Introduction

Prion-mediated phenotypes and diseases result from the conformationally protean characteristics of particular amyloidogenic proteins. The prion state has the property of interacting with proteins in their non-prion conformation, thus inducing further prion conversion. The prion phenomenon has been described for a variety of different proteins involved in diverse biological processes ranging from translation termination in yeast, memory in *Aplysia*, antiviral innate immune responses [1], and most recently the action of the p53 tumor suppressor [2]. Since the prion and non-prion conformations have differing biological properties, the net result of this replicative process is protein-mediated information transfer, the characteristics of which vary from prion to prion. The ubiquity of prion replication indicates that this is a wide-ranging of means of information transfer in biological systems.

In the case of mammalian neurodegenerative diseases the prion state is pathogenic as well as transmissible. A hallmark of such conditions is the inexorable progression of pathology between synaptically connected regions of the central nervous system (CNS), consistent with advancing cell-to-cell prion spread. Experimental transmission in several settings has been convincingly demonstrated in the case of the amyloid beta (Aβ) peptide which features prominently in Alzheimer’s disease (AD), the intracytoplasmic protein tau, also involved in AD as well as various neurodegenerative diseases referred to as taupathies, and α-synuclein, the primary constituent of Lewy bodies found in Parkinson’s disease (PD) [1,3].

The prototypic and best-characterized prion diseases are the transmissible spongiform encephalopathies (TSEs) of animals and humans, including sheep scrapie, bovine spongiform encephalopathy (BSE), chronic wasting disease (CWD) of cervids, and human Creutzfeldt-Jakob disease (CJD). TSEs result from conformational
**Author Summary**

Prions are infectious proteins, originally discovered as the cause of a group of transmissible, fatal mammalian neurodegenerative diseases. Propagation results from conversion of the host-encoded cellular form of the prion protein to a self-propagating disease-associated conformation. It is believed that the self-propagating pathogenic form exists in a variety of subtly different conformations that encipher prion strain information. Here we explored the mechanism by which prion protein primary structural variants, differing at only a single amino acid residue, interact with prion strain conformations to control disease phenotype. We show that under conditions of co-expression, a susceptible prion protein variant influences the ability of an otherwise resistant variant to propagate an otherwise unfavorable prion strain. While this phenomenon is analogous to the expression of genetically-determined phenotypes, our results support a mechanism whereby dominant and recessive prion traits are epigenetically controlled by means of protein-mediated conformational templating.

Prion strain properties and the primary structure of PrP are the two major elements controlling prion transmission. Optimal disease progression appears to occur when the primary structures of PrP<sup>Sc</sup> constituting the infectious prion, and substrate PrP<sup>C</sup> diseases involving conformational templating [4].

TSEs have long incubation periods ranging from months to years, are invariably fatal, and currently incurable. A variant of CJD (vCJD) is unequivocally linked to prions causing BSE [5], the zoonotic potential of other TSE’s remains uncertain. Whereas all TSEs, including human genetic and sporadic forms, are genetically controlled by means of protein-mediated conformational templating. Wherever agent host-range, stable strain properties, and the ability to mutate and respond to selective pressure, early researchers assumed a viral etiology for these diseases. While this is not the case, the unequivocal infectivity of TSEs set these prions apart. Their singular capacity to cause fatal neurodegeneration in genetically tractable animal models, and the ability to propagate and quantify infectivity, in vivo, in cell culture or cell-free conditions, provide unparalleled settings to elucidate general mechanisms and devise integrated therapeutic approaches for all diseases involving conformational templating [4].

TSEs have long incubation periods ranging from months to years, are invariably fatal, and currently incurable. A variant of CJD (vCJD) is unequivocally linked to prions causing BSE [5], the zoonotic potential of other TSE’s remains uncertain. Whereas all TSEs, including human genetic and sporadic forms, are experimentally transmissible, most are naturally infectious and frequently occur as unanticipated epidemics. Scrapie is one such example, and several iatrogenic epidemics have been reported. More than 1,500 sheep developed scrapie following administration of a scrapie-contaminated vaccine [6]. A similar recent event led to an ~20-fold increase in the rate of scrapie in Italy [7].

Prion strain properties and the primary structure of PrP are the two major elements controlling prion transmission. Optimal disease progression appears to occur when the primary structures of PrP<sup>Sc</sup> constituting the infectious prion, and substrate PrP<sup>C</sup> expressed in the host are closely related [8–10]. Underscoring the importance of primary structure on transmission, susceptibility and disease presentation are strongly influenced by several primary structure-related PrPC, to the corresponding prion, or scrapie form, PrP<sup>Sc</sup>. Since TSEs share numerous properties with nucleic acid-based pathogens, including agent host-range, stable strain properties, and the ability to mutate and respond to selective pressure, early researchers assumed a viral etiology for these diseases. While this is not the case, the unequivocal infectivity of TSEs set these prions apart. Their singular capacity to cause fatal neurodegeneration in genetically tractable animal models, and the ability to propagate and quantify infectivity, in vivo, in cell culture or cell-free conditions, provide unparalleled settings to elucidate general mechanisms and devise integrated therapeutic approaches for all diseases involving conformational templating [4].

**Results**

Transgenic mice to assess the effects of the OvPrP A/V136 dimorphism on scrapie pathogenesis

We created Tg mice expressing OvPrP encoding either A or V at residue 136. Using semi-quantitative Western and immuno dot blotting we ascertained that levels of expression in the CNS of Tg(OvPrP-A136)3533<sup>−/−</sup> and Tg(OvPrP-V136)4166<sup>−/−</sup> mice were close to that of PrP expressed in the CNS of wild type mice (Fig. 1A).

Both lines of Tg mice tolerated these levels of expression without spontaneously developing recognizable signs of disease (Table 1). In contrast, Tg mice of both genotypes intracerebrally (ic) inoculated with brain homogenates from scrapie-affected sheep succumbed to the neurological effects of prion disease following variable incubation periods (Table 1). Rapid disease onset occurred following inoculation of Tg(OvPrP-V136)4166<sup>−/−</sup> mice with SSBP/1 prions [15,16], which consistently produced an ~130 d mean incubation time, While SSBP/1 also caused disease in Tg(OvPrP-A136)3533<sup>−/−</sup> mice, mean incubation times were ~230 to 280 d longer (Fig. 1B and Table 1). In contrast, CH1641 prions [17] induced disease in all inoculated Tg(OvPrP-A136)3533<sup>−/−</sup> mice with a mean ~310 d onset of disease, whereas no disease was registered in Tg(OvPrP-V136)4166<sup>−/−</sup> mice after >560 d. These distinct transmission profiles are consistent with previously recognized strain differences between SSBP/1 and CH1641 scrapie prions [17]. Consistent with this notion, western blot analysis of proteinase K-treated brain extracts of diseased Tg(OvPrP-A136)3533<sup>−/−</sup> mice confirmed that the molecular profiles which distinguish PrP<sup>Sc</sup> constituting SSBP/1 and CH1641 prions [18] were maintained upon transmission (Fig. 1C). These results demonstrate that Tg(OvPrP-A136)3533<sup>−/−</sup> and Tg(OvPrP-V136)4166<sup>−/−</sup> mice are capable of distinguishing scrapie strain-specific transmission patterns, and in turn that these properties are influenced by the A/V136 dimorphism.

The influence of the OvPrP A/V136 dimorphism on PrP<sup>Sc</sup> conversion kinetics, conformation, and CNS deposition

Previous studies revealed a positive correlation between PrP<sup>Sc</sup> conformational stability and the incubation times of mouse and cervid prions [19,20], but not of hamster prions [21,22]. We performed guanidine denaturation treatments on PrP<sup>Sc</sup> in brain extracts of SSBP/1 infected Tg(OvPrP-V136)4166<sup>−/−</sup> mice with short incubation times and SSBP/1 infected Tg(OvPrP-A136)3533<sup>−/−</sup> mice with long incubation times. Analyses using mAb 6H4 revealed distinct stability curves for OvPrP<sup>Sc</sup>-V136 and OvPrP<sup>Sc</sup>-A136. The conformational stability of OvPrP<sup>Sc</sup>-V136 was lower than OvPrP<sup>Sc</sup>-A136 in the range of GdnHCl concentrations between 1 and 2 M. (Fig. 2A) and GdnHCl<sub>1/2</sub> values were 1.78 and 2.17 respectively. This confirmed that the
conformation of OvPrP Sc-V136 produced in Tg(OvPrP-V136)4166+/− mice with rapid incubation times was less stable than OvPrP Sc-A136 produced in Tg(OvPrP-A136)3533+/− mice with longer incubation times. We refer to these conformations as unstable (U) and stable (S), and to the rapidly and slowly propagating prions composed of these conformers as SSBP/1-V136(U), and SSBP/1-A136(S).

We then used histoblotting [23], a widely used method for characterizing strain-specific differences in PrP Sc distribution [20,24], with mAb 6H4 to characterize OvPrP Sc-A136(S) and conformation of OvPrP Sc-V136 produced in Tg(OvPrP-V136)4166+/− mice with rapid incubation times was less stable than OvPrP Sc-A136 produced in Tg(OvPrP-A136)3533+/− mice with longer incubation times. We refer to these conformations as unstable (U) and stable (S), and to the rapidly and slowly propagating prions composed of these conformers as SSBP/1-V136(U), and SSBP/1-A136(S).

We then used histoblotting [23], a widely used method for characterizing strain-specific differences in PrP Sc distribution [20,24], with mAb 6H4 to characterize OvPrP Sc-A136(S) and

OvPrPSc-V136(U) deposition in the CNS. While OvPrPSc-A136(S) had a punctate pattern of accumulation throughout the midbrain, pons, and oblongata of slow incubation time Tg(OvPrP-A136)3533+/2 mice (Fig. 3A), the neuroanatomical distribution of OvPrPSc-V136 in the same sections of rapid incubation time Tg(OvPrP-V136)4166+/2 mice was distinctly different, being more intense and diffusely deposited than OvPrPSc-A136(S) (Fig. 3B). Since Tg(OvPrP-A136)3533+/2 and Tg(OvPrP-V136)4166+/2 mice were both engineered using the same cosSHa.Tet cosmid vector which drives expression from the PrP gene promoter, we conclude that these differences are not the result of expression OvPrPC-A136 and OvPrPC-V136 in different neuronal populations.

The OvPrP A/V136 dimorphism influences strain-specific PrP conversion in vitro

We used brain extracts of Tg(OvPrP-A136)3533+/2 or Tg(OvPrP-V136)4166+/2 mice as sources of OvPrPSc-A136 and OvPrPSc-V136 substrates for protein misfolding amplification (PMCA) [25] using SSBP/1. While neither template spontaneously converted to PrPSc in the absence of seeded prions (Fig. 4A and E), SSBP/1 reproducibly converted OvPrPSc-V136 to OvPrPSc-V136 during a single round of PMCA (Fig. 4C). In contrast, conversion was not observed after a single round of PMCA when OvPrPSc-A136 was used as template (Fig. 4B and Fig. 5A). We therefore used serial PMCA (sPMCA) [26] over 10 rounds to address whether conversion of OvPrPSc-A136 to OvPrPSc-A136 might be detected after prolonged replication. Serial PMCA was performed in triplicate using equal amounts of PrP from three different Tg(OvPrP-A136)3533+/2 or Tg(OvPrP-A/V136) mice using mAb 6H4 (B) and mAb PRC5 (C). Times of onset of disease for analyzed mice are also provided. OvPrP-V136 is indicated by blue symbols and text; OvPrP-A136 is indicated by red symbols and text.

Epigenetic Dominance of Prion Conformers

OvPrPSc-V136(U) deposition in the CNS. While OvPrPSc-A136(S) had a punctate pattern of accumulation throughout the midbrain, pons, and oblongata of slow incubation time Tg(OvPrP-A136)3533+/2 mice (Fig. 3A), the neuroanatomical distribution of OvPrPSc-V136(U) in the same sections of rapid incubation time Tg(OvPrP-V136)4166+/2 mice was distinctly different, being more intense and diffusely deposited than OvPrPSc-A136(S) and total PrPSc in Tg(OvPrP-A/V136) mice (black line). Black asterisks compare differences between OvPrPSc-A136(S) and total PrPSc in Tg(OvPrP-A136)3533+/2 and Tg(OvPrP-A/V) mice; blue asterisks compare differences between OvPrPSc-A136(S) in Tg(OvPrP-A136)3533+/2 mice and OvPrPSc-V136(U) in Tg(OvPrP-V136)4166+/2 mice. C. Conformational stability analysis using mAb PRC5 of OvPrPSc-A136(S) in Tg(OvPrP-A136)3533+/2 mice (solid line) and OvPrPSc-A136(U) in Tg(OvPrP-A/V136) mice (dashed line).

PLOS Pathogens | www.plospathogens.org
OvPrPSc-A136 was undetectable with mAbs 6H4 or PRC5 until round eight, after which levels decreased during rounds nine and 10 (Fig. 4B and F).

Forced templating of a dominant PrPSc conformation in mice expressing both susceptibility alleles

Having established that Tg mice expressing OvPrPC-V136 and OvPrPC-A136 propagate SSBP/1-V136(U) and SSBP/1-A136(S) prions with relatively rapid and slow incubation times respectively, we produced Tg(OvPrP-A/V136) mice expressing both OvPrPC-A136 and OvPrPC-V136 and inoculated them with SSBP/1 to examine whether disease developed with fast, slow or intermediate kinetics. Although more rapid than the ~130 d onset of disease in Tg(OvPrP-A/V136) mice expressing both OvPrPSc-A136 and OvPrPSc-V136 and inoculated them with SSBP/1 to examine whether disease developed with fast, slow or intermediate kinetics. Although more rapid than the ~130 d onset of disease in Tg(OvPrP-A/V136) mice expressing both OvPrPSc-A136 and OvPrPSc-V136 and inoculated them with SSBP/1 to examine whether disease developed with fast, slow or intermediate kinetics. Although more rapid than the ~130 d onset of disease in Tg(OvPrP-A/V136) mice expressing both OvPrPSc-A136 and OvPrPSc-V136 and inoculated them with SSBP/1 to examine whether disease developed with fast, slow or intermediate kinetics.

Stability assessments using mAb 6H4 showed that the denaturation curves of OvPrPSc produced in the brains of diseased Tg(OvPrP-A/V136)4166+/− mice and Tg(OvPrP-A/V136)3533+/− mice were superimposable over most of the range of GdnHCl concentrations (Fig. 2A), indicating that OvPrPSc produced in Tg(OvPrP-A/V) mice shared the conformation of OvPrPSc-V136(U) produced in SSBP/1 infected Tg(OvPrP-V136)4166+/− mice. In accordance with this notion, histoblotting using mAb 6H4 showed that the neuroanatomical distribution of OvPrPSc(V136) in the brains of diseased Tg(OvPrP-A/V) mice mirrored the diffuse deposition of the OvPrPSc-V136(U) conformer located in similar sections of rapid incubation time Tg(OvPrP-V136)4166+/− mice (Fig. 3C).

While the rapid SSBP/1 incubation times, and properties of the converted PrPSc in diseased Tg(OvPrP-A/V) were consistent with propagation of SSBP/1-V136(U) prions, remarkably, western blotting of diseased Tg(OvPrP-P/A/V136) brain extracts with mAb PRC5 revealed substantial conversion of OvPrP-A136 to OvPrPSc-A136 (Fig. 2D). Densitometric comparisons of OvPrPSc levels using mAbs 6H4 [Fig. 2B] and PRC5 [Fig. 2D] allowed us to estimate relative conversion efficiencies of each allele product in the brains of diseased Tg(OvPrP-P/A/V136) mice. Using samples from diseased Tg(OvPrP-A136)3533+/− mice probed with mAbs 6H4 and PRC5 as normalizing controls for differences in the affinities of the two mAbs for OvPrP-A136, we estimated by Western or dot blotting that OvPrPSc-A136 comprised ~45% of total PK-resistant PrP in the brains of diseased Tg(OvPrP-P/A/V136) mice.

Figure 3. Representative OvPrPSc distribution in the CNS of diseased transgenic mice. OvPrP-V136 and OvPrP-A136 are indicated by blue and red text respectively. Times of onset of disease (d) for individual mice analyzed in histoblots are provided. Sections through the midbrain, pons and oblongata are shown for SSBP/1 infected Tg(OvPrP-A136)3533+/− mice (A and D); Tg(OvPrP-V136)4166+/− mice (B and E); and Tg(OvPrP-P/A/V) mice (C and F). In panels G and H, sections were not treated with PK and show distribution of total PrP. Histoblots in panels A–G were probed with mAb 6H4; histoblots in D–H were probed with mAb PRC5.

doi:10.1371/journal.ppat.1003692.g003
We then used mAb PRC5 to determine the conformation of OvPrPSc-A136 among total OvPrPSc produced in the brains of diseased Tg(OvPrP-A/V136) mice. The 1.64 GdnHCl1/2 value of OvPrPSc-A136 produced under these conditions was distinct from that of OvPrPSc-A136(S) produced in long incubation time Tg(OvPrP-A136)3533/+ mice without PK treatment; in C and G, the first lanes of each panel correspond to brain extracts from Tg(OvPrP-V136)4166/+ mice without PK treatment. In D and H, the first lanes of each panel correspond to mixtures of brain extracts from Tg(OvPrP-V136)4166/+ and Tg(OvPrP-V136)4166/+ mice without PK treatment. In B–D and F–H, three different brains, indicated by #1–#3 were used as sources of substrates. In each case, the second lane of the second panel contains PK treated SSBP/1. Panels A and E are sPMCA using the indicated templates in the absence of a prion seed. Numbers in black above each lane refer to the round of sPMCA. C refers to a control in which no SSBP/1 seed was added. In each case C, and all numbered lanes were treated with PK. Blots were probed with mAbs 6H4 or PRC5 as indicated.

doi:10.1371/journal.ppat.1003692.g004

Figure 4. Detection of OvPrPSc by sPMCA. In A and E, the first two lanes of each panel correspond to brain extracts from Tg(OvPrP-P-A136)3533/+ and Tg(OvPrP-P-V136)4166/+ mice respectively without PK treatment. A136, V136, and A136/V136 refer to substrates from Tg(OvPrP-P-A136)3533/+ mice, Tg(OvPrP-P-V136)4166/+ mice, and mixtures of the two respectively. In B and F, the first lanes of each panel correspond to brain extracts from Tg(OvPrP-P-A136)3533/+ mice without PK treatment; in C and G, the first lanes of each panel correspond to brain extracts from Tg(OvPrP-V136)4166/+ mice without PK treatment; in D and H, the first lanes of each panel correspond to mixtures of brain extracts from Tg(OvPrP-P-A136)3533/+ and Tg(OvPrP-P-V136)4166/+ mice without PK treatment. In B–D and F–H, three different brains, indicated by #1–#3 were used as sources of substrates. In each case, the second lane of the second panel contains PK treated SSBP/1. Panels A and E are sPMCA using the indicated templates in the absence of a prion seed. Numbers in black above each lane refer to the round of sPMCA. C refers to a control in which no SSBP/1 seed was added. In each case C, and all numbered lanes were treated with PK. Blots were probed with mAbs 6H4 or PRC5 as indicated.

doi:10.1371/journal.ppat.1003692.g004

We then used mAb PRC5 to determine the conformation of OvPrPSc-A136 among total OvPrPSc produced in the brains of diseased Tg(OvPrP-P-A/V136) mice. The 1.64 GdnHCl1/2 value of OvPrPSc-P-A136 produced under these conditions was distinct from that of OvPrPSc-P-A136(S) produced in long incubation time Tg(OvPrP-P-A136)3533/+ mice (GdnHCl1/2 = 2.11), and their non-superimposable PRC5 denaturation curves were significantly different in the range of 1.5–2.5 M GdnHCl (Fig. 2C). These findings demonstrated that the conformation of OvPrPSc-A136 in rapid incubation time Tg(OvPrP-P-A/V) mice was distinct from OvPrPSc-A136(S) produced in long incubation time Tg(OvPrP-P-A136)3533/+ mice. We refer to this novel conformation as OvPrPSc-P-A136(U), and to the resulting prions as SSBP/1-A136(U).

Histoblotting using mAb PRC5 confirmed the comparatively limited and punctate distribution pattern of OvPrPSc-A136(S) in the CNS of long incubation time Tg(OvPrP-P-A136)3533/+ mice (Fig. 3D) that we observed with mAb 6H4 (Fig. 3A). As expected, OvPrPSc-P-V136(U) in the CNS of diseased Tg(OvPrP-P-V136)4166/+ mice was refractory to detection by mAb PRC5 (Fig. 3E). We probed histoblots of the CNS from diseased Tg(OvPrP-P-A/V136) mice with mAb PRC5 to assess the appearance and distribution of OvPrPSc-P-A136(U). In contrast to the punctate deposits of OvPrPSc-P-A136(S) in long incubation time Tg(OvPrP-P-A136)3533/+ mice (Fig. 3A and D), OvPrPSc-P-A136(U) in Tg(OvPrP-P-A/V136) mice (Fig. 3F) acquired a diffuse deposition and a distribution pattern that was equivalent to OvPrPSc-P-V136(U) in Tg(OvPrP-P-V136)4166/+ mice (Fig. 3B). Consistent with the co-expression of each allele in identical cell populations of Tg(OvPrP-P-A/V) mice, spatial distributions of 6H4- and PRC5-reactive PrP coincided in all analyzed sections of Tg(OvPrP-P-A/V) mice (Fig. 3G and H).
PMCA reproduces strain specific effects of one allele product on another

To simulate the combined effects of OvPrP-A136 and OvPrP-V136 on PrP conversion in Tg(OvPrP-A/V136) mice in vitro, we mixed equal quantities of OvPrPC-A136 and OvPrPC-V136 in PMCA reactions seeded with SSBP/1. Under these conditions, similar to when OvPrPC-V136 was present in isolation (Fig. 4C), we observed early, reproducible conversion to OvPrPSc in round one (Fig. 4D). Probing of western blots with mAb PRC5 showed that OvPrPSc-A136 was a component of this converted material (Fig. 4H). Thus, similar to our observations in Tg mice, the presence of OvPrPC-V136 induced the relatively rapid conversion of OvPrPC-A136 to OvPrPSc-A136 by SSBP/1. Interestingly, subsequent conversion of both OvPrPC-A136 and OvPrPC-V136 diminished in rounds two to five, ultimately becoming undetectable through rounds six to 10 (Figs. 4D and H).

SSBP/1 was originally produced from a pool of diseased sheep brains from the positive selection line in the Neuropathogenesis Unit (NPU) Cheviot sheep flock, and has subsequently been passaged as a pool. We next compared the seeding properties of SSBP/1 with those of SSBP/1-A136(S) or SSBP/1-V136(U) prions derived from SSBP/1-infected Tg(OvPrP-A136)3533+/− or Tg(OvPrP-V136)4166+/− mice. We monitored conversion of OvPrPSc-A136 or OvPrPSc-V136 in isolation, but not OvPrPSc-A136. However, unlike
SSBP/1 and SSBP/1-V136(U), such prions failed to facilitate conversion of OvPrP<sup>A</sup>-A136 in the presence of OvPrP<sup>V</sup>-V136 (Fig. 3D).

**Discussion**

**Novel transgenic mouse models for analysis of the OvPrP-A/V136 dimorphism**

Previous studies described the production of Tg mice expressing OvPrP, and reported their susceptibility to scrapie prions [27–32]. The most widely characterized models are tg338 mice expressing OvPrP-V136 [31], and Tg059 [33] or Tg04l [29] lines expressing OvPrP-A136. In the case of tg338 mice, the transgene was comprised of a bacterial artificial chromosome insert of 125 kb of sheep DNA, while in the case of Tg059 and Tg04l mice the neuron specific enolase promoter was used to drive OvPrP expression. These lines are maintained on different heterogeneous genetic backgrounds, and CNS expression levels in tg338 mice are ~8–10-fold higher than wild type, while Tg059 and Tg04l lines each over express OvPrP-ARQ at levels ~2–4-fold higher than those found in sheep brain. Spontaneous neurological dysfunction has been reported in Tg lines over expressing OvPrP [27,31].

Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice express transgene-encoded PrP, either slightly lower, or slightly higher than PrP levels normally expressed in the CNS of wild type mice. Since Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> lines were produced using the cosSHa.Tet cosmid vector which drives expression from the PrP gene promoter [34], we expected expression of OvPrP<sup><small>A</small></sup>-A136 and OvPrP<sup><small>V</small></sup>-V136 in identical neuronal populations, and therefore that both alleles are co-expressed in the same cells of Tg(OvPrP-A/V) mice. Finally, other than variable transgene insertion loci, both lines are otherwise syngeneic on an inbred Prnp<sup>0/0</sup>/FVB background.

Previous studies reported on Tg mice expressing OvPrP with V at 136, referred to as Tg(OvPrP)14882<sup>/+</sup> mice, that were also produced in a Prnp<sup>0/0</sup>/FVB background using the cosSHa.Tet cosmid vector [32]. However, in that study, comparable Tg mice expressing OvPrP-A136 were not reported. Median SSBP/1 scrapie incubation times in Tg(OvPrP)14882<sup>/+</sup> mice were 75 d, and this line expresses OvPrP at levels only slightly higher than Tg(OvPrP-V136)4166<sup>/+</sup> mice. While we exercise caution when comparing results from mice produced by different groups, the otherwise similar properties of Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice suggest that even slight differences in the levels of transgene expression can have significant effects on prion incubation time.

A clear link to codon 136 genotype and susceptibility/resistance to different sheep scrapie isolates has been described in multiple previous studies. Importantly, the influence of residue 136 on the transmission of SSBP/1 and CH1641 prions in Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice is in accordance with the properties of these isolates in sheep of various genotypes [17]. Generally, increased susceptibility to scrapie is associated with expression of OvPrP-V136, with A/A136 being the most resistant, and V/V136 the most susceptible genotypes. In the case of SSBP/1 incubation periods are ~170 days in V/V136 sheep, while transmission to A/A136 sheep is relatively inefficient, with no disease recorded after >1000 days [33]. While SSBP/1 eventually transmits to Tg(OvPrP-A136)5333<sup>/+</sup> mice with incubation times exceeding 400 days, the general effects of the A/V136 dimorphism on SSBP/1 transmission observed in sheep are recapitulated in Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice (Table 1). Similarly, CH1641, which propagates efficiently in A/A136 sheep [35], preferentially propagates in Tg(OvPrP-A136)5333<sup>/+</sup> mice (Table 1). In previous studies, CH1641 transmitted to Tg(OvPrP-V136) mice with an ~250 d mean incubation time [36].

Although SSBP/1 incubation times are prolonged in A/V136 compared to V/V136 sheep [35], in our studies incubation times were shorter in Tg(OvPrP-A/V) than in Tg(OvPrP-V136)4166<sup>/+</sup> mice. While the condition of A/V136 heterozygosity has not been previously modeled in Tg mice, this difference may result from double the levels of transgene expression in Tg(OvPrP-A/V) mice compared to Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice. Tg(OvPrP-A/V) mice were derived by mating Tg(OvPrP-A136)5333<sup>/+</sup> with Tg(OvPrP-V136)4166<sup>/+</sup> mice, and therefore express greater total levels of OvPrP than Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice (Fig. 1A). Since the levels of OvPrP-V136 are equivalent in Tg(OvPrP-V136)4166<sup>/+</sup> and Tg(OvPrP-A/V) mice, and we show that OvPrP-A136 also becomes available for conversion, this situation results in more available substrate for conversion. While previous studies revealed an inverse correlation between transgene expression levels and prion incubation times in Tg mice [8], whether shorter incubation periods in Tg(OvPrP-A/V) mice than in Tg(OvPrP-V136) mice reflect overall differences in PrP<sup>expression</sup> levels remains uncertain. Differences in scrapie pathogenesis between mice and sheep may also reflect the influence of additional factors on disease in the natural host including other PrP<sup>polymorphisms</sup> [37,38], and different involvements of the lymphoreticular system in sheep compared to Tg mice.

**Novel insights into the role of the A/V136 polymorphism on strain selection and prion propagation**

Our observations in Tg mice expressing individual allele products suggested that rapid or prolonged SSBP/1 incubation times in Tg(OvPrP-V136)4166<sup>/+</sup> and Tg(OvPrP-A136)5333<sup>/+</sup> mice respectively, reflected preferential conversion by SSBP/1 prions of OvPrP<sup><small>V</small></sup>-V136, rapidly producing a relatively unstable OvPrP<sup><small>S</small></sup>-V136(U) conformation that was diffusely deposited in the CNS, compared to the slower conversion of OvPrP<sup><small>A</small></sup>-A136 to the more stable OvPrP<sup><small>S</small></sup>-A136(S) conformer which accumulated in the CNS with a punctate pattern (Figs. 1–3). Our results are consistent with the selection by the A/V136 dimorphism of SSBP/1-1(A136(S) and SSBP/1-V136(U) prions in Tg(OvPrP-A136)5333<sup>/+</sup> and Tg(OvPrP-V136)4166<sup>/+</sup> mice respectively. We also show that PMCA recapitulates the influence of the A/V136 polymorphism on the kinetics of SSBP/1 propagation observed in Tg mice. The general conclusions from these studies agree with previously published assessments of the mechanism of conformational selection by distinct PrP primary structures [39,40].

Based on the rapid SSBP/1 incubation times in Tg(OvPrP-A/V136) mice, and shared conformational and distribution properties of OvPrP<sup>S</sup> produced under these conditions with OvPrP<sup><small>S</small></sup>-V136(U) in Tg(OvPrP-V136)4166<sup>/+</sup> mice, we speculated that OvPrP-A136 played no part during the propagation of SSBP/1 prions in Tg(OvPrP-A/V) mice. To address this we used mAb PRC5 to exclusively monitor conversion of OvPrP<sup><small>A</small></sup>-A136. Surprisingly, in contrast to its relatively slow conversion when OvPrP<sup><small>A</small></sup>-A136 is expressed in isolation, co-expression with OvPrP<sup><small>V</small></sup>-V136 in Tg(OvPrP-A/V136) mice facilitated rapid conversion of OvPrP<sup><small>A</small></sup>-A136 to OvPrP<sup><small>S</small></sup>-A136. The conformation and diffuse CNS distribution of the resulting OvPrP<sup><small>S</small></sup>-A136(U) were equivalent to that of OvPrP<sup><small>S</small></sup>-V136(U) and not OvPrP<sup><small>A</small></sup>-A136(S). Collectively, these results lead us to conclude that once
diminishing during rounds two to five, and conversion ultimately produced (Fig. 4C and G), these results are consistent with inhibited OvPrPC-V136 in isolation, failed to convert OvPrPC-A136 to PrPSc with either OvPrP C-V136 or mixtures of OvPrP C-V136 and V136. Expressed in isolation, conversion of OvPrPSc-A136 to OvPrPSc-A136 by PMCA, using PMCA. Similar to our observations in Tg mice, SSBP/1 about the effects of the A/V136 dimorphism of prion propagation was sustained out to round 10 when OvPrP Sc-A136 was not demonstrated by the inability of the OvPrPC-V136(U) conformer to template OvPrPSc-A136 when it is expressed in isolation.

Effects of OvPrP genotype on the propagation of scrapie prions were not controlled during the isolation and propagation of SSBP/1. Passage of SSBP/1 through Tg mice therefore allowed us to generate prions composed solely of OvPrP Sc-A136, OvPrPSc-V136, or mixtures of both, and to draw additional conclusions about the effects of the A/V136 dimorphism of prion propagation using PMCA. Similar to our observations in Tg mice, SSBP/1 failed to convert OvPrPSc-V136 to OvPrPSc-A136 by PMCA, except in the presence of OvPrPSc-V136 (Figs. 4 and 5). These conversion properties are shared with SSBP/1-V136(U) prions, but are distinct from SSBP/1-A136(S) prions, which show facile conversion of both OvPrPSc-V136 and OvPrPSc-A136. These results suggest that the SSBP/1-V136(U) is the dominant strain in the natural SSBP/1 isolate. Multiple parameters could account for this, including, but not restricted to, the effects of OvPrP genotype, for example as a result of exclusive propagation in sheep of the V136/V136 genotype, route of transmission in the infected sheep, and differential/selective prion replication in the lymphoreticular or central nervous systems of sheep. While our analyses indicate the presence of both OvPrP-V136 and OvPrP-A136 alleles in SSBP/1 (Table 1), it is important to note that SSBP/1 was derived from a pool of sheep brains of undefined genotypes. PCR approach precludes assessment of the extent to which alleles are present in a sample, raising the possibility that the one or other allele exists as a minor component in SSBP/1.

Our findings also suggest that PrPSc conformers may cross-inhibit PrP conversion. In case of SSBP/1-A136(S) prions, the presence of OvPrPSc-V136 inhibited PMCA of OvPrPSc-V136 (Fig. 5C). Also, while SSBP/1 seeding of PMCA reactions containing mixtures of OvPrPSc-A136 and OvPrPSc-V136 resulted in robust, reproducible conversion to OvPrPSc-A136 as early as round one (Fig. 4H), total PrPSc production was ephemeral with subsequent PrPSc formation diminishing during rounds two to five, and conversion ultimately becoming undetectable after round six. Since early PrPSc conversion was sustained out to round 10 when OvPrPSc-A136 was not produced (Fig. 4G and H), these results are consistent with inhibited conversion of OvPrPSc-V136 to OvPrPSc-V136 by OvPrPSc-A136. While early (round one) PMCA conversion of PrPSc by SSBP/1 with either OvPrPSc-V136 or mixtures of OvPrPSc-V136 and OvPrPSc-A136 correlates with early onset of disease following SSBP/1 infection of both Tg(OvPrP-V136) and Tg(OvPrP-A/V136) mice, the subsequent inhibitory effects of OvPrPSc-A136 observed in PMCA would be impossible to detect in vivo, since Tg(OvPrP-A/V) mice succumb to the lethal effects of early PrPSc accumulation. Consistent with an inhibitory effect of OvPrPSc-A136(U), prions from Tg(OvPrP-A/V) mice, while they converted OvPrPSc-V136 in isolation, failed to convert OvPrPSc-A136 to PrPSc in the presence of OvPrPSc-V136 (Fig. 3D). Thus, the properties of prions from this defined genetic background differ from SSBP/1. We emphasize that, despite PCR data supporting the presence of OvPrP-A136 alleles in this isolate, SSBP/1 was derived from sheep of undefined OvPrP genotypes, rather than sheep with a defined heterozygous OvPrP-F/A-V136 genotype.

Wider implications for the mechanism of prion propagation

The inter-related effects of PrP primary and higher order structures on prion transmission were addressed in the Conformational Selection Model, which proposed that strains are composed of a range of PrPSc conformers, or quasi-species, and that only a subset of PrPSc conformations is compatible with each PrP primary structure [41]. While this model also took into account the effects of polymorphic variation on prion propagation, it did so only in the context of Tg mice expressing individual PrP allele products. Transgenic studies of the human codon 129 methionine (M)/valine (V) polymorphism, and the analogous codon 132 M/leucine (L) polymorphism in elk, indicated that these dimorphisms acted to restrict or promote the propagation of particular prion strains [39,40]. While the responses of Tg(OvPrP-A136/3333+/− and Tg(OvPrP-V136/4166+/−) mice are consistent with this notion, that is selection of the U conformer by OvPrP-V136, and the S conformer by OvPrP-A136, our unprecedented ability to analyze allele specific conversion in infected Tg(OvPrP-A/’A136) mice reveals a more complex mechanism where mixtures of PrP variants may assist or inhibit the propagation of strains under various conditions. For example, SSBP/1 or SSBP/1-V136(U) prions facilitate conversion of OvPrPSc-C136 to OvPrPSc-A136(U) only in the presence of OvPrPSc-V136. Expressed in isolation, conversion of OvPrPSc-A136 is favored by the OvPrPSc(S) conformer. Our results demonstrate that co-expression of different polymorphic forms of PrP, which would be the norm in humans and animals, have profound effects on conformational selection of prion strains.

The results reported here address the molecular mechanisms associated with the phenomenon of prion strain over-dominance first observed by Dickinson and Outram [42], and subsequently reported in other settings involving co-expression of long and short incubation time PrP alleles [43]. While this phenomenon was reconciled at the time by the assumption that TSEs were caused by unidentified viral agents, our results now indicate that the suggestion raised by those studies, namely that over-dominance most likely resulted from physical interaction of allele products of the scrapie incubation time locus during infection, was prescient. Our results support a molecular mechanism involving cross-templating of an otherwise resistant allele product by a dominant prion conformer, in this case OvPrPSc(U), which, we speculate, involves physical association of otherwise “susceptible” and “resistant” allele products. Consistent with the observations reported here, prion strain interference may also utilize similar mechanisms of conformational selection in a host expressing different PrP allele products infected with long and short incubation period strains with different PrPSc conformational stabilities [44,45].

In conclusion, we have used a combination of transgenic, immunologic, and in vitro approaches to explore the mechanism by which PrP primary structure variations and the conformations enciphered by different prion strains interact to control TSE propagation. While our results support previous studies indicating that PrP susceptibility polymorphisms, expressed in isolation, act to restrict or promote the propagation of particular prion conformers, we now show that under conditions of allele co-expression a dominant conformer may alter the conversion potential of an otherwise resistant PrP polymorphic variant to an unfavorable prion strain. While such responses are analogous to the phenotypic expression of genetically determined heritable traits, dominant prion conformers act epigenetically by means of protein-mediated conformational templating. By expanding the range of possible conformations adoptable by a particular prion protein primary structure, such interactive effects provide a mechanism for promoting strain fitness, and, we speculate, strain diversification. While the precise number scrapie strains in sheep and goats remains uncertain, the description of at least 24 additional major sheep PrP polymorphisms, and combinations

Epigenetic Dominance of Prion Conformers

Materials and Methods

Ethics statement
All animal work was conducted according to the National Institutes of Health guidelines for housing and care of laboratory animals, and performed under protocols approved by the Colorado State University Institutional Animal Care and Use Committee, with approval number 11-2996A.

Transgenic mice
Sequences upstream of codon 44 of the OvPrP-A136 and V136 coding sequences were replaced with the corresponding sequence from mouse PrP. The resulting constructs contained the OvPrP coding sequence, except for addition of an extra residue for glycine at codon 31, and the mouse PrP N-terminal signal peptide instead of OvPrP signal peptide. Tg mice were generated by cloning the OvPrP-A136 and OvPrP-V136 expression constructs into the cosHIa.Tet cosmid vector [34], and microinjection of embryos from inbred Prnp<sup>0/0/129Ola</sup> background [46].

Inocula
SSBP/1 originated as a homogenate of three natural scrapie brains that were subsequently passaged mostly through Cheviot sheep at the Neuropathogenesis Unit (NPU), Edinburgh UK [15,16]. CH1641 is a naturally infected cheviot sheep from the CH1 flock [17]. The presence of OvPrP-A136 or OvPrP-V136 was ascertained by restriction fragment length polymorphism analysis of the PCR amplified PRNP coding sequences.

Conformational stability assay
Brain homogenates containing 5 µg protein were incubated with various concentrations of guanidine hydrochloride (GdnHCl) in 96-well plates for 1 h at room temperature. Samples were adjusted with PBS to a final concentration of 0.5 M GdnHCl, pH 8.0, 2 mM EDTA, pH 8.0, and 2% SDS at 55°C overnight. Genomic DNA was precipitated with isopropanol. The partial OvPrP coding sequence was amplified by PCR with the forward and reverse primers: 5’-GGACAGGGGCAGTCCTGGAA-3’, 5’-GTGATGCACTTTGCTGACACACT-3’. PCR products were purified with QiAquick Gel Extraction kit (QIAGEN Science, MA, USA), digested with BspH I that only recognizes the OvPrP-V136 allele, and the products were resolved on a 1.2% agarose gel.

Protein misfolding cyclic amplification
Tg mice were perfused with PBS/5 mM EDTA. Ten % brain homogenates (w/v) were prepared in PBS containing 150 mM NaCl, 1.0% Triton X-100, and the complete TM cocktail of protease inhibitors (Roche, Mannheim, Germany). Samples were clarified by brief, low-speed centrifugation. Protein concentrations of brain homogenates used as substrates for PMCA were adjusted to contain equivalent amounts of OvPrP-A136 or OvPrP-V136, based on the estimated relative levels of transgene expression. Substrates in which OvPrP-A136 and OvPrP-V136 were mixed were adjusted based on the estimated relative levels of transgene expression, so that approximately equal amounts of each allele product were present in the PMCA reaction. PMCA reactions were performed as described previously [20,47] at a seed to substrate ratio of 1:100. One cycle corresponded to 20 seconds of sonication followed by 30 minutes incubation at 37°C. Controls samples were incubated for the same duration at 37°C without sonication. Amplified and control samples were digested with PK at a final concentration of 0.33 µg/µl and analyzed on western blots using mAbs 6H4 or PRC5.

Determination of incubation times
Anesthetized mice were inoculated intracerebrally with 30 µl of 1% (w/v) brain extracts prepared and diluted in PBS. General health was monitored daily. Onset of prion disease was determined by observation of the progressive development of at least three of the following clinical signs: truncal ataxia, loss of extensor reflex, difficulty righting from a supine position, plastic tail, head bobbing or tilting, kyphotic posture, circling and paresis/paralysis. Animals were diagnosed when at least two investigators agreed with the manifestation of these signs. Incubation time is defined as the period between the time of inoculation to the day on which subsequently progressive clinical signs were initially recorded.

Analyses of PCR amplified PRNP coding sequences
Brain homogenates containing 500 µg protein were digested with 400 µg/ml proteinase K (PK) in 0.4 M NaCl, 10 mM Tris–HCl, pH 8.0, 2 mM EDTA, pH 8.0, and 2% SDS at 55°C overnight. Genomic DNA was precipitated with isopropanol. The partial OvPrP coding sequence was amplified by PCR with the forward and reverse primers: 5’-GGACAGGGGCAGTCCTGGAA-3’, 5’-GTGATGCACTTTGCTGACACACT-3’. PCR products were purified with QiAquick Gel Extraction kit (QIAGEN Science, MA, USA), digested with BspH I that only recognizes the OvPrP-V136 allele, and the products were resolved on a 1.2% agarose gel.

Samples were adjusted with PBS to a final concentration of 0.5 M GdnHCl, pH 8.0, 150 mM NaCl, 0.5% sodium deoxycholate, 0.5% Igepal CA-630 for 1 h at 37°C. PK was
inactivated with 2 mM PMSF. The membrane was incubated in 3 M guanidine thiocyanate in Tris-HCl, pH 7.8 for 10 min at room temperature. After four washes with PBS, the membrane was blocked with 5% nonfat milk in TBST for 1 h, and probed with mAbs 6H4 (1:20,000) or PRC5 (1:5,000) overnight at 4°C, followed by HRP-conjugated IgG secondary antibody. The membrane was developed with ECL Plus and scanned with GE image quant 4000. The signal was analyzed with ImageQuant TL 7.0 software.

**Histoblotting**

Histoblots were produced and analyzed according to previously described protocols [23]. Images were captured with a NikonDMDX 1200F digital camera in conjunction with Metamorph software (Molecular Devices).
