livestock, generating significant health and welfare problems throughout sub-Saharan Africa. When ingested in a tsetse fly bloodmeal, trypanosomes must detect their new environment and initiate the development responses that ensure transmission. The best-established environmental signal is citrate/\textit{cis} aconitate (CCA), this being transmitted through a protein phosphorylation cascade involving two phosphatases: one that inhibits differentiation (TbPTP1) and one that activates differentiation (TbPIP39). Other cues have been also proposed (mild acid, trypsin exposure, glucose depletion) but their physiological relevance and relationship to TbPTP1/TbPIP39 signalling is unknown. Here we demonstrate that mild acid and CCA operate through TbPIP39 phosphorylation, whereas trypsin attack of the parasite surface uses an alternative pathway that is dispensable in tsetse flies. Surprisingly, glucose depletion is not an important signal. Mechanistic analysis through biophysical methods suggests that citrate promotes differentiation by causing TbPTP1 and TbPIP39 to interact.

**Introduction**

Eukaryotic developmental events are a response to single or multiple external cues. Commonly, the existence of multiple cues ensures that cells do not embark prematurely on a developmental process that could damage their viability or fitness [1]. Additionally, the presence of multiple cues can lower the threshold at which cells respond to differentiation signals or refine their response, with inputs from distinct signalling pathways co-operating to generate a specific developmental outcome (e.g. [2,3]). In this way, quite sophisticated perception mechanisms can contribute to an appropriate and timely developmental response when cells encounter conditions where differentiation is the optimal survival response to a changing environment.

Although cell type differentiation is most studied in the programmed specialisation of metazoan cells as they form tissues or adapt for particular functions in the body, unicellular organisms can also undergo development in response to external signals. Exemplary of this are the differentiation responses of vector-borne parasites. These undergo development within distinct environments in their mammalian host, as well as during colonisation of their arthropod vectors to ensure their transmission [4,5]. Among the best studied of these are the kinetoplastid parasites, representing the earliest branching extant eukaryotes [6] that are responsible for a range of tropical diseases such as visceral and cutaneous Leishmaniases (caused by different *Leishmania* spp.), American trypanosomiasis (‘Chagas’ disease’), caused by *Trypanosoma cruzi* and Human, and Animal, African trypanosomiasis (HAT, AAT, caused by *Trypanosoma brucei* [7]). For both *Leishmania* and *T. cruzi* several signals have been discovered that can trigger life-cycle differentiation including low temperature, pH balance [8] and, most recently in *Leishmania*, iron availability [9]. For African trypanosomes, citrate-\textit{cis} aconitate (CGA) is routinely used in differentiation studies [10]. In *T. brucei* the optimal response to CGA requires the generation of a transmissible life cycle stage in the blood called ‘stumpy’ forms [11], which are non-dividing and show partial adaptation for conditions in the midgut of tsetse flies, the parasite’s vector. For example, mitochondrial activity is elevated in the insect forms of the parasite compared to the proliferative bloodstream ‘slender’ forms, which are able to meet their energy demands through their metabolism of blood glucose through glycolysis alone [12]. Stumpy forms are sensitive to CGA through their expression of members of a surface carbohydrate transporter family, called PAD (Proteins Associated with Differentiation) proteins [13]. These proteins transport CGA and at least one family member, PAD2, is elevated by the temperature reduction associated with passage from a homeothermic to poikilothermic environment, sensitising parasites to physiological concentrations of CGA [14,15]. The molecular details of the development from slender to stumpy forms are not well...
**Author Summary**

African trypanosomes are important pathogens transmitted by tsetse flies in sub-Saharan Africa. Upon transmission, trypanosomes detect citrate and cis-aconitate in the bloodstream, this inactivating a negative regulator of differentiation, the tyrosine phosphatase TbPTP1. One TbPTP1 substrate is another phosphatase, TbPIP39, which is more active when phosphorylated (after TbPTP1 inhibition) and promotes differentiation. These differentiation regulators have provided tools to monitor whether one or more environmental signals are used to initiate trypanosome development and their relevance in vivo. This is important because different studies over the last 30 years have disputed the physiological importance of different signals. Here we have, firstly, compared the efficacy of the different reported differentiation signals, establishing their relative importance. We then monitored TbPIP39 phosphorylation to show that two signalling pathways operate: one signalled by citrate or mild acid, the other stimulated by external protease activity. Thereafter, we showed that, of these different signals, protease activity is dispensable for differentiation in tsetse flies. Finally, we used biophysical methods to investigate how citrate causes TbPIP39 and TbPTP1 to interact, enabling their regulatory cross-talk. These studies have established the importance of different developmental signals in trypanosomes, providing molecular insight into how the development signal is transduced within the pathogen.

understood, although laboratory adapted lines that have lost the capacity to become stumpy (‘monomorphic lines’) can generate stumpy-like forms upon exposure to cell permeable cAMP and AMP analogues [16–18], or through TbTORC4 depletion [19].

A key molecular regulator of trypanosome differentiation to tsetse midgut procyclic forms is the tyrosine phosphatase TbPTP1 [20]. This enzyme acts as an inhibitor of parasite differentiation such that inactivation of the enzyme, or reduction of its levels by RNAi, elicits spontaneous differentiation in the absence of any trigger. Recently, a substrate of TbPTP1 was identified as a serine/threonine DsdxT class phosphatase, TbPIP39 [21]. This molecule is dephosphorylated on tyrosine 278 by TbPTP1 and thereby held inactive, this inhibition being reinforced because TbPIP39 itself promotes the activity of TbPTP1. In the presence of CCA, however, the activation of TbPTP1 by TbPIP39 is reduced, such that TbPIP39 becomes phosphorylated and differentiation is stimulated [21,22]. This appears to be mediated via trafficking to the glycosome, a peroxisome-like organelle in trypanosomes that is the site of glycolysis and several other metabolic activities [23].

As in other kinetoplastid parasites, a number of other stimuli of trypanosome differentiation have been reported in addition to CCA, although the use of different cell lines and developmental forms has complicated interpretation of their efficacy or physiological relevance. These reported stimuli include (i) mild acid conditions [24], (ii) exposure of the parasite surface to limited protease digestion [25–27] and (iii) a reduction of glucose mediated through either the use of glucose depleted media [28], or exposure to phloretin, an inhibitor of glucose uptake [29]. Of these, both mild acid and protease treatment induce adenylate cyclase activity [30] and are restricted to transmissible stumpy forms, since bloodstream slender cells are not viable after exposure to these conditions [31], whereas glucose depletion has only been evaluated in monomorphic slender forms.

Here we have systematically investigated the importance of distinct stimuli of trypanosome differentiation, their physiological relevance and, in the case of CCA, mechanistic basis. Firstly, we used the phosphorylation of TbPIP39 as a marker for operation of the citrate-dependent signalling cascade to determine whether a single, or multiple transduction pathways can elicit differentiation. This revealed that independent pathways for the initiation of trypanosome differentiation exist, one (stimulated by CCA and mild acid) operating via the TbPTP1–TbPIP39 signalling pathway, whereas an alternative stimulus, protease treatment, signals via an alternative route. Analysis of the contribution of each pathway in tsetse flies supports a physiological role for TbPTP1–TbPIP39 signalling, with insect trypsin activity not being required to stimulate parasite differentiation signal in vivo. Thereafter, we investigated the interaction between TbPTP1 and TbPIP39 and found that this is dependent upon the presence of the citrate differentiation signal, revealing a hitherto unexpected interplay between these molecules.

**Results**

Analysis of the efficacy of distinct differentiation stimuli

To date, a number of stimuli have been reported to induce trypanosome life cycle differentiation, but these have been analysed in different cell lines and under varying experimental conditions. Our identification of TbPIP39 as a downstream substrate of the CCA-responsive regulator TbPTP1 [21] provided tools to systematically investigate the pathways through which the development of trypanosomes is signalled. Therefore, we carefully analysed, in parallel, trypanosome differentiation stimulated via four reported triggers: cis-aconitate (CA), mild acid, pronase treatment or glucose deprivation using phloretin, a glucose transport inhibitor. Initially the efficacy of each pathway was evaluated such that bloodstream stumpy forms were exposed to 6 mM cis-aconitate, were incubated for 2 hours at pH 5.5, were treated with 4 units pronase from Streptomyces griseus for 10 minutes or were incubated in the presence of 100 μM phloretin. In each case, differentiation was monitored by flow cytometry for the expression of the developmental surface marker EP procyclin.

Figure 1 shows EP procyclin expression for stumpy or procyclic cells (Figure 1A) or stumpy cells incubated in the absence of any trigger (Figure 1B), demonstrating that stumpy cells do not express EP procyclin, although a reversible weak procyclin expression can be detected after incubation, reflecting cold-related expression of this marker [14]. However, when exposed to cis-aconitate (Figure 1C), mild acid (Figure 1D) or pronase (Figure 1E), the stumpy forms underwent effective differentiation into procyclic forms, with the expression of EP procyclin being evident after 2 hours, and becoming progressively stronger throughout the time course of the experiment. For the mild acid (Figure 1D) and pronase treatment (Figure 1E) there was some heterogeneity in procyclin expression due to stress associated killing or damage to some cells, this being absent for the CA treatment. In contrast, phloretin treated cells did not express EP procyclin (Figure 1F). To confirm that the phloretin treatment was effective, pleomorphic slender cells were incubated for 2 days in HMI-9 in the presence or absence of phloretin, or in the presence of cis-aconitate (Figure 2). Phloretin treatment arrested the growth of the treated cells within 24 hours, as expected if glucose uptake were prevented (Figure 2A). Nonetheless, these cells did not outgrow as differentiated forms when incubated in procyclic form medium nor did they express EP procyclin (Figure 2B), contrasting with CA treated cells. Furthermore, incubation of stumpy forms in a more physiologically relevant medium [32] containing low glucose (~0.5 mM final concentration) did not stimulate their differentiation, unless cis-aconitate was also included (Figure S1 in Text S1).
Hence, neither pleomorphic slender or stumpy forms differentiated in response to phloretin and stumpy cells were not stimulated by low glucose medium, demonstrating the glucose depletion is not an effective differentiation stimulus.

Having confirmed cis-aconitate, mild acid and pronase treatment as effective stimuli of differentiation, we monitored the phosphorylation of TbPIP39 under each condition using a phospho-specific antibody directed against tyrosine 278 residue in the protein. This is the site of TbPTP1 phosphatase activity [21], such that tyrosine 278 phosphorylation is diagnostic for the activity of this signal transduction pathway. Figure 3 shows the level of TbPIP39, detected using a polyclonal antibody to the protein, and the level of phosphorylated TbPIP39 detected using the tyrosine 278-phosphospecific antibody. As expected, untreated cells showed no evidence of TbPIP39 phosphorylation, whereas the level of phosphorylated TbPIP39 progressively increased throughout differentiation in the CA treated samples, with this being phosphorylated. Similarly, mild acid exposure generated phosphorylated TbPIP39, indicating activity of the TbPTP1/TbPIP39 signalling pathway under that treatment.

Figure 1. Evaluation of differentiation stimuli on stumpy forms. Flow cytometry traces of EP procyclin expression on AnTat 1.1 90:13 stumpy cells. Stumpy forms (St) and Procyclic forms (Pc) were used as negative and positive controls for the EP procyclin staining, respectively (A) and samples from untreated stumpy cell cultures were also collected at the same timepoints as cells exposed to the different differentiation stimuli (B). A weak reversible cold induced expression of EP procyclin is observed. To stimulate differentiation cells were treated with 6 mM cis-aconitate (C), mild acid (D), pronase (E) and phloretin (F). Samples were assayed at 0 h, 1 h, 2 h, 4 h, 6 h, 24 h or 48 h after exposure to each proposed trigger. The flow cytometry traces are representative of five independent experiments, each giving similar results.

doi:10.1371/journal.ppat.1003689.g001
regimen. Interestingly, however, no phosphorylated TbPIP39 was detected after pronase treatment, despite the effective induction of differentiation in these cells as determined by EP procyclin expression (see Figure 1E, from the same experiment). As expected, exposure to phloretin did not induce TbPIP39 phosphorylation.

Figure 2. Phloretin is unable to induce differentiation of pleomorphic slender form cells to procyclic forms. *T. brucei* AnTat 1.1 90:13 cells (8 x 10^5/ml) were cultured in HMI-9 at 37°C before the addition of 6 mM cis-aconitate, 100 μM phloretin or the same volume of 70% ethanol as a solvent control. After culture for 48 hours at 37°C, the cells were harvested, washed in phloretin-free procyclic medium (SDM-79), then inoculated into P-79 and incubated a further 5 days at 27°C. **A.** Phloretin treatment caused growth arrest within 24 hours in the pleomorphic slender cell cultures, with no outgrowth of procyclic cells being detected after transfer to phloretin-free procyclic medium. Cis-aconitate treated cells differentiated and proliferated as procyclic forms under the same culture conditions. **B.** The expression of the procyclic specific marker EP procyclin was monitored by flow cytometry for each culture. Whereas most cis-aconitate induced pleomorphic slender cells efficiently differentiated to procyclic forms within 48 hours, and expressed high levels of EP procyclin, phloretin treated cultures remained procyclin negative.

Figure 3. Differential TbPIP39 phosphorylation in response to different differentiation signals. Stumpy cells were exposed to 6 mM cis-aconitate (CA), mild acid (pH 5.5), pronase (4 units/ml) and phloretin (100 μM) and isolated protein samples were then reacted with a phospho-specific antibody recognising the sequence (ELDHWRTDEY*TK C) (anti-phospho TbPIP39) (middle panels). The same blot was also reacted with an anti-TbPIP39 polyclonal antibody (left hand panel) and with an antibody detecting trypanosome alpha tubulin as a loading control (right hand panels). Phosphorylated TbPIP39 was observed with CA and mild acid treatment, but not pronase.

doi:10.1371/journal.ppat.1003689.g003
Figure 4. RNAi mediated ablation of TbPIP39 reduces the differentiation efficiency of cells treated with cis-aconitate and mild acid, but not pronase. TbPIP39-RNAi stumpy cells, either uninduced (−Dox) or induced (+Dox) with doxycycline in vivo were harvested, inoculated into HMI-9 at 37°C before the exposure to ‘no treatment’ (A), 6 mM cis-aconitate (CA) (B), mild acid (pH 5.5) (C) or pronase (4 units/ml) (D). Samples of the untreated and treated (B–D) cultures were prepared at 0 h and 4 h and differentiation analysed by the expression of the differentiation marker EP.
Differentiation triggers operate independently in the procyclin. The treated cells showed a population of undifferentiated trypanosomes (left hand peak) representing slender cells in the population and dead or damaged cells, particularly after pronase treatment. Panel E shows histograms of the percentage of EP procyclin expressing cells at 4 h after exposure to the different treatments, the results being the mean and standard deviation of 4 experiments (3 for pronase treatment). Asterisks indicate significance (p<0.001). TbPIP39 depletion resulted in reduced differentiation for the cis-aconitate and mild acid treated samples, but not those exposed to pronase.

do1:10.1371/journal.ppat.1003689.g004

These results indicated that CA and mild acid exposure of stumpy cells induces differentiation via TbPTP1/TbPIP39, whereas pronase treatment stimulates an alternative pathway that does not generate phosphorylated TbPIP39. To test this hypothesis we exploited a pleomorphic T. brucei AnTat1.1 TbPIP39 RNAi cell line that generates effective and inducible TbPIP39 depletion in stumpy forms [21]. Our prediction was that TbPIP39 depletion would reduce the efficiency of differentiation for those stimuli (CA, mild acid) that operate via this signalling pathway, whereas there would be no effect upon pronase treatment. Figure S2 in Text S1 shows Western blots indicating the level of TbPIP39 in stumpy forms in which RNAi against the TbPIP39 transcript had been induced, or not, by provision of doxycycline to the drinking water of infected mice. In each case there was a clear evidence of TbPIP39 depletion in those samples where RNAi was induced in the host animals this being particularly evident as the cells underwent differentiation, whereupon the levels of TbPIP39 normally increase (see Figure 3 and [21]).

To assess the differentiation efficiency of the cells, EP procyclin expression was monitored at 4 h after exposure to each trigger, before the outgrowth of differentiated cells and the consequences of the low levels of TbPIP39 that remain after RNAi induction complicate the analysis [21]. Figure 4A shows that untreated cells did not differentiate, with only the weak cold-related expression of procyclin detected, as also seen in Figure 1B. When triggered with CA (Figure 4B) TbPIP39 RNAi reduced the differentiation efficiency, and a similar response was also observed when cells were treated with mild acid (Figure 4C). Upon pronase treatment there was a population of unstained cells, representing undifferentiated slender cells (also seen in Figures 4A–C) and dead or damaged cells generated by the pronase treatment. However, when analysing EP procyclin expressing cells, either induced or uninduced to deplete TbPIP39, approximately equivalent differentiation efficiency was observed (Figure 4D), consistent with TbPIP39-independent differentiation. The same outcome was observed in four independent experiments, with TbPIP39 depletion reducing differentiation triggered by CA (p<0.001; general linear mixed model) and mild acid (p<0.001) but not pronase (p=0.4270) (Figure 4E). We conclude that two independent pathways can stimulate differentiation, one initiated by CA or mild acid, that acts via TbPIP39 phosphorylation, and one, stimulated by pronase, that does not.

**Differentiation triggers operate independently in the tsetse midgut**

We analysed the relevance of the different signalling pathways in vitro by assaying tsetse infections when protease activity was blocked using inhibitors. Thus, batches of tsetse flies were fed with trypanosomes in horse serum either in the presence or absence of 1 mg/ml of soybean trypsin inhibitor (STI), a treatment predicted to block the insect midgut trypsin-like activities that comprise a major digestive component of the tsetse midgut [33] and which have been reported to stimulate differentiation in vivo [34,35] and in vitro [26]. Confirming the efficacy of inhibition, an analysis of 30 tsetse extracts revealed that midgut trypsin/chymotrypsin activity was reduced 84%–100% in three replicate experiments (P<0.01), irrespective of whether trypanosomes were included in the serum meal (Figure 5A). Stumpy forms were then fed to flies in horse serum in the presence or absence of STI and differentiated cells analysed in extracted midguts 4 hours after feeding. Replicate stumpy samples were also exposed to CA in culture and particular care was taken to ensure that tsetse fed and in vitro prepared samples were processed under identical conditions in order to eliminate effects attributable to cold-induced procyclin expression [14]. In each case, since neither flow cytometry nor automated fluorescence analysis proved possible due to the debris present in the tsetse midgut extracts, we analysed EP procyclin expression using a careful visual scoring system, categorising the labelling of cells as ‘bright’ (representing a homogenous, bright, EP signal detected on the whole cell), ‘faint’ (a faint and/or non-homogeneous EP signal detected on the whole cell, with a brighter flagellum and/or uneven, punctuated staining pattern) or ‘negative’ (no EP signal detected). Figure 5B demonstrates that under these conditions, EP procyclin was strongly expressed on ~90% of cells from tsetse midguts regardless of the presence or absence of protease inhibitor, matching in vitro differentiation in the presence of CA (representative images are shown in Figure 5C and Figure S3 in Text S1). Untreated samples showed only faint EP procyclin expression associated with cold shock during sample processing. Furthermore, similar numbers of cells were observed in STI treated and untreated midgut extracts, eliminating the possibility that only those few cells able to differentiate had survived in the midguts of the flies fed trypsin inhibitor. We conclude that blocking protease activity in the tsetse midgut does not prevent differentiation.

Having demonstrated that inhibiting trypsin activity in the bloodmeal did not prevent the differentiation of stumpy forms, we repeated the analysis using the pleomorphic TbPIP39 RNAi line to determine the influence of inhibiting the TbPIP39 signalling pathway alone, or in combination with trypsin inhibition. Specifically, parasites were grown in mice provided, or not, with doxycycline in their drinking water to induce TbPIP39 gene silencing during the infection. Aliquots of the resulting cells were then fed to tsetse flies either in the presence or absence STI, such that in individual analyses either or both proteolytic activity and cellular TbPIP39 was depleted. Gut extracts were isolated 4 h after feeding, and the differentiation of the midgut parasites analysed by immunofluorescence for the expression of EP procyclin as before, with at least 1000 cells being scored for each sample from a total of 3 replicate experiments (Figure 6). Confirming the data in Figure 5, trypsin inhibition alone did not inhibit differentiation (p=0.5706; Wilcoxon Mann Whitney rank sum test). However, with TbPIP39 depletion, the percentage of weakly stained cells increased from approximately 17.9% (17.9%, 17.8% + or − STI, respectively) for the uninduced samples to 25.4% (24.3%, 26.5% + or − STI, respectively), and overall differentiation was reduced, weakly but significantly (p=0.0073), even when a Bonferroni correction was used to account for the number of tests (thereby setting the significance threshold at 0.008). Interestingly, however, when both RNAi was induced and proteases were inhibited, the efficiency of differentiation was more significantly reduced (p<0.0009) with respect to untreated samples. Although the observed effects were expected to be minor, given the transient inhibition of differentiation upon TbPIP39 depletion in vitro, these analyses indicated
having been taken to precisely mimic the processing of tsetse derived samples. Scoring was carried out by immunofluorescence, with EP procyclin staining scored as negative, faint or bright in each case. In all cases samples were processed for immunofluorescence in parallel and imaged under identical settings. C. Representative images of trypanosomes derived from tsetse midguts 4 h after feeding either in the presence or absence of soybean trypsin inhibitor. Cells were stained with antibody to EP procyclin (Green) and DAPI (Blue). A cell categorised as ‘faint labelling is arrowed. The lower images show phase contrast images of the equivalent fields. Bar = 20 μm.

Figure 5. Protease activity is not necessary for differentiation in tsetse flies. A. Protease activity (against Chromozym Try substrate) in midgut extracts from tsetse flies fed horse serum containing T. brucei TSW strain trypanosomes, or T. brucei AnTat.1.1, either in the presence or absence of Soybean trypsin inhibitor (STI). Each bar represents the average protease activity ±SEM of 10 midguts. B. EP procyclin expression of stumpy trypanosomes incubated in vitro in HMI-9 or derived from tsetse midguts 4 h after feeding with horse serum containing the parasites, with or without soybean trypsin inhibitor (+STI). Stumpy cells were analysed at 0 hours, or after 4 hours in vitro in the presence or absence of cis-aconitate (‘CA’). To control for the chilling on ice associated with tsetse midgut dissection, some in vitro derived samples were also chilled for 1 hour at 4 °C, particular attention that inhibition of differentiation is observed in vivo upon TbPIP39 depletion, with a minor contribution when trypsin activity is also inhibited.

The interaction between TbPTP1 and TbPIP39 is citrate dependent

The in vivo experiments supported the function of the TbPTP1/TbPIP39 pathway in differentiation, but the technical limitations with these studies highlighted that more detailed analysis of these signalling events required in vitro analysis. Therefore, we sought to gain mechanistic understanding of the interaction between TbPTP1 and TbPIP39 using biochemical methods.

Initially, we investigated whether residues in TbPIP39 predicted from homology modelling to comprise part of a citrate-binding pocket [21] (Figure S4 in Text S1) would influence the regulatory cross talk between TbPIP39 and TbPTP1, whereby TbPIP39 activates TbPTP1, unless in the presence of citrate [21]. To analyse this, recombinant TbPIP39 was generated in which either the aspartic acid at position 57 was mutated to alanine (generating DxAxT; ‘PIP39 D mutant’), both aspartic acid residues in the DxDxT motif were mutated (generating DxAxT; ‘PIP39 DD mutant’) or the TV motif at position 63 and 64 was mutated to AA (‘PIP39 6364 mutant’) (Figure S4 in Text S1; the respective recombinant proteins are shown in Figure 7A). The residues at position 57, 63 and 64 are each predicted to be involved in citrate binding whereas mutating both aspartic acid residues is known to render the enzyme catalytically inactive [21,36]. The wild type (Figure 7B) and TbPIP39 mutants (Figure 7C–E) were each then tested for their ability to enhance TbPTP1 activity and the sensitivity of this to citrate inhibition. Figure 7 demonstrates that each of the TbPIP39 mutants (TbPIP39 D, TbPIP39 DD, TbPIP39 6364) enhanced the activity of TbPTP1 at equivalent levels to the wild type TbPIP39, regardless of their individual activity. However, this was not sensitive to the presence of citrate for any of the mutants, contrasting with the wild type protein where there was a citrate-dependent decrease in TbPTP1 activity [P<0.0072]. Unlike citrate, isocitrate (which does not act as a differentiation trigger) did not generate a decrease in activity when wild type TbPIP39 was used (Figure 7F). This demonstrated that the regulatory cross talk between TbPTP1 and TbPIP39 depended upon the integrity of the citrate binding residues in TbPIP39.

Having examined regulatory interaction between the molecules we examined their biophysical interactions in the presence or absence of citrate using surface plasmon resonance. Specifically, TbPTP1 protein was immobilised and covalently stabilised on a nitrilotriacetic acid (NTA) chip and then interactions with wild type or mutant TbPIP39 tested in the presence or absence of citrate (Figure 8). In the absence of citrate, no interaction between TbPTP1 and TbPIP39 (wild type or any of the TbPIP39 mutants) was observed (Figure 8A, Figure S5 in Text S1). In contrast, wild type TbPIP39 showed interaction with TbPTP1 in the presence of citrate, consistent with a 1:1 binding stoichiometry, the predicted half-life for the complex being around 10 seconds (on rate: 0.015 μM−1·s−1; off rate: 0.068 s−1) (Figure 8B, 8C, Figure S5 in
Interestingly, when the mutant forms of *Tb* PIP39 were tested in combination with *Tb* PTP1 by surface plasmon resonance, each also showed a citrate-dependent interaction with *Tb* PTP1, matching that of the wild type *Tb* PIP39 (Figure 8D–F). Moreover, isocitrate, which does not stimulate differentiation [26,37], also promoted the interaction between *Tb* PTP1 and wild type *Tb* PIP39 (on rate: 0.014 M-1.s-1; off rate: 0.064 s-1) indicating that the interaction is not contributing to the specific differentiation stimulus (Figure S5 in Text S1). When analysed by isothermal calorimetry neither the wild type nor any of the *Tb* PIP39 mutant proteins was able to bind citrate independently of *Tb* PTP1 (Figure S6 in Text S1). Overall, these experiments indicated that individual mutation of specific residues in *Tb* PIP39 predicted to be involved in citrate binding did not prevent the citrate-dependent interaction of *Tb* PIP39 with *Tb* PTP1 detected by SPR and that this interaction was also generated by isocitrate, which is not a differentiation trigger.

In conclusion, the ability of citrate to reduce the phosphatase activity of *Tb* PTP1/*Tb* PIP39 was lost upon mutation of the predicted citrate-binding residues in *Tb* PIP39. Nonetheless, regardless of the integrity of these residues, these molecules continue to interact in a citrate (or isocitrate) dependent-manner. Based on these analyses we propose that citrate causes *Tb* PIP39 and *Tb* PTP1 to bind to one another, at least in *vivo*, but that citrate also independently blocks the ability of *Tb* PIP39 to enhance *Tb* PTP1 activity. Hence, *in vivo*, the transport of citrate in the bloodmeal by PAD proteins would stimulate the initiation of parasite differentiation through the co-ordinated inhibition of *Tb* PTP1 and activation of *Tb* PIP39.

**Discussion**

When ingested in a tsetse fly bloodmeal trypanosomes rapidly initiate differentiation in order to adapt to their new environment. Our earlier studies have demonstrated that the CCA differentiation signal is transduced via PAD proteins through a phosphatase-signalling cascade, whereby *Tb* PTP1 is inactivated and *Tb* PIP39 becomes phosphorylated and activated [20–22]. Here we have used these components to investigate the molecular basis of differentiation initiated by CA and to demonstrate that independent signalling pathways can operate to stimulate development.

Firstly, the availability of phospho-specific *Tb* PIP39 antibodies and pleomorphic RNAi lines targeting *Tb* PIP39 allowed the relationship between different differentiation signalling pathways to be investigated. This demonstrated that CA and mild acid are triggers that both result in the phosphorylation of *Tb* PIP39 on tyrosine 278, with differentiation via these signals being inhibited by RNAi against *Tb* PIP39. In contrast, pronase stimulates
demonstrate that inhibiting this protease activity alone does not initiation of differentiation in trypanosomes, the molecule responsible is likely to be novel, potentially at the cell surface or within the flagellar pocket membrane.

Our findings reveal the presence of independent differentiation signalling pathways in trypanosomes (Figure 9A), with activation by different stimuli converging downstream of TbP39. Supportive of the existence of independent signalling pathways, reporter assays for the activation of EP procyclin expression in bloodstream forms have demonstrated enhanced expression when both CA and proteases were used compared with either stimulus alone [26]. Our in vivo experiments supported this observation, since the depletion of TbP39 by RNAi reduced differentiation, the significance of this being increased in the presence of protease inhibitors. Although the reduction of TbP39 by RNAi is incomplete, significantly reducing the magnitude of the effect observed in vivo, trypsin/chymotrypsin-type protease inhibition was almost complete when monitored in the midgut of treated flies. Hence, although trypsin activities have been reported [33] and proposed to be involved in the transformation of trypanosomes in vivo [34,35] and in vitro [26], our experiments demonstrate that inhibiting this protease activity alone does not prevent the initiation of parasite differentiation in tsetse flies. Unfortunately, a complementary analysis of differentiation in the complete absence of TbP39 via a gene knockout and add-back approach is not possible in parasite lines capable of generating stumpy forms.

In contrast to the above reported triggers we did not observe any induction of differentiation for either bloodstream stumpy forms or bloodstream slender forms when parasites were exposed to phloretin or low glucose conditions. Phloretin blocks glucose uptake by the trypanosome and has been reported to induce the expression of a subset of procyclic specific transcripts in monomorphic bloodstream forms [29]. An effect of glucose depletion has also been reported earlier, whereby glucose-depleted medium generated the outgrowth of differentiated procyclic forms from a monomorphic cell culture [28]. Although these findings seem consistent with the rapid loss of glucose from the tsetse blood meal, they may also reflect a monomorphic cell line specific response, or the outgrowth of a small, differentiated subpopulation when cells are subcultured into procyclic form media. Alternatively, phloretin may induce transformation of monomorphic slender forms toward more stumpy-like forms, since stumpy forms elevate the expression of some procyclic form transcripts including procyclins in preparation for differentiation in the tsetse fly or in vitro [29]. Nonetheless, overall our results eliminate glucose deprivation alone as an efficient differentiation trigger for transmissible stumpy forms, making the physiological relevance of this trigger questionable.

Through biochemical and biophysical analyses, our experiments also revealed that TbPTP1 and TbP39 interact in a citrate or isocitrate dependent manner, this being retained even when individual residues proposed to be important in citrate binding within TbP39 are mutated. However, mutation of these residues prevented the citrate-dependent reduction of TbPTP1/TbP39 activity. These results contrast with a model where citrate binding to TbP39 would prevent its interaction with TbPTP1 [21,22], potentially through steric hindrance within the catalytic region. Instead, our results show that the presence of citrate can allow TbPTP1 and TbP39 to physically engage, at least in vitro, potentially in a substrate trapping type interaction although this is not specific for citrate or the predicted citrate binding capacity of TbP39. Hence, in a bloodstream, TbPTP1 could be sequestered by interaction with TbP39 such that excess unbound TbP39 could become stably phosphorylated by its, as yet uncharacterised, kinase thereby promoting differentiation. Furthermore, these experiments revealed that the predicted citrate binding residues in TbP39 are required for the regulatory cross talk between TbP39 and TbPTP1 but not their specific interaction, suggesting that citrate has distinct ‘dock’ and ‘block’ activities on the TbP39/TbPTP1 complex, with only the ‘blocking’ function being specific for citrate (Figure 9B).

The integration of the combined signals of temperature reduction, CCA reception and protease attack of the parasite surface could ensure a strong differentiation response. Given their sensitivity to citrate/cis-aconitate and resistance to protease attack [40], these responses will be limited to the transmissible stumpy form, with slender cells in the blood meal being rapidly killed. The role of multiple signal inputs that converge to drive differentiation is characteristic of several developmental systems including in fungi [41], cell type differentiation in Drosophila development [42,43] and in mammalian bone formation [44], as well as in arthropod-borne parasites [5,8]. In parasites, this stringent control would ensure that the initiation of an irreversible developmental programme occurs only under the correct environmental conditions, avoiding the risk of initiating an inappropriate and lethal differentiation response whilst still in the mammalian host.

Materials and Methods

Ethics statement

Animal experiments in this work were carried out in accordance with the local ethical approval requirements of the University of Edinburgh and the UK Home Office Animal (Scientific Procedures) Act (1986) under licence number 60/4373.

Parasite growth and transfection

Bloodstream and procyclic form trypanosomes were cultured in vitro in HMI-9 [45] medium or SDM-79 [46] medium respectively. T. brucei An Tac1.1 slender and stumpy parasites were obtained 3 and 6 days post infection, respectively, and purified by DEAE chromatography. TbP39 RNAi lines were described in [21].

For the initiation of differentiation the following conditions were used:

**cis-aconitate.** 6 mM cis-aconitate provided in HMI-9 medium.
Mild acid. Stumpy cells were incubated in HMI-9 media, whose pH was adjusted to 5.5. After 2 hours incubation at 37 °C, 5% CO₂ the cells were collected, washed twice in fresh HMI-9 media and transferred to 27 °C [24].

Pronase. Stumpy cells (2.5×10⁶ cells/ml) were resuspended in PSG buffer containing 4 u/ml pronase (Biochemika) and incubated for 10 minutes at 25°C [25,26]. After incubation, the cells were collected by centrifugation, washed twice in filtered...
PSG and resuspended in fresh HMI-9 media and transferred to 27°C.

**Phloretin.** *T. brucei* AnTat 1.1 90:13 cells (8 x 10⁵/ml cell density) were treated with 100 μM phloretin (Biomol) and cultured in HMI-9 at 37°C for 48 hours in a CO₂ incubator [29]. After two days, the cells were harvested and following two washes in phloretin-free procyclic form medium (SDM-79), they were inoculated into fresh SDM-79 and incubated for a further 5 days at 27°C. Cell numbers were monitored daily using a Beckman Coulter Z2 particle counter.

**DNA cloning and protein expression and analysis**

Recoded wild type (wt) and ExExT (DD) synthetic pH451TbPIP39 constructs [21] were used to produce mutants predicted to have reduced ability to bind citrate (Figure S4 in Text S1). A commercial site-directed mutagenesis kit (Stratagene) was used with the mutagenesis Primer 1 and Primer 2 (Table S1) to produce TbPIP39D57A (TbPIP39D) and Primer 3 and Primer 4 (Table S1) to produce T63A-V64A (TbPIP39 6364). Each of these pH451TbPIP39 constructs (TbPIP39wt, TbPIP39D, TbPIP39 6364 and TbPIP39DD) were reamplified with recoded TbPIP39 specific Primer 5 and Primer 6 (Table S1) and integrated into the pGEX4T1 (GE Healthcare Life sciences) protein expression vector for recombinant protein production. Expression and purification of His tagged TbPTP1 and GST tagged TbPIP39 (TbPIP39wt, TbPIP39D, TbPIP39 6364 and TbPIP39DD) were performed as described in [21]. Phosphatase activity was measured by monitoring the TbPTP1 (0.01–1 μg) catalyzed hydrolysis of pNPP to p-nitrophenol [20].

Methods for protein expression and purification for biophysical analyses are described in the Supplementary data.

**Surface plasmon resonance (SPR) equipment and reagents**

SPR measurements were performed on a BIACore T200 instrument (GE Healthcare). Ni²⁺-nitrilotriacetic acid (NTA) sensor chips, 1-ethyl-3- (3-diaminopropyl) carbodimide hydrochloride (EDC) and N-hydroxysuccinimide (NHS) were purchased from GE Healthcare.

**Immobilization and covalent stabilization TbPTP1**

Pure His-PTP1 was immobilized and covalently stabilized on an NTA sensor chip. Briefly, following Ni²⁺ priming (60 s of 500 μM NiSO4 in 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 μM EDTA; 20 mM MgCl₂, at 5 μl.min⁻¹) dextran surface carboxylate groups were activated by injection of 20 μl of 0.2 M EDC; 50 mM NHS at 5 μl.min⁻¹. Protein (between 10 nM and 100 nM) in 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 μM EDTA; 20 mM MgCl₂ was captured and covalently stabilized on the surface to between 100 and 300 RU by injection at 30 μl.min⁻¹. Following attainment of the desired RU signal a brief injection of 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 350 mM EDTA (30 s at 30 μl.min⁻¹) was used to remove non-covalently attached protein, followed by quenching of the unreacted succinimide esters by an injection of 20 μl of 1 M H₂N(CH₂)₂OH, pH 8.5 at 3 μl.min⁻¹. Non-covalently bound proteins were washed off the surface with excess 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 μM EDTA; 20 mM MgCl₂ at

Methods for protein expression and purification for biophysical analyses are described in the Supplementary data.

Figure 9. Model for the initiation of differentiation via different triggers. A. CCA and mild acid result in an increase in TbPIP39 phosphorylation that stimulates differentiation. For CCA, this is mediated via the transport of citrate/cis-aconitate via surface PAD proteins. Mild acid may inhibit TbPTP1, and/or stimulate the activity of the kinase that phosphorlates TbPIP39. Pronase also stimulates differentiation, independently of TbPTP1/TbPIP39. B. Mechanistically, CCA stimulates both the interaction between TbPTP1 and TbPIP39 (Dock), and inhibition of the stimulatory effect of TbPIP39 on TbPTP1 (Block).

100 µl.min⁻¹. Final protein immobilized levels were between ~70 and 290 RU.

SPR single cycle kinetic experiments

SPR single cycle kinetic titration binding experiments were performed at 25°C, using a 2-fold dilution series, in 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 µM EDTA; 20 mM MgCl₂ (or with buffer supplemented with 2 mM citrate) at 100 µl min⁻¹ with a 60 seconds contact time and a 60 seconds dissociation time. The sensor surface was regenerated between experiments by dissociating any formed complex 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 µM EDTA; 20 mM MgCl₂ (or with buffer supplemented with 2 mM citrate). The apparent equilibrium dissociation constants (Kd) were calculated from double reference corrected sensograms by global fitting of a 1:1 binding model, including a mass transport term, using analysis software (v.1.0, GE Healthcare) provided with the BIACore T200 instrument.

Western blotting, flow cytometry and immunofluorescence

Protein expression analyses by western blotting and flow cytometry were carried out according to [21]. Immunofluorescence was carried out according to [13]. For quantitative scoring of differentiation in tsetse midguts the following criteria were used: ‘Bright’: homogenous, bright EP signal detected on the whole cell, ‘Faint’: faint and/or inhomogeneous EP signal detected on the whole cell (with a brighter flagellum and/or uneven, punctuated pattern); ‘Negative’- no EP signal detected. In all cases illumination and imaging settings were identical.

Phase-contrast and Immunofluorescence microscopy images were captured on a Zeiss axioskop2 (Carl Zeiss microimaging) with a Prior Lamern 200 light source using a QImaging Retiga 2000RCCD camera; the objective was a Plan Neofluar ×63 (1.25 NA). Images were captured via QImage (QImaging).

Tsetse fly feeding and dissection

All tsetse flies were taken from the Glossina morsitans morsitans (Westwood) colony at LSTM, which is maintained at 26°C and 65–80% relative humidity, and fed on the supernatant of defibrinated horse blood. Male flies were fed only once, 24–72 hours after eclosion from the pupa. A minimum of 50 males were offered a feed on one of the meals described above for 72 hours after eclosion from the pupa. A minimum of 50 males were offered a feed on one of the meals described above for 72 hours after eclosion from the pupa. The guts were then gently separated with 2 mM citrate at 100 µl min⁻¹, with a 60 seconds contact time and a 60 seconds dissociation time. The sensor surface was regenerated between experiments by dissociating any formed complex 10 mM HEPES, pH 7.5; 150 mM NaCl; 0.05% P20; 50 µM EDTA; 20 mM MgCl₂ (or with buffer supplemented with 2 mM citrate). The apparent equilibrium dissociation constants (Kd) were calculated from double reference corrected sensograms by global fitting of a 1:1 binding model, including a mass transport term, using analysis software (v.1.0, GE Healthcare) provided with the BIACore T200 instrument.

Preparation of the meals containing Soybean trypsin inhibitor

Horse serum was prepared by filtering through a 0.2 µm syringe filter the supernatant of defibrinated horse blood (TCS Biosciences Ltd., Buckingham, UK). Soybean (Glycine max) trypsin inhibitor (STI, Sigma Aldrich) was added to some aliquots of the serum at 1 mg/ml. All the serum aliquots were re-filtered and warmed to 37°C. Stumpy enriched populations of AnTat1.1 90:13 cells were mixed with 37°C HMB media and incubated for one hour at 37°C at 5% CO₂. Cells were pelleted for 6 minutes at 836 g and resuspended in either 2 ml warmed horse serum or 2 ml warmed horse serum containing 1 mg/ml STI. The cells were then used immediately to feed tsetse flies after briefly checking cell viability by microscopy. The experiment was repeated three times, each time using a different batch of horse blood to prepare the serum. For the protease activity assays with T. b. brucei strain TSW196, aliquots of TSW196 blood from infected rats and mixed with 2 ml horse serum in the presence or absence of 1 mg/ml STI and immediately fed to tsetse flies.

Protease activity of midgut extracts was assayed using Chromozym TRY (Z-Val-Gly-Arg-pNA, Bachem, Switzerland) largely as described in [47].

Supporting Information

Table S1 Oligonucleotides used in this study to generate mutant forms of TbPIP39.
