Abstract

The East African Rift Systems (EARS) exerted a major influence on river drainage basins and the regional climate of east Africa during the Cenozoic. Recent studies have highlighted an offshore branch of the EARS in the western Indian Ocean, where the Kerimbas Graben and the Davie Ridge represent its sea floor expression. However, to date, a clear picture of the impact and timing of this EARS offshore branch on the physiography of the continental margin of the western Indian Ocean, and associated sediment dispersal pathways, is still missing. This study presents new evidence for four giant and supra-elevated canyons along the northern portion of the Davie Ridge offshore Tanzania. Seismic and multibeam bathymetric data highlight that the southernmost three canyons which are now inactive, supra-elevated relative to the adjacent sea floor of the Kerimbas Graben and disconnected from the modern slope systems offshore the Rovuma and Rufiji River deltas. Regional correlation of dated seismic horizons, integrated with well data and sediment samples and high resolution bathymetric data, proves that the tectonic activity driving the uplift of the Davie Ridge in this area started in the Plio-Quaternary during the middle-upper Miocene and is still active, as suggested by the presence of fault escarpments at the sea floor and by the location and magnitude of recent earthquakes. Our findings contribute to placing the Kerimbas Graben and the Davie Ridge offshore Tanzania in the regional geodynamic context of the western Indian Ocean and show how the tectonics of the effect of the offshore branch of the EARS modified the physiography of the margin, re-routing the deep-water drainage network since the middle Miocene. Future studies are needed to understand the influence of changing sea floor topography on the western Indian Ocean circulation on sediment distribution pathways, and to evaluate the potential of the EARS.
underline the need of considering the offshore tectonic activity in generating
tsunamigenic events in future tsunami hazards assessments in East Africa.

1. Introduction

Tectonics exerts an overarching control on the evolution of terrestrial and marine
topography landscapes, mainly through the modification of surface topographic relief
(Leeder and Jackson, 1993; Schumm et al., 2000). In the last decades, a huge effort has
increased our understanding of geodynamic processes leading to the onset of the East
African Rift Systems (EARS; Ebinger and Sleep, 1998; Moucha and Forte, 2011 and
references therein). However, there is very little knowledge of the links between the
Neogene EARS tectonics of the EARS and the development of structural features in the
western Indian Ocean.

The timing of the initiation of the EARS can be traced back to the Oligocene (Macgregor, 2015, and references therein). The origin of the EARS has been
related to the onset of a mantle plume, which generated a topographic anomaly
beneath the Ethiopian and East Africa plateaux (Ebinger and Sleep, 1998) generated a
topographic anomaly referred to as the EARS. Normal
faulting and regional uplift associated with the EARS exerted a major control on the
evolution development of the drainage basins of large African rivers, such as the Congo,
Nile and Zambesi (Goudie, 2005; Stankiewicz and de Wit, 2006; Roberts et al., 2012),
and on the formation of rift lakes (Cohen et al., 1993; Macgregor, 2015).

After the seminal work of Mougounet al. (1986), a recent study by Franke et al. (2015)
highlighted the stratigraphy and architecture of the offshore branch of EARS in the
western Somali-Indian Ocean Basin offshore Mozambique. Here, the rift consists of
juvenile fault zone at about 17° S, and of the Lacerda half-graben and the southern part of the Kerimbas graben up to ca. 10° S following previous results using remote sensing data, earthquakes distribution and focal mechanisms (Franke et al., 2015) and references therein). Farther north, offshore of Tanzania, the EARS stretches along the northern part of Kerimbas Graben, which is characterized by a well-developed N-S trending depression bordered by normal faults and confined on its eastern side by the Davie Ridge (Fig. 1). Although the effects of EARS in modifying subaerial landscapes, and its consequence on the evolution of early hominid humans evolution and atmospheric circulation, have been established (Sepulchre et al., 2006; Maslin et al., 2014), the control of EARS on location and shape of the deep-water drainage network have not been investigated, and a clear picture of the evolution of the western Indian Ocean is still missing.

Our contribution presents the discovery of four giant deep-water canyons (up to 15 km wide and up to 850 m deep in water depths >2,500 m), herein named C-1 to C-4 from north to south, incising the Davie Ridge and of which three (C-2 to C-4) are currently disconnected from the active slope channels offshore the Rovuma and Rufiji River deltas. The three canyons appear to be relict features corroborating the existence of an older drainage network that was destroyed by recent tectonic activity associated with the offshore branch of EARS. Our findings reveal how EARS affected the physiography of the western Indian Ocean, resulting in the formation of a new sediment routing system, and provides new insights in the chronology and outbuilding architectural features of the margin.
The history of the Western Indian Ocean can be traced back to the Early Jurassic, when the onset of rifting occurred between Madagascar and Africa (Reeves and de Wit, 2000; Reeves et al., 2016). Sea floor spreading started in the Middle Jurassic and continued until the Early Cretaceous (Coffin and Rabinowitz, 1992), leading to the southward drift of Madagascar along the dextral strike-slip structures of the Davie Fracture (or at least along part of it, see below and discussion in Klimke and Franke, 2016) and the Lebombo-Explora Fracture Zones (Reeves and de Wit, 2000). From the Cretaceous to the Paleogene (mid-Oligocene), the East African margin was characterized by a period of stability and thermal subsidence (Kent et al., 1971; Salman and Abdula; 1995), which was recorded by deposition of the Kilwa Group in Tanzania (Nicholas et al., 2006; 2007). The passive margin phase was interrupted by a period of neo-rifting and tectonic reactivation: the onset of new mantle circulation beneath the African continent (Ebinger and Sleep; 1998; Moucha and Forte, 2011), known as the African super-swell (Nyblade and Robinson, 1994), evolved into the EARS (Chorowitz, 2005), with synchronous initiation along its western and eastern branches (Roberts et al., 2012). Normal faulting and rifting were widespread along the Tanzanian margin during the Miocene, promoting the formation of topographic highs, such as Zanzibar, Pemba and Mafia Islands, and lows, such as the coastal basins and the Kerimbas Graben (Kent et al., 1971; Mougenot et al., 1986). Recent studies, however, highlighted the presence of folding and inversion structures on a seismic profile across the channel north of Zanzibar Island (Sii and Underhill, 2015), suggesting that the islands are compressional features associated with fault reactivation and basin inversion.

32.1. Kerimbas Graben and Davie Ridge in the offshore of Tanzania
The EARS consists of a series of tectonic basins bordered by uplifted shoulders, which extend for thousands of kilometres along two main lineaments, called the western and eastern branches (Chorowitz, 2005). The continuation of the eastern branch offshore of Tanzania can be traced along the Pemba and Mafia basins, while farther to the south it runs along the Kerimbas and Lucerna Lacerda Grabens (Fig. 1), until ending in a juvenile fault zone at about 17° S further to the south, in the offshore Mozambique (Fig. 1; Mougenot et al., 1988; Franke et al., 2015).

The Kerimbas Graben was firstly recognised by Mougenot et al. (1988) north of the Saint-Lazare Seamount (Fig. 1). A compilation of recently acquired multibeam data (Dorschel et al., 2018) highlight that the graben, north of a 12° S, can be divided into three zones based on sea floor morphology and water depth (Fig. Figs. 1 and 2). In zone 1, which extends from the Saint-Lazare Seamount up to 11.5° S (Fig. 2), the graben is asymmetric, with the western side running along the base of the slope of the northern Mozambique margin and gently dipping at ca. 0.7° to the east, whereas the eastern flank corresponds to a 12° west-dipping fault escarpment (Fig. 2, blue arrow). The sea floor eastward of the escarpment shows a series of morphological steps related to N-S trending faults before gently dipping towards the Indian Ocean (Fig. 2). In zone 2, between 11.5° S and 10° 20' S, the Kerimbas Graben is a 30-40 km wide symmetric graben bounded by ca. 15° steep flanks (Fig. 2, green and red arrows). N-S trending lineaments, representing fault escarpments, are visible at the flat sea floor, which shows a flat floor lying at an average water maximum depth of ca. 2,900 m and, gently dipping to the north (Figs. 1-2). The western side of the Kerimbas Graben runs along the base of the slope in the offshore Rovuma River delta, whereas the eastern side corresponds to the Davie Ridge (Fig. 1-2). A series of channels and gullies cut the western flank and are visible on the sea floor (Figs.
The second zone, located just offshore the Rovuma River between 10° S (Fig. 2), corresponds to a bathymetric sill with a maximum water depth of ca. 2,750 m (Fig. 2), located just offshore the main Rovuma Channel between 10° 20’ S and 9° 05’ S (Fig. 1). Here, and it is lying at ca. 2,750 metres of water depth (Fig. 2). In this area, the Kerimbas Graben shows asymmetric flanks, with a gentler western side up to 1.5° and a 12° dipping eastern side. In the third zone 4, reaching approximately 8.5° 40’ S, the graben shows a different morphology with a maximum water depth up to ca. 3,500 metres and a maximum width up to 90 km (Figs. 1, 2). In this area, the western flank of the graben partially corresponds to a structural high (the Seagap Ridge) generated by the movement tectonics of the Seagap transform fault Seagap Ridge (Fig. 2; Revees et al., 2016), while the western side corresponds to the northern termination of the Davies Ridge (Fig. 2). A series of arcuate steps are visible on the sea floor of the graben, likely associated to normal faults developing at the base of the Davie Ridge (see supplementary Figure S1).

The Davie Ridge appears as a bathymetric high roughly extending N-S that dissects the continental slope in the offshore East Africa for more than 1,000 km south of 9° S (Mahanjane, 2014; Courgeon et al., 2018). The ridge shows different maximum elevation of the Davie Ridges (calculated as the depth difference between the top of the ridge and the floor of the Kerimbas Graben along a section, see Figs. 1 and -2) shows in the different zones described above (Fig. 2), with an overall decrease in elevation to the north (Fig. 2). Heirtzler and Burroughs (1971) when discovering the firstly described the Davie Ridge described it as a ridge-like feature, asymmetric, with a steep western flank (up to 30°) and a gently dipping eastern flank (ca. 0.65° in the offshore Rovuma delta; Fig. 1). Heirtzler and Burroughs (1971) interpreted the ridge as a transform fault resulting from the southward drift of Madagascar relative to the African continent. The
continuation of the Davie Ridge north of 9° S, where the ridge does not have a prominent morphological expression on the sea floor (Fig. 1), has been derived by gravimetric and magnetic data showing a series of anomalies, up to 2.5° S (Rabinowitz, 1971; Scrutton, 1978; Coffin and Rabinowitz, 1987). The entire lineament, extending from ca. 20° S to 2.5° S, named the Davie Fracture Zone by Scrutton (1978), was interpreted as the bathymetric expression of the transform fault that accommodated southward drift of Madagascar (Scrutton, 1978). A recent study from Klimke and Franke (2016), however, argued the existence of a transform fault extending from northern Mozambique up to Kenya and interpreted the Davie Ridge visible on the bathymetry between 15° S and 9° S (on the eastern side of the Lacerda and Kerimbas grabens) as a rift-flank uplift, originated during the Neogene and probably correlated with the evolution of the EARS in the offshore domain. This interpretation is in agreement with GPS vector data (Calais et al., 2006), and focal mechanisms of recorded earthquakes, showing pure normal faulting with N-NW trending nodal planes and roughly E-W extensional failure (Grimison and Chen, 1988; Yang and Chen, 2010).

### 3.2. Data and Methods

#### 3.2.1. 2D Seismic data

The present study uses two seismic datasets: (1) the GLOW survey (Paleogene GLOBal Warming events, GLOW Cruise; Kroon and the Shipboard Scientific Party, 2010) performed onboard of the R/V Pelagia in 2009 and consisting of 2,450 km of seismic lines; and (2) the multi-client 2D seismic dataset Tanzania, acquired by WesternGeco-Schlumberger in 1999-2000 and consisting of 5,550 km of seismic lines.
The GLOW seismic survey was performed using an array of four airgun sources (10, 20, and 2× 40 in³) and a 24-channel streamer as a receiver. The seismic data were recorded using the GeoResources Geo-Trace 24 system. The peak frequency of the combined signal of the guns is within the range of 50-150 Hz, with lower amplitude frequencies up to 400 Hz. The guns were towed in a frame at a depth of 1.7 metres, 42 metres behind the stern of the ship, and fired every 10 seconds at a pressure of 115 bars. The average sailing speed was 4.2 knots, which resulted in an average distance between the shots of 21 metres. The streamer consisted of four 63 m long active sections with 6 channels each (channel interval 10.5 metres). Each channel consists of ten 1-m-spaced Teledyne T2 hydrophones. The streamer is ended by a 0.5 m tail-end, which contains the last terminating end connector. The receiver was attached to the ship by a tow leader of 60 m and a stretch member of 25 m. The streamer was towed at a depth of 1 metre below the surface. Three (front, mid, end) I/O systems 5010 DigiBIRDS were used to keep the streamer at depth. During the recording of line 2 one bird failed. From line 3 onwards only 2 birds (front, end) were used. This had no noticeable effect on the streamer position. The record length was 7,500 ms (including the water column) and the sampling rate was 2 kHz for the first lines. From line 5 onwards the sampling rate was 1 kHz. The data were recorded with a 10 Hz high pass filter. The vertical resolution of the seismic data in the investigated section ranges between 2.5 and 5 metres, calculated considering a peak frequency of 150-200 Hz and interval velocities of 1,800-2,900 msec⁻¹. Processing of the data was performed at NIOZ by means of the software package RadexPro (DECO Geophysical, Moscow). The processing sequence included data loading, 30-700 Hz bandpass filtering, amplitude correction, an interactive velocity analysis, NMO correction, 6 fold CDP-stacking, Stolt F-K migration and water column muting. The present study uses two seismic datasets: (1) a seismic survey (Paleogene Basin Research
GLObal Warming events, ‘GLOW’ Cruise, Kroon and the Shipboard Scientific Party, 2010) performed on board of the RV Pelagia in 2009 consisting of 2,450 km of seismic lines, and (2) the multi-client 2D seismic dataset Tanzania, acquired by WesternGeco-Schlumberger in 1999-2000 consisting of 5,550 km of seismic lines.

The GLOW seismic survey was performed carried using three 3 airgun s sources (of 20, 30 and 40 in cubic inch 3) each as a source and a 24-channel streamer as a receiver. The streamer consisted of four 63 m long active sections with 6 channels each, and the seismic data were recorded. Data recording was performed using the Geo-Resources Marine MultiGeo-Trace 24 hard- and software. The system has a 24 channel digital pre-amplification system and 24 channel bandpass filter already integrated. The record length was 7,500 ms (including the water column) and, the sampling rate was 2 kHz. The data were recorded with a 10 Hz high pass filter. Processing of the data was performed at NIOZ by means of the software package RadexPro (DECO Geophysical, Moscow). The processing sequence included data loading, 30-700 Hz bandpass filtering, amplitude correction, an interactive velocity analysis, NMO correction, CDP-stacking, Stolt F-K migration and water column muting.

The 2D survey offshore Tanzania was shot by Western Geophysical using a 5,200-m-long streamer length and with hydrophones at a 12.5 m receiver interval. In 2012, the legacy 2D was reprocessed by WesternGeco using Anisotropic Kirchoff pre-stack Time Migration (add ref), to obtain an improved signal resolution. One of the key processing challenges was represented by the presence of strong sea-bed multiples and inter-bed multiples. The reprocessed 2D seismic lines have produced an overall better reflection detail, enhanced data resolution, and improved fault definitions and events continuity, thus which providing much higher confidence during interpretation.
of geological features. **The vertical resolution of the seismic data in the investigated section ranges between 7 and 14 metres, calculated considering a peak frequency of 50-60 Hz and interval velocities of 1,800-2,900 m sec\(^{-1}\).**

A post-stack seismic attribute, the **Seismic attributes were generated for helping interpretation. In particular, the root-mean-square (RMS) seismic amplitude, was used to support the interpretation. In detail, the RMS, which represents the square root of the arithmetic mean of the squares of the seismic amplitudes within a defined window interval, helped to unravel the presence of coarse-grained facies (Rijks and Jauffred, 1991; Chen and Sidney, 1997; Brown, 2004).**

**Additional data used in this study include the multichannel seismic profiles acquired during the R/V VEMA cruises 3618 and 3619 (Coffin and Rabinowitz, 1982), and available through the Marine Geoscience Data System (http://www.marine-geo.org/index.php), and published seismic profiles (Mougenot et al., 1986; Franke et al., 2015).**

Three seismic horizons, named H1 to H3, and associated seismic sequences (S1 to S4), were identified based on seismic facies and reflector terminations, mapped throughout the study area, and integrated with all the data available in literature in order to develop a chronological framework for the Davie Ridge.

**32.2. Multibeam Echosounder data**

During the GLOW survey, **multibeam survey bathymetric data were collected with the** Kongsberg EM302 multibeam echosounder, permanently installed
on board the R/V Pelagia. The maximum swath opening angle is 150 degrees. The
transmitter array has a beam opening angle of 1 degree while the receiver array had a
beam opening angle of 2 degrees. These arrays are connected to a transceiver unit
(TRU). The TRU receives the ships attitude (corrections for heave, roll, and pitch and
heading) from a Kongsberg MRU5 motion sensor. A Seapath200 serves as positioning
and heading system and also sends its data to the TRU. The sound velocity in the water
column was determined from a salinity/temperature CTD deployment and calculated
using the Chen-Millero formula (Chen and Millero, 1977). Processing of the data
was performed using the Neptune (Kongsberg) and Fledermaus (QPS)
software packages. The data were presented as a 100 × 100 m surface grid, that has
been integrated with the Southwest Indian Ocean Bathymetric Compilation
(swIOBC; Dorschel et al., 2018), available at a 250 m horizontal resolution.

32.3. Sediment samples
Short seabed samples were collected during the GLOW cruise using a NIOZ designed
box corer. The box core has a barrel with a diameter of 30 cm and a height of 55
cm. The box corer was supplied with a lid that closes the box from the top as soon as it
has penetrated the sediment. This configuration avoided the sloshing of the
water above the sediment surface during the recovery of the core, resulting in an undisturbed sample of the seabed surface
sediments. On deck the bottom water was siphoned off and the surface sediments were
described and photographed. Four plastic liners were inserted and retrieved from the
core. These subsamples were stored at a temperature of 4°C. A key objective of the
GLOW survey was to take sediment cores where fossil stratigraphic layers crop out at
the sea floor in order to provide age control on seismic reflectors. This occurred on
flanks of submarine channels (see supplementary material). Samples were washed over a 63 micron sieve and dried at 40° C in an oven. Washed residues were studied for index fossils, and biostratigraphic age assignments were made using following Wade et al. (2011).

3.4. Well data

Eight exploration wells (Fig. 1) with check-shots, velocity models, and biostratigraphic information were made available for this study by Royal Dutch Shell and Shell Tanzania. The wells were tied to specific seismic reflectors, allowing the age determination of the seismic horizons and correlating specific reflectors to

3.5. Seismic interpretation

Three seismic horizons, named H1 to H3, and associated seismic sequences, were identified based on seismic facies and reflector terminations and mapped throughout the study area. In detail, the three sequences, named S1 to S3 from deep to shallow, show diagnostic seismic facies, reflection geometries, and RMS amplitude values. Sequence S2 was further subdivided in two units (named S2a and S2b) by horizon J (Figs. 3, 4).

The history of the Western Indian Ocean can be traced back to the Early Jurassic, when the onset of rifting occurred between Madagascar and Africa (Revees and de Wit, 2000; Revees et al., 2016). Sea floor spreading started in the Middle Jurassic and continued until the Early Cretaceous (Coffin and Rabinowitz, 1992), leading to the southward drift of Madagascar along the dextral strike-slip structures of the Davie Fracture (or at least along part of it, see below and discussion in Klimke and Franke, 2016) and the
Lebombo-Explora Fracture Zones (Reeves and de Wit, 2000). From the Cretaceous to the Paleogene (mid-Oligocene), the East African margin was characterized by a period of stability and thermal subsidence (Kent et al., 1971; Salman and Abdula; 1995), which was recorded by deposition of the Kilwa Group in Tanzania (Nicholas et al., 2006; 2007). The passive margin phase was interrupted by neo-rifting and tectonic reactivation: the onset of new mantle circulation beneath the African continent (Ebinger and Sleep; 1998; Moucha and Forte, 2011), known as the African super-swell (Nyblade and Robinson, 1994), evolved into the EARS (Chorowitz, 2005), with synchronous initiation along its western and eastern branches (Roberts et al., 2012). Normal faulting and rifting was widespread along the Tanzanian margin during the Miocene, promoting formation of topographic highs, as Zanzibar, Pemba and Mafia Islands, and lows, such as the coastal basins and the Kerimbas Graben (Kent et al., 1971; Mougenot et al., 1986). Recent studies, however, highlighted the presence of folding and inversion structures on a seismic profile across the channel north of Zanzibar Island (Sii and Underhill, 2015), suggesting that the islands are compressional features associated with fault reactivation and basin inversion.

3.1. Kerimbas Graben and Davie Ridge in the offshore of Tanzania

The EARS consists of a series of tectonic basins bordered by uplifted shoulders, which extend for thousands of kilometres along two main lineaments, called the western and eastern branches (Chorowitz, 2005). The continuation of the eastern branch offshore of Tanzania can be traced along the Pemba and Mafia basins and along the Kerimbas and Lucerna Grabens further to the south (Fig. 1; Mougenot et al., 1988; Franke et al., 2015).
The Kerimbas Graben was firstly recognised by Mougenot et al. (1988) north of the Saint-Lazare Seamount (Fig. 1). A compilation of recently acquired multibeam data highlight that the graben, north of a 12° S, can be divided in three zones based on sea floor morphology and water depth (Figs. 1 and 2). The southern part (zone 1; Fig. 2), between the Saint Lazare Seamount up to 10° 20’ S, is a 30-40 km wide symmetric graben bounded by ca. 15° steep flanks, and it shows a flat floor lying at a maximum depth of ca. 2900 m, gently dipping to the north (Figs. 1, 2). The western side of the basin runs along the base of the slope in the offshore Rovuma delta while the eastern side corresponds to the Davie Ridge (Fig. 1). A series of channels and gullies cut the western flank and are visible on the sea floor (Fig. 1). The second zone corresponds to a bathymetric sill, located just offshore the main Rovuma Channel between 10° 20’ S and 9° 05’ S (Fig. 1), and it is lying at ca. 2750 metres of water depth (Fig. 2). In this area, the graben shows asymmetric flanks, with a gentler western side up to 1.5° and a 12° dipping eastern side. In the third zone, reaching approximately 8° 40’ S, the graben shows a different morphology with a maximum water depth up to ca. 3500 metres and a maximum width up to 90 km (Figs. 1, 2). In this area, the western flank of the graben partially corresponds to a structural high generated by movement of the Seagap Ridge (Fig. 2; Revees et al., 2016), while the western side corresponds to the northern termination of the Davies Ridge (Fig. 1). A series of arcuate steps are visible on the floor of the graben, likely associated to normal faults developing at the base of the Davie Ridge (see supplementary Figure S1).

The Davie Ridge appears as a bathymetric high roughly extending N-S that dissects the continental slope in the offshore East Africa for more than 1000 km south of 9° S (Mahanjane, 2014; Courgeon et al., 2018). The ridge shows different maximum elevations (calculated as the depth difference between the top of the ridge and the floor
of the Kerimbas Graben along a section, see Fig. 2) in the different zones described above (Fig. 2), with an overall decrease in elevation to the north. Heirtzler and Burroughs (1971) when discovering the Davie Ridge described it as a ridge-like feature, asymmetric, with a steep western flank (up to 30°) and a gently-dipping eastern flank (ca. 0.65° in the offshore Rovuma delta; Fig. 1). Heirtzler and Burroughs (1971) interpreted the ridge as a transform fault resulting from the southward drift of Madagascar relative to the African continent. The continuation of the Davie Ridge north of 9° S, where the ridge does not have a prominent morphological expression on the sea floor (Fig. 1), has been derived by gravimetric and magnetic data showing a series of anomalies, up to 2.5° S (Rabinowitz, 1971; Scrutton, 1978; Coffin and Rabinowitz, 1987). The entire lineament, extending from ca. 20° S to 2.5° S, named the Davie Fracture Zone by Scrutton (1978), was interpreted as the bathymetric expression of the transform fault that accommodated southward drift of Madagascar (Scrutton, 1978). A recent study from Klimke and Franke (2016), however, argued the existence of a transform fault extending from northern Mozambique up to Kenya and interpreted the Davie Ridge visible on the bathymetry between 15° S and 9° S (on the eastern side of the Lacerda and Kerimbas grabens) as a rift-flank uplift, originated during the Neogene and probably correlated with the evolution of the EARS in the offshore domain. This interpretation is in agreement with GPS vector data (Calais et al., 2006), and focal mechanisms of recorded earthquakes, showing pure normal faulting with N-NW trending nodal planes and roughly E-W extensional failure (Grimison and Chen, 1988; Yang and Chen, 2010).

4. Results

4.1. Stratigraphy of the Davie Ridge
The stratigraphy of the Davie Ridge is highlighted in Figure 3, on a seismic profile oriented NNSW-SSE along the crest of the ridge, and in Figure 4, on a section oriented W-E crossing the eastern side of the Kerimbas Graben. Three laterally-continuous seismic horizons, named H1 to H3, and associated seismic sequences (S1 to S3), were identified based on seismic facies and reflector terminations, mapped throughout the study area, and integrated with all the data available in literature in order to develop a chronological framework for the Davie Ridge. The three sequences, bounded by three key stratigraphic horizons (H1 to H3) plus the sea floor, are recognised. Each sequence, named S1 to S3 from shallow deep to deep shallow, shows diagnostic seismic facies, reflection geometries, and RMS amplitude values and reflection geometries.

Horizon H1 at the base of sequence S1 presents a laterally variable seismic reflection amplitude (Fig. 3). At places, H1 shows channel-like erosional features that cuts older sediments, as highlighted by the presence of the presence of truncated reflectors (Fig. 4). Overall, sequence S1 (confined between H1 and H2), shows low amplitude to transparent reflections, wavy and discontinuous (Fig. 3), characterize sequence 3 (confined between H2 and H3). When visible, seismic reflections are often wavy to discontinuous (Fig. 3). Overall, S3-S1 shows has low RMS amplitude values (Fig. 4). Higher amplitude reflections, sub-horizontal or shingled, characterize the infill of the erosional features (Fig. 4). The base of the sequence (H3) corresponds to an erosional surface showing a laterally variable seismic reflection amplitude. Below horizon H3H1, seismic reflections are mainly sub-parallel, with small lateral changes of seismic amplitude response and overall-low RMS amplitude values.

Horizon 2 shows a lateral change in seismic reflection amplitude and a marked erosional character, as highlighted by truncated reflectors belonging to S1. Sequence S2
(confined between H2 and H3) is divided into two units by horizon J (Figs. 3, 4). Unit S2a (between H2 and J) shows complicated seismic facies, comprising parallel to wavy reflection packages laterally changing from low to high amplitude often accompanied by a change in thickness (Figs. 3, 4). High amplitude reflections characterize the infill of v-shaped (channel-like) erosional depressions (Fig. 4). Overall, S2a shows high RMS amplitude values (Fig. 3). Tabular to lens-shaped deposits showing chaotic to transparent reflections are widespread within S2a and are characterized by low RMS amplitude values (Fig. 4). Unit S2b (between H2 and J) is characterized by an upper unit (2a) with continuous, high-frequency and low amplitude reflections, mainly with low RMS amplitude values (Figs. 3, 4). The unit presents intervals characterized by higher-amplitude and wavy reflections, wavy or showing a v-shaped basal contact, with higher RMS amplitude values. The upper part of S2b is concordant with the overlying sequence S3, and the main difference is a downward increase in the reflection amplitude, as shown by the RMS profile (Fig. 3). Horizon J mainly develops at the top of a series of high-RMS-amplitude reflection packages (Fig. 3). In the high-resolution GLOW seismic profiles, sequence S1-S3 (between H3 and the sea floor and H1) is characterized by an upper unit (S34ba) mainly characterized by an alternation of parallel and continuous reflections organized in high- and low-amplitude packages (Fig. 3), and a lower unit (S43ba) showing
discontinuous to chaotic seismic reflections with a laterally variable amplitude and a lower unit (1b) mainly characterized by an alternation of parallel and continuous reflections, organized in high- and low-amplitude packages (Fig. 3). Overall, S1-S3 shows low RMS amplitude values, and a continuous positive reflection defines horizon 1-3 (Fig. 3). S2 (between H1 and H2) is characterized by an upper unit (2a) with continuous, high-frequency and low amplitude reflections, mainly with low RMS amplitude values (Fig. 3). In places, the unit presents intervals characterized by higher-amplitude reflections, wavy or showing a v-shaped basal contact with high RMS amplitude values. The upper part of S2 is concordant with the overlying S1, and the main difference is a downward increase in the reflection amplitude, as shown by the RMS. The lower part of S2 (2b) shows a more complicated seismic facies, comprising parallel to wavy reflection packages laterally changing from low to high amplitude often accompanied by a change in thickness (Fig. 3). High amplitude reflections often characterize the infill of v-shaped (channel-like) erosional depressions. Tabular to lens-shaped deposits showing chaotic to transparent reflections are widespread within the lower part of the sequence, and are characterized by low RMS amplitude values. Horizon 2 shows a lateral change in seismic reflection amplitude and a marked erosional character. Low amplitude to transparent reflections characterize sequence 3 (confined between H2 and H3). When visible, seismic reflections are often wavy to discontinuous (Fig. 3). Overall, S3 shows low RMS amplitude values. The base of the sequence (H3) corresponds to an erosional surface showing a laterally variable seismic reflection amplitude. Below horizon H3, seismic reflections are mainly sub-parallel, with small lateral changes of seismic amplitude response and overall low RMS amplitude values.

4.2. Super-elevated abandoned canyons on the Davie Ridge
Four giant canyons intersect the crest of the Davie Ridge, approximately running WSW
to ENE and named C-1 to C-4 from north to south (Figs. 3, 45). C-1 likely represents the
landward continuation of the Tanzania Channel, discovered by Bourget et al. (2008) in
the Indian Ocean abyssal plain (Fig. 1). Where highlighted by multibeam bathymetry,
the canyons are up to 15 km wide and up to 850 metres deep (Fig. 45), and their -

The thealweg of each canyon, measured on the crest of the Davie Ridge, lies at
progressively deeper water depths northward, changing from ca. 2,700 meters for C-4 to
ca. 3,500 meters of water depth for C-1, which is located about 100 kilometres to the
north (Fig. 45). While canyons C-4 to C-2 show a U-shaped basal surface, canyon C-1
pre-ent has aa flat bottom (Fig. 5) topography. Seismic profiles highlight that most of
the canyons lack a sedimentary infill, except for canyon C-1, showing ca. 0.10013-

mseceters-thick of basal deposits characterized by with high-amplitude and parallel
reflections (Fig. 5). Due to the northward thinning of S1-S3 and S2, While canyon C-4
only cuts across horizon H1-H3, while canyon C-1 cuts down to horizon H3-H1 (Figs. 3,
45). Multibeam data acquired along the crest of the Davie Ridge show the morphology
of the canyons (Fig. 45). Channel C-1 shows presents steep flanks, up to 25°, with the
southern one hosting the escarpments of two small landslides (Fig. 45, and see
supplementary Figure S2). The lack of landslide deposits along the canyon axis suggests
that the slumped material was removed by turbidity currents flowing along the canyon,
indicating a recent activity. Direct sampling of the canyon supports this hypothesis, as
cr-coarse-grained turbidite deposits are present closely below the sea floor (see
supplementary figure Figure S1S2). A gentler topography characterizes canyon C-2,
showing < 10° dipping flanks (Fig. 45). The canyon is cut by a normal fault that creates
a step on the sea floor on which sediments, probably transported by bottom currents,
may accumulate forming a field of sediment waves (Fig. 45 and see supplementary
Figure S3). A small sediment drift is visible on its northern side and is probably originated by the action of bottom currents as well, which can be also related to bottom current activity (Fig. 45). The North Atlantic Deep Water (NADW) current is responsible of the deep-water circulation in the western Indian Ocean along the Davie Ridge (van Aken et al., 2004). The orientation of the crest of the sediment waves suggests that bottom currents are directed towards NNE, in agreement with direct observations of the NADW in this area (van Aken et al., 2004). Canyon C-3 is the most noticeable feature on the sea floor as it shows a strong meandering behaviour while crossing the ridge (Fig. 45). The canyon presents up to 25° steep flanks, with normal faults on its western side (Fig. 45). The multibeam data reveal a small landslide escarpment on the eastern side, with slumped material accumulating on the canyon floor, suggesting that activity of turbidity currents along the canyon was ceased at the time the landslide occurred (Fig. 4-5 and see supplementary Figure S4). In addition, the smoothed surface topography of the landslide escarpment and of the deposits suggests that bottom currents probably reworked this area. C-4 is the shallower canyon discovered during the GLOW cruise (Fig. 45). The canyon shows a meander-like morphology, with a gentler southern side and steep, up to 20°, northern flank presenting a series of arcuate escarpments, probably generated by sediment failures (Fig. 4-5 and see supplementary Figure S5). The lack of a thick pelagic cover on the canyon flanks allowed direct sediment sampling of outcropping strata (Box-corer samples GW04 and GW13), providing additional age constraints (Table 1). A 3D view of the area (Fig. 56) highlights the geometric relation between the canyons, the Davie Ridge and the Kerimbas Graben. The canyons only incise the Davie Ridge, without and are not visible on the affecting the sea floor of the Kerimbas Graben, which shows a rather flat topography only interrupted by N-S trending fault escarpments (Figs. 4, 6). Indeed, the
thalwegs of the southernmost three canyons are uplifted relatively to the adjacent westward sea floor in the Kerimbas Graben, and the canyons on the Davie Ridge implying that the canyons are disconnected from the active slope canyons in the offshore Rovuma and Rufiji River deltas. The presence of N-S fault escarpments visible on the multibeam bathymetry and in cross section on seismic lines data generate topographic steps on the sea floor (supplementary Figure S1), suggesting a recent activity of the offshore branch of the EARS, as discussed also by Franke et al. (2015). This is further confirmed by the location and focal mechanism of recent earthquakes (Grimison and Chen, 1988; Yang and Chen, 2010, and supplementary Figure S1).

4.3. Chronology of the Davie Ridge

The chronology of the Davie Ridge, summarized in Figure 7, was estimated using biostratigraphic information from eight explorations wells, sediment samples, and correlations with published data. The correlation of horizons H1 to H3 with dated stratigraphic horizons presented in previous studies (Scrutton, 1978; Mougenot et al., 1986; Coffin and Rabinowitz, 1992; Coffin and Rabinowitz, 1992; McDonough et al., 2013; O’ Sullivan, 2013; Franke et al., 2015; Sii and Underhill, 2015; Klimke and Franke, 2016; Sansom, 2018) allowed for the definition of the chronology of the Davie Ridge, summarized in Figure 6. Additional chronological constraints come from the results of the recent hydrocarbon exploration in the area (McDonough et al., 2013; Sii, and Underhill, 2015; Sansom, 2018) and correlate with DSDP Site 242 (Wade, unpublished). Taking into account the vertical resolution of the seismic data, sediments in proximity of Considering the above: Horizon H1 (Fig. 7) are dated by the Last Occurrence of Sphenolithus delphix (top Chattian, ~23.1 Ma; Raffi et al., 2006) and
correlates with the base of Ng1 sequence of Sansom (2017), with the top Oligocene reflector (O) of Franke et al. (2015), and with horizon A1 of Mougenot et al. (1986). Horizon H2 is dated by the disappearance of Helicosphaera perch-nielseniae and Sphenolithus heteromorphus (Serravallian, ~13.5 Ma; Raffi et al., 2006; Boesiger et al., 2017) and correlates with horizon A32 of Mougenot et al. (1986). Horizon J, for which biostratigraphic information is not available in the wells, most likely corresponds to horizon A3 of Mougenot et al. (1986), which has been also defined as the late Miocene reflector (LM) which has been defined by Franke et al. (2015). Horizon H1 corresponds to the top of Ng1 sequence of Sansom (2017), base Pliocene (5.3 Ma), and correlates with horizon A4 of Mougenot et al. (1986), which has been defined by Franke et al. (2015) as the late Miocene reflector (LM). Horizon H3 most likely correlates with A1 of Mougenot et al. (1986) and the top Oligocene reflector (O) of Franke et al. (2015). In addition, the age of Sequence S2, and consequently of horizon H1-H3, is confirmed by the planktonic foraminifer assemblages of outcropping stratigraphic layers sampled on Davie Ridge (Table 1). In detail, box corer sample GW04, recovered from the northern flank of C-1 (Fig. 4-5 and supplementary material), represents Zone M14 (age 5.57-6.13 Ma; Wade et al., 2011), while box corer sample GW13, recovered from the southern flank of C-4 (Fig. 4-5 and supplementary material), is constrained to Zone PL1 (age 5.54-5.82 Ma; Wade et al., 2011).

5. Discussion and Conclusions

Correlation of seismic data and related attributes allowed evaluation of the deep-water depositional history in the offshore Tanzania. In detail, moving upward from Sequence...
sequence S3 to Sequence S2, the stratigraphy of the Davie Ridge recorded a progressive increase in the accumulation of coarse-grained gravity-driven deposits.

This is suggested by the presence of large turbidite channels, visible in the seismic profiles as v-shaped erosional features hosting high-amplitude reflection packages with shingled reflections (Abreu et al., 2003), and by the overall increase in the RMS amplitude (Figs. 3, 67), considered a proxy for sandy sediments (Rijks and Jauffred, 1991; Chen and Sidney, 1997; Brown, 2004). In addition, in the lower part of sequence S2, turbidity current deposits alternate with debris flow and mass transport deposits, as suggested by their seismic facies and internal architecture of specific intervals (Fig. 3). (Hampton et al., 1996; Posamentier and Kolla, 2003). Mass transport deposits are the result of gravity-induced remobilization of pre-existing sediments on a submarine slope, and on seismic data are represented by a variety of facies, spanning from chaotic or highly disrupted seismic facies to coherent reflections (Hampton et al., 1996; Posamentier and Kolla, 2003; Frey-Martínez, 2010).

The upper part of sequence S1 and the lower unit of part of Sequence S2, which mainly accumulated between the lower and middle late Miocene in age, formed after the establishment of the EARS in Tanzania (Roberts et al., 2012; Sansom, 2017; 2018): at that time, it is possible that topographic uplift in the hinterland increased the progradation of the paleo-Ruvuma and paleo-Rufiji deltas, enhancing deep-water sediment transport and triggering a widespread margin instability, as also discussed in Sansom (2017; 20172018). The presence of turbidite channels and coarse-grained deposits in this stratigraphic interval of the Davie Ridge suggests that sediment sourced from the Tanzanian margin was directly delivered towards the basin, also by means of the giant canyons now present on top of the Davie Ridge.

Indeed, considering that the canyons incise the Davie Ridge without reaching horizon
H3H1, a maximum age for their formation is the age of sequence S2, or even younger.

Moving progressively upward, the upper part of S2 marks a decrease in the activity of turbidite channels, as testified by a reduction of channelized features, which are totally absent in sequence S4. The lack of deposits associated with turbidity currents and debris flows, as highlighted by the seismic data (Figs. 3, 45), suggests that the Davie Ridge was at that time a topographic relief bathymetric high on the sea floor that acted as barrier for gravity-driven flows triggered originated along the Tanzanian shelf and slope.

During deposition of sequence S4S3, turbidite channels were still active in the slope area offshore the Rovuma River delta, and further to the north (Liu et al., 2016), and thick turbidite sequences accumulated in the Kerimbas Graben (Franke et al., 2015; Sansom, 2018). Box corer samples and sea floor features visible on the multibeam bathymetry (Fig. 45 and supplementary material) testify suggest that Canyon C-1, at the northern end of the Davie Ridge, is the only active system and that sedimentation from bottom currents and reduced pelagic and hemipelagic deposition dominates the stratigraphy of the basin outside it.

All these evidences suggest that major the uplift of the Davie Ridge disconnected canyons C-4 to C-2 from their feeder systems, re-routing the sediments delivered into the western Indian Ocean towards the north. Canyon C-1, which is one of the largest deep-water system discovered so far (Fig. 78, supplementary S6), represents the termination of a large drainage basin that extends from the Rovuma River to the southern Rufiji River deltas, and that probably connects with the Tanzania Channel about 500 km away towards NE (Bourget et al., 2008). Hence, the Tanzania Channel currently is the main pathway of organic and inorganic particulate matter from the Tanzanian shelf and slope area towards the Indian Ocean abyssal plain. The chronological constraints available show that the topographic deformation of the sea
floor associated with the offshore branch of the EARS can be traced back to the late middle-upper Miocene, in agreement with previous studies (Franke et al., 2015). In addition, our results suggest that the tectonic processes driving the uplift of the Davie Ridge that progressively disconnected the deep-water canyons from their feeding systems likely started in the Plio-Quaternary (Fig. 8), are still active today, as demonstrated by the fault displacements visible on the modern sea floor (Figs. 5, 6) and by the recent recorded earthquakes (supplementary S1), showing a body magnitude $M_b$ up to 6.4 (Grimison and Chen, 1988; Yang and Chen, 2010), demonstrate that the area is still tectonically active, as also indicated by the fault displacements visible on the modern sea floor (Fig. 6). The rapid sea floor deformation triggered by an earthquake may be a potential tsunamogenic source (Kanamori and Kikuchi, 1993), and as a consequence the offshore tectonics of the EARS needs to be taken into account for tsunami hazards assessment along the coastlines of southern Tanzania and Mozambique.

This study has two main implications about regarding how the formation of the Davie Ridge relates within the regional geodynamic context and about how the effects tectonics of the offshore branch of the EARS controls the depositional history of the western Indian Ocean. Based on gravimetric and magnetic data, previous studies proposed the existence of a continuation of the Davie Ridge north of 9° S, where it lacks a morphological expression on the sea floor (Coffin and Rabinowitz, 1987; Revees and de Wit, 2000; Revees et al., 2016). With this assumption, the Davie Fracture Zone was correlated up to 2.5° S (Scrutton, 1978; Rabinowitz, 1971; Coffin and Rabinowitz, 1987), and was interpreted as the result of the southward drift of Madagascar with respect to Africa, implying that Madagascar was previously part of the modern Kenya. The inferred Plio-Quaternary Miocene age for the Davie Ridge uplift may suggest that its origin is unrelated with the initial opening of the western Indian
Ocean and with the strike-slip movement of Madagascar, as also proposed by Klimke and Franke (2016). This result would imply the need of new palaeogeographic models to explain the Mesozoic evolution of the Indian Ocean and the position of Madagascar when attached to Africa. Notwithstanding, it is also possible that the Davie Ridge formed in the response to the recent reactivation of pre-existing Mesozoic tectonic lineaments, but the lack of imaging of the deeper stratigraphic sequences down to the basement does not allow to discuss this point any further.

The discovery of giant and abandoned canyons on the deep-water Davie Ridge highlights that the tectonics of the offshore branch of the EARS has had a profound control on the physiography of the margin and on the transport of sediment and organic matter towards the Indian Ocean. Future studies supported by additional data acquisitions are needed to have a full picture of the modern drainage system and its distal continuation in water depth greater than 4000 metres. There are still outstanding questions regarding Further studies are needed to have a full picture of the modern drainage system and its distal continuation in water depth greater than 4000 metres, and to understand the role of sea floor deformation on bottom current circulation in the western Indian Ocean and the potential of the offshore tectonic activity of the EARS in generating tsunamigenic earthquakes or submarine landslides.

Acknowledgments

The Paleogene GLObal Warming events (GLOW) cruise, onboard of RV Pelagia, was funded by the ESF EUROCORES program Netherlands Organisation for Scientific Research (NWO). PNP was supported by NERC UK-IODP grant NE/F523293/1. BW was supported by the Joint Oceanographic Institutions/US Science Support Program.
We thank the Royal Netherlands Institute for Sea Research (NIOZ) for technical and logistic support during and after the cruise. We thank the scientific party for all their support on board the vessel, in particular Niamh O’Sullivan and Chris Nicholas are also thanked. We are grateful to the Tanzania Petroleum Development Corporation (TPDC), WesternGeco and Schlumberger, Royal Dutch Shell and Shell Tanzania for giving access to the seismic and well data, the possibility and allowing the publication of this work to work and publish the dataset. We would also like to thank Schlumberger and for providing academic licenses of the seismic interpretation software Petrel, their software (Petrel). PNP was supported by NERC UK-IODP grant NE/T523293/1. BW was supported by the Joint Oceanographic Institutions/US Science Support Program. The Editor, an anonymous reviewer, and Marco Ligi are thanked for their constructive and detailed comments which improved the manuscript significantly.

The authors have no conflict of interest to declare.

Data Availability Statement

For more information about the data acquired during the GLOW cruise contact Dick Kroon and Henk de Haas. The bathymetric data are available at doi.org/10.1002/2017GC007274. The other data that support the findings of this study are not publicly available due to privacy restrictions.

Figure 7. Bathymetric cross sections near the shelf-edge of the largest canyons visible on the modern sea floor (in black), modified from Normark and Carlson (2003). Topographic cross section of the Grand Canyon (in brown). Bathymetric cross sections of the deep-water canyons C-1 (the Tanzania Channel) and C-4, in red.

Figure 8. Conceptual scheme for the evolution of the study area since the upper Oligocene. Age constraints on key horizons suggest that the uplift of the Davie Ridge (DR) and the formation of the Kerimbas Graben (KG) occurred in the last few millions of years started during the middle-upper Miocene. The Seagap Fault (SF) is highlighted in yellow. Note how the deep-water drainage system changed through time in response to the tectonics of the offshore branch of the EARS, from a series of coalescing canyons to a single system, where the Tanzania Channel is the only active conduit.
