Interferon Treatment for Chronic Hepatitis C Infection in Hemophiliacs—
Influence of Virus Load, Genotype, and Liver Pathology on Response

By John P. Hanley, Lisa M. Jarvis, Janet Andrews, Rosemary Dennis, Peter C. Hayes, Juan Piris, Robert Lee, Peter Simmonds, and Christopher A. Ludlam

In this study, we assessed the effectiveness of interferon treatment in 31 hemophiliacs with chronic hepatitis C virus (HCV) infection. Interferon alfa-2a (3 MU three times weekly) was administered for 6 months. Response was assessed by both serial alanine transaminase (ALT) levels, clearance of viremia by polymerase chain reaction (PCR), and HCV RNA levels measured by a sensitive semiquantitative polymerase chain reaction (PCR) method. HCV genotype was determined by restriction fragment length polymorphism (RFLP), and evidence of changing genotypes during interferon therapy was sought. Severity of liver disease was assessed by both noninvasive and invasive methods, including laparoscopic liver inspection and biopsy. Sustained normalization of ALT levels occurred in eight patients (28%), and seven (24%) became nonviremic as assessed by PCR (<80 HCV/mL). Responders universally cleared HCV RNA within 2 months of starting interferon. Genotype 3a was associated with a favorable response to interferon. No evidence was found for a change in circulating genotype in patients who failed to respond to interferon or who relapsed. This study confirms that response rates to interferon are low in hemophiliacs as compared with other groups with chronic HCV infection. We have also demonstrated that virus load measurement over the first 8 to 12 weeks of treatment is an extremely useful method to identify responders at an early stage.

ALMOST ALL HEMOPHILIACS who received clotting factor concentrates before the introduction of effective viral-inactivation techniques were infected with hepatitis C virus (HCV). The majority of individuals exposed to the virus have become chronic carriers, characterized by both persistent fluctuating viremia and variable abnormalities in liver function tests. There is a wide spectrum of liver disease in these patients, ranging from only minor histologic evidence of chronic hepatitis to cirrhosis and hepatocellular carcinoma.

Interferon has been used to treat chronic HCV in both nonhemophiliacs and hemophiliacs. Response to treatment has been assessed by serial serum alanine transaminase (ALT) levels, clearance of viremia by polymerase chain reaction (PCR), and direct assessment of liver histology. Clearance of viremia is likely to be a prerequisite for a long-term response rather than normalization of ALT. To date, there have only been a few small studies on the efficacy of interferon in hemophiliacs. Some of these studies have suggested that the response to interferon in hemophiliacs may be lower with chronic HCV infection. We have monitored response to interferon using a sensitive semiquantitative PCR to detect HCV RNA. In addition, we have assessed the extent of liver disease in these patients using both invasive and noninvasive methods, and have critically evaluated whether these investigations are useful in predicting the response to interferon.

PATIENTS AND METHODS

Patient characteristics. A total of 31 patients (30 male and one female) were treated (Table 1). All patients were anti-HCV–positive by Abbott second-generation enzyme immunoassay (A-EIA; Abbott, Westbaden-Dalkenheim, Germany) and were also positive on confirmatory testing by second-generation recombinant immunoblot assay (RIBA-2; Chiron Corp, Emeryville, CA) for antibody to nonstructural proteins 5-1-1 (NS4), c100-3 (NS4), c33c (NS3), and core-associated antigen c22-3.

All had previously received non–virus-inactivating factor concentrates, and 30 of 31 had persistently elevated serum ALT levels (ALT levels were measured on ≥3 occasions over the 6 months before treatment). Serum ALT level was normal in one individual. HCV RNA was detected in all patients by PCR as described below. Six patients were anti-HIV–positive (pretreatment CD4 counts, 4, 20, 140, 180, 250, and 360 cells/mm3, respectively), and all were HBSAg-negative. In addition, all patients were negative for antismooth muscle and antimitochondrial antibody and had normal levels of a-fetoprotein, ceruloplasmin, and α1-antitrypsin.

Pretreatment assessment. Informed consent was obtained from all patients participating in the study. Before starting interferon treatment, a detailed assessment was undertaken of the extent of liver disease in each patient, with particular reference to the presence or absence of cirrhosis, using both noninvasive and invasive methods. The role of invasive investigations in the assessment of liver disease was discussed with all patients. Those with anti-FVIII or anti-FIX inhibitors were not offered invasive investigations, and individuals with von Willebrands disease were not offered liver biopsy. It was emphasized that the investigations were not essential for administration of interferon but would provide information to counsel the individual as to the extent of liver disease.

The following investigations were performed after appropriate factor concentrate replacement. (1) Upper gastrointestinal endoscopy was performed in 27 patients to identify the presence or absence of esophageal varices. (2) Laparoscopy was performed under sedation using a 5-mm pediatric laparoscope (Olympus, Tokyo, Japan) or microlaparoscope (Imagyin, Laguna Niguel, CA) in 21 patients. The degree of hepatic inflammation (none, mild, or marked), degree of surface fibrosis (none, moderate, or pronounced), and presence of cirrhosis and portal hypertension were assessed. In 15 patients, a trunci biopsy was taken during the laparoscopy, and histology was assessed using both the Sheffield scoring system (data not

starting interferon and after 3 and 6 months' therapy. To increase sensitivity of the PCR method, samples were formed using serum samples separated within 3 hours of collection and stored at -70°C. Virus RNA was extracted from 0.5 mL, virus to be undetectable in the serum, ie, PCR-negative (NR). Seven of 29 (24%) became PCR-negative for HCV RNA (CR). In addition two of 29 (7%) achieved at least a 102-copies/mL reduction in HCV RNA (PR). In 20 of 29 (69%), serum HCV RNA levels were unchanged (NR).

There was a statistically significant difference in age between responders (mean age, 46 years) and NR (mean age, 33 years; two-sample t-test, \( P = .044 \)). However, multivariate analysis showed no independent relationship between age and response after adjusting for the effect of genotype on response (see below).

Response was not associated with HIV status, body weight, severity of hemophilia, duration of infection, annual factor concentrate consumption, serum ferritin, or serum IgS (data not shown).

Patterns of ALT and HCV RNA responses. Normalization of ALT levels correlated with clearance of viremia as measured by PCR (Spearman rank correlation, \( r = .53, P = .003 \); Table 2). Of eight patients who had a normalized ALT, five also became HCV RNA-negative, whereas in three there was no corresponding reduction in virus load. Of four patients who achieved a partial reduction in ALT, only one became nonviremic. Fifteen of 17 in whom ALT level was unchanged also had no change in virus load. Only one individual who had no change in ALT became nonviremic. Median ALT values in patients who became nonviremic versus those who failed to clear HCV RNA are shown in Fig 1. In one patient only, there was a transient HCV RNA clearance at 2 months, but at 3 months the HCV RNA titer returned to the pretreatment level of \( 10^7 \) HCV/mL. This was associ-

We have shown that the response to interferon therapy in hemophiliacs with chronic HCV infection is poor and appears inferior to that of other groups of infected patients. In this study, only 28% had a normalized serum ALT after 6 months' treatment with interferon, and 24% became PCR-negative for HCV RNA. Furthermore, sustained responses were uncommon. This compares with initial ALT CR of 50% and sustained responses of 20% to 25% reported in nonhemophiliacs. Early investigators used ALT to assess response. More recent studies have confirmed that clearance of HCV RNA is a prerequisite for long-term response. The importance of HCV quantitation has been increasingly recognized. We describe herein a sensitive semiquantitative PCR method for HCV RNA detection with a lower sensitivity threshold.

Severity of liver disease was assessed by methods outlined earlier. Of 28 abdominal ultrasound scans evaluated, five (18%) demonstrated splenomegaly and seven (25%) showed an abnormal liver (five with hepatomegaly and two with an abnormal liver texture). In seven of 25 (28%), esophageal varices were demonstrated at endoscopy. Of 20 laparoscopic liver inspections, 10 (50%), four (20%), and six (30%) showed none, mild, or pronounced surface fibrosis, respectively, with five patients with pronounced fibrosis having cirrhosis. Inflammation was identified laparoscopically in all patients, being mild in 14 (70%) and marked in six (30%). Evidence of portal hypertension was visible in five (25%). Liver histology was evaluated in 14 patients and showed mild, moderate, and severe (including cirrhosis) histologic changes in four (29%), seven (50%), and three (21%), respectively.

Analysis of response to interferon against laparoscopic liver appearance, liver histology, presence/absence of hepatomegaly, splenomegaly, and esophageal varices showed no evidence that any of these variables were associated with response to interferon.

Follow-up information. Within 3 months of discontinuing interferon, five of seven patients who became nonviremic have relapsed, with reappearance of serum HCV RNA and elevated ALT levels. In two patients who achieved a partial reduction in virus load, HCV RNA levels returned to pretreatment values within 1 month of stopping interferon. Only two patients remain HCV RNA–negative with normal ALT. The three patients who showed normalized ALT levels without a corresponding reduction in HCV RNA developed elevated ALT levels within 2 months of stopping interferon.

**DISCUSSION**

We have shown that the response to interferon therapy in hemophiliacs with chronic HCV infection is poor and appears inferior to that of other groups of infected patients. In this study, only 28% had a normalized serum ALT after 6 months' treatment with interferon, and 24% became PCR-negative for HCV RNA. Furthermore, sustained responses were uncommon. This compares with initial ALT CR of 50% and sustained responses of 20% to 25% reported in nonhemophiliacs. Early investigators used ALT to assess long-term response. More recent studies have confirmed that clearance of HCV RNA is a prerequisite for long-term response.

The importance of HCV quantitation has been increasingly recognized. We describe herein a sensitive semiquantitative PCR method for HCV RNA detection with a lower sensitivity threshold.
Fig 3. Rate of virus clearance in HCV RNA responders (n = 7). In 6 of 7 patients who became nonviremic, there was a prompt reduction in HCV RNA to < the limit of detection within 8 weeks of commencing interferon. In one individual (patient no. 2), initial clearance of HCV RNA at week 4 was followed by a transient increase in virus titer to $10^4$ copies/mL at weeks 8 and 12, before sustained clearance between weeks 16 and 24.

The limit of detection of 80 HCV/mL. This compares with $3.5 \times 10^5$ equivalents/mL when the branched DNA (bDNA) assay is used. Using bDNA, we would have failed to detect viremia in four (13%) of our patients and incorrectly classified six (20%) as responders who merely showed a partial reduction in HCV RNA levels. Clearly, sensitive quantitative assays are essential to monitor response to treatment, and some studies may have overestimated response rates by using relatively insensitive methods for RNA quantitation. We found that HCV RNA was cleared within 8 weeks of starting interferon in seven patients who responded. Using this method, it would therefore be possible to differentiate responders from nonresponders at an early stage of treatment and discontinue interferon in nonresponders. Alternatively, these individuals could be offered a dose-escalation, although there are few data available in hemophiliacs concern-

reasons for this are not entirely clear. Temporary noncompli-
genotype (Kruskal-Wallis test, \( P = .77 \)). (C) subtype a; (E) subtype b.
There is usually a good correlation between normalization
ALT and HCV RNA clearance in responders to interferon.
However, discrepancies between ALT and HCV RNA re-
sponses have been described previously.\(^2\) We have identi-
some individuals who achieved a biochemical response
without a corresponding reduction in virus load. Clearly,
these patients are not true responders, and biochemical re-
lapse is inevitable once interferon is discontinued. Since
ALT is not an entirely accurate measure of response, studies
using ALT alone to assess response may also overestimate
true responders. Interestingly, there was one individual who
cleared HCV RNA without an associated ALT response.
This raised the possibility of other non-HCV coexisting liver
pathology resistant to interferon treatment, but none has been
identified. Another individual relapsed during interferon
therapy. Such episodes of "breakthrough hepatitis" are well
recognized and may be associated with the development of
neutralizing antibodies to interferon.\(^2\) A change in HCV
genotype may also be an explanation for breakthrough hepatis-
tis, and a change in the dominant genotype in hemophiliacs
with interferon has been reported.\(^3\) In this study, we
did not detect any changes in the circulating genotype in
any patients during interferon therapy. However, it is recog-
nized that the RFLP method will not detect co-infecting
genotypes circulating at low frequencies. In addition, inter-
feron NR may be associated with a change in variants of the
same genotype (termed quasi-species). Analysis of variants
within an individual before and after interferon treatment is
in progress.

Several studies assessing response to interferon have been
performed on cohorts of hemophiliacs infected with HCV.\(^5^9\)
Some of these studies have suggested that the overall initial
response rates are somewhat lower in hemophiliacs than in
other groups with HCV. Interestingly, response rates in the
earlier studies are superior to those performed more recently.
This may be a reflection of the relatively small number of
patients studied, or may have been caused by progression of
liver disease in cohorts of hemophiliacs, leading to dimin-
ished responses to interferon. In addition, although the data
available provide conflicting results, long-term response ap-
pears unusual. In the largest study,\(^9\) only one of 20 (5%) achieved a sustained response to interferon. In the only trial
that assessed response by liver biopsy,\(^2\) four of seven re-
sponders had a long-term response. Our study, which con-
tains the largest treated group of hemophiliacs with HCV
reported to date, supports the view that long-term responses
to interferon are uncommon in hemophiliacs. Sustained re-
response rates may be improved by longer courses of inter-
feron.

Attempts have been made to identify factors that may predict response to interferon.\(^9\) Absence of cirrhosis,
younger age, low serum HCV RNA level, and genotypes 2
and 3 are all factors associated with a favorable response
to interferon. As yet, the presence of adverse factors has not
been considered sufficient to absolutely exclude some indi-
viduals with HCV from interferon therapy. There has been
particular concern, in view of the generally poor response
to interferon in hemophiliacs, that treatment with interferon
is inappropriate in the majority of individuals. Not only are
patients exposed to a potentially toxic drug with unpleasant
side effects, but the cost of a course of interferon is consid-
erable.

We have tried to identify parameters that may predict response to interferon in hemophiliacs with HCV. Assess-
ment of liver disease has included both invasive and noninva-
sive methods. We have shown that genotype 3a is associated
with a favorable response, but we failed to identify any other
statistically significant independent variables, including pre-
treatment virus load, associated with a poor response to inter-
feron. In view of this, despite the apparent poor response
to interferon in hemophiliacs, it is not possible to predict
accurately which individuals are likely to respond.

In conclusion, the results of interferon treatment for HCV
in hemophiliacs are disappointing. Interferon alfa-2a 3 MU
three times per week for 6 months is unlikely to result in a long-term sustained response. Monitoring response with a sensitive semi-quantitative PCR to quantify HCV RNA is extremely useful to identify responders at an early stage of treatment. Those who fail to clear HCV RNA should discontinue interferon. Dose-escalation is unlikely to benefit many patients, but may be attempted in selected individuals.
