Abstract
The multidimensional, heterogeneous, and temporal nature of speech databases raises interesting challenges for representation and query. Recently, annotation graphs have been proposed as a general-purpose representational framework for speech databases. Typical queries on annotation graphs require path expressions similar to those used in semistructured query languages. However, the underlying model is rather different from the customary graph models for semistructured data: the graph is acyclic and unrooted, and both temporal and inclusion relationships are important. We develop a query language and describe optimization techniques for an underlying relational representation.

1. Introduction
In recent years, annotated speech databases have grown tremendously in size and complexity. In order to maintain or access the data, one invariably has to write special purpose programs. With the introduction of a general purpose data model, the annotation graph (Bird and Liberman, 1999), it is possible to abstract away from idiosyncrasies of physical format. However, this does not magically solve the maintenance and access problems. In this paper, we contend that some form of query language is essential for annotation graphs, and we report our research on such a language.

Query languages for databases have two, sometimes conflicting, purposes. First they should express – as naturally as possible – a large number of data extraction and restructuring tasks. Second, they should be optimizable. This means that they should be based on a few efficiently implemented primitives; they should also make it easy to discover optimization strategies that may involve query rewriting, execution planning and indexing. The relational algebra and its practical embodiment, SQL, are examples of such languages, however they are unsuitable for annotation graphs first because it is difficult (or impossible – depending on the version of SQL) to express many practical queries, and second because the optimizations that are necessary for annotation graph queries are not in the repertoire of standard relational query optimizations.

The recent development of query languages for semistructured data (Buneman et al., 1996; Quass et al., 1995; Deutsch et al., 1998) offer more natural forms of expression for annotation graphs. In particular, these languages support regular path patterns – regular expressions on the labels in the graph – to control the matching of variables in the query to vertices or edges in the graph. While regular path patterns are useful, the usual model of semistructured data, that of a labeled tree, is not appropriate for annotation graphs. In particular, it fails to capture the quasi-linear structure of these graphs, which is essential in query optimization.

After reviewing some existing languages for linguistic annotations, we present the annotation graph model, its relational representation, and some relational queries on annotation graphs. Then we develop a new query language for annotation graphs that allows complex pattern matching. It is loosely based on semistructured query languages, but the syntax simplifies the problem of finding regions of the data that bound the search. Finally, we describe an optimization method that exploits the quasi-linear structure of annotation graphs.

2. Query Languages for Annotated Speech
If linguistic annotations could be modeled as simple hierarchies, then existing query languages for structured text would apply (Clarke et al., 1995; Sacks-Davis et al., 1997). However, it is possible to have independent annotations of the same signal (speech or text) which chunk the data differently. As a simple example, the division of a text into sentences is usually incommensurable with its division into lines. Such structures cannot be represented using nested, balanced tags.

The fundamental problem faced by any general purpose query language for linguistic annotations is the navigation of these multiple intersecting hierarchies. In this section we consider two query languages which address this issue.

2.1. The Emu query language
The Emu speech database system [www.shlrc.mq.edu.au/emu] (Cassidy and Harrington, 1996; Cassidy and Harrington, 1999) provides tools for creation and analysis of data from annotated speech databases. Emu annotations are arranged into levels (e.g. phoneme, syllable, word), and levels are organized into hierarchies. Emu supports multiple independent hierarchies, such that any specific level may participate in more than one orthogonal structure. An example is shown in Figure 1 (Cassidy and Bird, 2000).

A database of such annotations can be searched using the Emu query language. The language has primitives for sequence, hierarchy and “association”, as illustrated below.

[Phonetic=a|e|i|o|u] – matches a disjunction of items on the phonetic level

[Phonetic=vowel -> Phonetic=stop] – matches a sequence of vowel followed immediately by stop.

[Word!=dark ˆ Phoneme=vowel] matches a word not labelled dark immediately dominating vowel.
[\text{Word!} \neq x \Rightarrow \text{Tone} = H^*] \text{ Find any word associated}^1 \text{ with a } H^* \text{ tone }

Note that the language lacks a wildcard, and \text{Word!} \neq x serves this purpose in the absence of any actual word x.

More complex queries are built up using nesting. There is no (non-atomic) disjunction or negation in the language. An example of a nested query follows; here, the query finds any syllable dominating a stop that precedes a vowel which is associated to a high tone.

\begin{verbatim}
[\text{Syllable=S} \quad
\text{[Phonetic=stop} \Rightarrow
\text{[Phonetic=vowel} \Rightarrow \text{Tone} = H^*]]
\end{verbatim}

Cassidy has shown how expressions of this query language can be translated into a first-order query language, in this case, SQL (Cassidy, 1999).

In the Emu query language, the dominance relation is symmetric. (A separate type hierarchy is used to order the levels.) This property makes it possible to navigate a path through multiple hierarchies without using variables. For example, The following expression finds an NP which dominates a word dark that is dominated by an intermediate phrase that bears an L- tone.\textsuperscript{2}

\begin{verbatim}
[ \text{syntax=NP} \quad \text{[ word=dark } \text{ intermediate=L- ]}]
\end{verbatim}

These expressions correspond to the “where” clause of a conventional query language. The Emu query language lacks an explicit “select” clause. Rather the selected material is the left-most element of the where clause, by default, or else the single element distinguished with a hash prefix. The query result is a column of these elements, and this is typically processed with an external statistics package.

\subsection*{2.2. The MATE query language}

The MATE project is developing standards and tools for annotating spoken dialogue corpora [mate.nis.sdu.dk]. Like Emu, MATE supports intersecting hierarchies; Figure 2 illustrates four hierarchies built over the same dialogue transcript (Carletta and Isard, 1999). These hierarchies happen to intersect at their fringe, however this need not be the case.

\footnote{This “association” can have either a temporal interpretation as overlap (Bird and Klein, 1990) and an atemporal interpretation as some essentially arbitrary binary relation; both interpretations are encompassed by our model.}

\footnote{We are grateful to Steve Cassidy for providing this example.}

MATE uses XML to represent these structures. Each node in Figure 2 corresponds to an XML element, and the node labels correspond to an attribute of the element or its content. For example, swamp could be represented as \texttt{<word id="A6" num="sing">swamp</word>}, and np could be represented as \texttt{<phrase type="np"/>}. In the query language (Mengel et al., 1999), we can pick out these elements with the following expressions:

\begin{verbatim}
{\$w word}; \$w.orth = "swamp"
{\$p phrase}; \$p.type = "np"
\end{verbatim}

Hierarchical relationships, like the one between game and move or between move and swamp, are represented using nesting of XML elements or by hyperlinks. The query language has a transitive dominance relation \textasciitilde which navigates down through nested structures and hyperlinks. For example, we can find noun phrases dominating the word “swamp” with the expression:

\begin{verbatim}
{\$p phrase}; {\$w word};
{\$p.type = "np"}
& & {\$w.orth = "swamp"}
& & {\$w = $w}
\end{verbatim}

Each element spans an extent of textual material, and the query language supports a variety of temporal comparisons on these extents, reminiscent of Allen’s temporal relations (Allen, 1983). So long as two hierarchies intersect at their terminals (and not at non-terminals) then their non-terminals will be comparable using these temporal expressions.

However, the language directly supports queries on intersecting hierarchies. For example, we can find a word which is simultaneously a repair and a preposition, where \textasciitilde is the immediate dominance relation.\textsuperscript{3}

\begin{verbatim}
{\$w word} \texttt{($ph phrase) \texttt{($r repair)}} \texttt{($d disfluency);}
\texttt{($r 1\texttt{ "$w$)}} & & \texttt{($p type = "prep") \texttt{($d 1\texttt{ "$r$)}}}
\end{verbatim}

Unlike the Emu query language, the formal and computational properties of the MATE query language, vis-à-vis relational and semistructured query languages, are unexplored.

This concludes our brief survey of query languages for annotated speech. Other query languages exist; these two were chosen because of their interesting approach to the problem of intersecting hierarchies.

\footnote{We thank David McKelvie for furnishing this example.}
3. Annotation Graphs

Annotation Graphs were presented by Bird and Liberman as follows. Here we consider just the so-called “anchored” variety.

**Definition 1** An anchored annotation graph \( G \) over a label set \( L \) and timelines \( \{T_i, \leq_i\} \) is a 3-tuple \( \langle N, A, \tau \rangle \) consisting of a node set \( N \), a collection of arcs \( A \) labeled with elements of \( L \), and a time function \( \tau: N \rightarrow \bigcup T_i \), which satisfies the following conditions:

1. \( \langle N, A \rangle \) is a labeled acyclic digraph containing no nodes of degree zero;
2. for any path from node \( n_1 \) to \( n_2 \) in \( A \), if \( \tau(n_1) \) and \( \tau(n_2) \) are defined, then there is a timeline \( i \) such that \( \tau(n_1) \leq_i \tau(n_2) \);
3. If any node \( n \) does not have both incoming and outgoing arcs, then \( \tau: n \rightarrow t \) for some time \( t \).

Note that annotation graphs may be disconnected or empty, and that they must not have orphan nodes. It follows from the above definition that every node has two bounding times, and we will make use of this property later. It also follows from the definition that timelines partition the node set.

The formalism can be illustrated with an application to a simple speech database, the TIMIT corpus of read speech (Garofolo et al., 1986). This database contains recordings of 630 speakers of 8 major dialects of American English, each reading 10 phonetically rich sentences [www.ldc.upenn.edu/Catalog/LDC93S1.html]. Figure 3 shows part of the annotation of one of the sentences. The file on the left contains word transcription, and the file on the right contains phonetic transcription. Part of the corresponding annotation graph is shown underneath. Each node displays the node identifier and the time offset (in 16kHz sample numbers). The arcs are decorated with type and label information. The type \( W \) is for words and the type \( P \) is for phonetic transcriptions.

Observe that all the nodes in Figure 3 have time values. This need not be the case. For example, in the CALL-HOME telephone speech corpus [www.ldc.upenn.edu/Catalog/LDC96S46.html], times are only available for speaker-turn boundaries (see Figure 4).

### 4. Some Example Queries

Interesting cases for query are those that involve more than one of these primitives. Here are some simple queries to select subsets of the data.

1. Find word arcs whose phonetic transcription contains a ‘d’ and ends with a ‘k’.
2. Find phonetic arcs which immediately precede a vowel that overlaps a high tone.
3. Find words dominating a vowel which overlaps a high tone.

These queries can be interpreted against the fragment shown in Figure 7.

Such queries have a first-order interpretation in graphlog (Consens and Mendelzon, 1990). We employ a datalog syntax and the relations in Figure 5. We begin by defining some auxiliary relations.

First we define a path relation that is sensitive to arc types. Two nodes \( X \) and \( Y \) are connected by a path of type \( \tau \) if there is a sequence of zero or more arcs, all of type \( \tau \), beginning at \( X \) and ending at \( Y \).

\[
\begin{align*}
\text{path}(X, X, T) & : - \text{arc}(X, X, T) \\
\text{path}(X, X, T) & : - \text{arc}(X, Y, T), \text{path}(Y, Y, T) \\
\text{path}(X, Y, T) & : - \text{arc}(X, Y, T), \text{path}(Y, Y, T) \\
\end{align*}
\]

An arc \( A \) “structurally includes” an arc \( B \) if there is a path from the start node of \( A \) to the start node of \( B \), and a path from the end node of \( B \) to the end node of \( A \).

\[
\begin{align*}
\text{incl}(A, B) & : - \text{arc}(A, X_1, Y_1, _1), \\
& \text{arc}(B, X_2, Y_2, _2), \\
& \text{path}(X_1, X_2, _1), \\
& \text{path}(Y_2, Y_1, _1) \\
\end{align*}
\]

Finally, an arc \( A \) “temporally overlaps” an arc \( B \) if the start node of \( A \) precedes the end node of \( B \), and the start node of \( B \) precedes the end node of \( A \). (See section 6. for details of the precedence relation.)

![Figure 7: An Annotation Graph Fragment](image-url)
A: He was changing projects every couple of weeks and he said he couldn’t keep on top of it. He couldn’t learn the whole new area that fast each time.

B: %mm.

A: %um, and he says he went in and had some tests, and he was diagnosed as having attention deficit disorder. Which you know, given how he's how far he's gotten, you know, he got his degree at Tufts and all, I found that surprising that for the first time as an adult they’re diagnosing this. %um I wonder about it. But anyway.

B: Yeah.

A: Yeah. Whatever's helpful.

B: Right. So he found this new job as a financial consultant and seems to be happy with that.

Figure 4: CALLHOME Telephone Speech Data and Graph Structure

Figure 5: The Arc, Time and Label Relations

Figure 6: Annotation Graph for Extended TIMIT Example
Now we can provide translations for the three queries listed above.

1. Find word arcs whose phonetic transcription contains a ‘d’ and ends with a ‘k’. We assume a relation path/3 which is the transitive closure of arc/4.

\[ \text{ans}(A) \leftarrow \text{arc}(A, X, Y, \text{word}), \]
\[ \text{path}(X, X1, \text{phonetic}), \]
\[ \text{arc}(A1, X1, X2, \text{phonetic}), \text{label}(A1, d), \]
\[ \text{path}(X2, X3, \text{p}), \]
\[ \text{arc}(A2, X3, Y, \text{phonetic}), \text{label}(A2, k) \]

2. Find phonetic arcs which immediately precede a vowel that overlaps a high tone:

\[ \text{ans}(A) \leftarrow \text{arc}(A, X, Y, \text{phonetic}), \]
\[ \text{arc}(A1, Y, Y1, \text{phonetic}), \text{label}(A1, [aeiou]), \]
\[ \text{ovlp}(A2, A) \]

3. Find words dominating a vowel which overlaps a high tone:

\[ \text{ans}(A) \leftarrow \text{arc}(A, X, Y, \text{word}), \]
\[ \text{arc}(A1, X1, X2, \text{phonetic}), \text{label}(A1, [aeiou]), \]
\[ \text{arc}(A2, X3, Y, \text{phonetic}), \text{label}(A2, h^*) \]
\[ \text{s_incl}(A, A1), \text{ovlp}(A1, A2) \]

While it is possible to give queries a first-order interpretation, the language is quite cumbersome, and we seek a more natural way to describe annotation graphs.

5. Query Syntax

In this section we introduce a query syntax which provides first an abbreviated notation for the queries expressed previously in datalog. Most importantly, the syntax allows us to recognize certain crucial optimizations.

5.1. Queries over arc data

The fundamental unit on which our query language is built is the arc. We form the join of the arc and label relations from Figure 5 and adopt names for our attributes. A query that finds the arc identifiers, types and labels of all edges in timeline t1 is shown below:

\[ \text{select ans(E,T,L)} \]
\[ \text{where [id: E, type: T, label: L]} \leftarrow \text{t1} \]

We follow the datalog convention of using uppercase symbols for variables and lowercase symbols for constants. The notation \[ \text{id: E, type: T, label: L} \] is used for arcs and describes a \textit{arc pattern}: it is matched against the arcs in the timeline t1 and binds the variables E, T, L for each match to the arc data in the timeline. For each such match it constructs a tuple \text{ans}(E,T,L) in the output. Arc patterns may contain constants, e.g. \[ \text{id: E, type: word, label: L} \] and there is no constraint on their width. In this sense they are "ragged" or "semistructured" tuples.

\[ \text{ovlp}(A, B) \leftarrow \text{arc}(A, X1, Y1, _), \text{arc}(B, X2, Y2, _), \]
\[ \text{time}(X1, X1t), \text{time}(X2, X2t), \]
\[ \text{time}(Y1, Y1t), \text{time}(Y2, Y2t), \]
\[ X1t \leq Y2t, Y1t \leq Y2t \]

Since attributes are distinguished by name rather than position, it is safe (and often convenient) to omit them when we do not need to constrain their value, or bind a variable.

To query over a collection of timelines timit we use cascaded bindings:

\[ \text{select ans(E,L)} \]
\[ \text{where TL < timit} \]
\[ \text{[id: E, start: X, end: Y, label: L, type: word] < - TL} \]
\[ \text{time(Y) - time(X) < 8000} \]

This selects the edge identifiers and labels (the names of the words) from all words in the timit corpus of a suitably short duration.

The form of this query follows a standard syntax for semistructured query languages (see (Abiteboul et al., 2000)). We shall concentrate here on the development of a syntax for patterns that specify paths and assume a standard syntax, e.g. \text{select ans(E,L)}, for returning results of the query.

5.2. Path patterns

Each arc has a start and end node. We can specify two adjacent arcs by requiring the start node of one arc to be the end node of another

\[ \text{id: E1, start: X, end: Y, type: T1, label: L1} \leftarrow \text{db} \]
\[ \text{id: E2, start: Y, end: Z, type: T2, label: L2} \leftarrow \text{db} \]

In this fashion we can specify any sequence of arcs. However we shall use an abbreviated syntax \[ [ \ldots ] \].\[ \ldots \] to specify the concatenation of edges, that is, the dot is an associative pattern concatenation operation. Thus the previous pair of patterns binds the same variables as the following single pattern

\[ \text{id: E1, start: X, end: Y, type: T1, label: L1} \leftarrow \text{db} \]
\[ \text{id: E2, end: Z, type: T2, label: L2} \leftarrow \text{db} \]

Within edge patterns we also allow arbitrary predicates. For example: \[ \text{[type: T, T = word or T = ph], [start: X, stop: Y, time(Y) - time(X) > 200]} \]. Predicates may also use attribute names as values. For example, \[ \text{[type: word], [type: X, X = word], [type=word] are equivalent.} \]

A sequence of arcs (phonemes, syllables, phrases, etc) is represented in our model using a concatenated sequence of arc patterns. To specify path patterns of arbitrary length we also allow arbitrary regular expressions on arcs. An arbitrary path of word arcs is represented by \[ \text{[type = word]*} \] and an arbitrary path of word or phoneme arcs by \[ \{(\text{type = word})|\text{(type = phoneme)}\}^* \]. Care must be taken in interpreting variables inside a Kleene * or a union. The rule is that such variables must be bound elsewhere in the program. We cannot bind variables inside a union or Kleene *. Thus \[ \text{[type: T]} \] is illegal.

Suppose we have a path pattern \[ \text{[type: word]*} \] and we want to refer to the first node on the path. The pattern \[ \text{[start: X, type: word]*} \] is illegal. (Even if it were legal this pattern could only only match paths of length 0 or 1.) To allow the binding of nodes outside of an edge pattern we take single variables in the sequence to
denote nodes. For example, \( X.\text{[type: T].Y} \) is equivalent to \([\text{start: X, type: T, end: Y}]\). Moreover, \( X.\text{[type: word]*.Y} \) binds \( X \) to the first node and \( Y \) to the last node on a path of word arcs. Now consider the following example:

\[
\begin{align*}
X.\text{[type = parse, label = sentence].Y} & \leftarrow \text{db} \quad (a) \\
X.\text{[type = word]*.\text{[type = word, label = opera]}.Y} & \leftarrow \text{db}
\end{align*}
\]

This matches the start and end node of any sequence that contains the word \textit{opera}. Another possibility is shown below.

\[
\begin{align*}
X.\text{[type = parse, label = sentence].Y} & \leftarrow \text{db} \quad (b) \\
X'.\text{[type = word, label = opera].Y'} & \leftarrow \text{db}
\end{align*}
\]

However, (a) and (b) are \textit{not} equivalent queries.

One might think, from example (a) above, that one could dispense with node variables by having a parallel composition operator. It turns out that there are many situations where this is impossible. The simplest instance is shown in Figure 8.

The annotation graph in Figure 8 cannot be uniquely described using parallel and serial composition. Instead, we need a set of expressions as follows:

\[
\begin{align*}
\text{A.}\{\text{[label: W].B.\text{[label: X].C.\text{[label: Y].D}} & \leftarrow \text{db} \\
\text{A.}\{\text{[label: V].C} & \leftarrow \text{db} \\
\text{B.}\{\text{[label: Z].D} & \leftarrow \text{db}
\end{align*}
\]

5.3. Arbitrary predicates on arcs

The bracket notation for describing arcs can also enclose arbitrary predicates. Predicates expressing the (temporal) overlap or inclusion of edges are particularly useful. Example (b) above may be expressed as:

\[
\begin{align*}
X'.\text{[type = word, label = opera].Y'} & \leftarrow \text{db} \\
\text{time}(X) & \leq \text{time}(X') \\
\text{time}(Y') & \leq \text{time}(Y)
\end{align*}
\]

Note that \text{subinterval}(E) can be thought of as a “method” of the edge, that is called when the pattern is matched.

5.4. Abbreviations

The preceding syntax is quite general; it has little to do with the specific conventions of linguistic data. Paths typically, though not always, follow the same type. Labels are also special. We propose the following syntactic sugar. (The proposal is tentative, all sorts of variations are possible).

Given a database of arcs \( db \), the notation \( db/t \) restricts the database to those arcs of type \( t \). Also the notation \( :l \) is an abbreviation for \( \text{label: l} \). For example, \( X.\{:[L].Y \leftarrow \text{db/word} \) is shorthand for \( X.\{\text{label:}
\]

\[
\begin{align*}
L, \text{type: word}.Y & \leftarrow \text{db}. \quad \text{Using this, example (a) becomes:} \\
X.\{[:sentence].Y \leftarrow \text{db/parse} \\
X.\{[:opera].[:t.*].Y \leftarrow \text{db/word}
\end{align*}
\]

5.5. Horizontal path expressions

5.6. Optimization: exploiting quasi-linearity

In the previous sections we developed a query language for annotation graph data and showed how an analysis of that language might help - in many practical cases – to lead to tractable implementations. Here we show how we can exploit the “almost sequential” notion of annotation graph data to support these implementations. In particular, we will show how to use the underlying temporal order to select a small fragment of the input data that will fit into main memory, bypassing many of the database optimization issues.

Consider the example in Figure 9. It shows a collection of nodes, where nodes a-f are timed and the rest are untimed. All the untimed nodes are linked by arcs to other nodes. In order to extract those portions of the database that are needed to answer a query, we will typically need to find efficiently all arcs contained in some arc or all arcs that might overlap some arc. Such queries can be answered by computing the transitive closure \( TA \) of the arc relation, but this is likely to be an expensive proposition \( O(n^2) \) in the number of nodes. An alternative is to store the two relations below.\(^{4}\) The relation \( time \) contains, for every node \( n \), the maximum time \textit{ante} of a timed node that precedes \( n \).

\(^{4}\)Our approach has similarities with Allen’s “reference intervals” (Allen, 1983).
and the minimum time post of a timed node that precedes n. If n is itself timed, the ante and post agree. It is a consequence of the definitions in section 3. that these times always exist. (Every node is bounded by some pair of timed nodes.) Note that node is a key for the time relation, and we shall refer to the attributes ante and post functionally, as ante(n) and post(n).

The relation TA’ is defined by TA’ = \{(m, n) | TA(m, n) ∧ post(m) > ante(n)\}. This means that the precedence relation TC can be reconstructed by the query:

\[
TC(m, n) : \neg post(m) < ante(n) ∨ TA’(m, n)
\]

With indexes on ante, post, and (source, target), this predicate can be efficiently computed.

The point of this decomposition is that we expect the relation TA’ to be relatively small. For example, in the Switchboard database (Godfrey et al., 1992), the maximum size of TC for any timeline is approximately 1.9 million, while the sizes of time and TA’ are, for this timeline, 1,992 and 10,585 respectively. Throughout the whole database, the largest value of TA’ was 15, 286. Evidently the decomposed representation will easily fit into main memory, while keeping TC in main memory may pose problems.

Finally, let us put together the ideas of the last two sections. Consider example (a) of the previous section. The important point is that all nodes are bounded by a sentence arc. This suggests the following technique:

- Repeatedly match X,[type = parse, label = sentence].Y
- For each match, obtain X’ = ante(X) and Y’ = post(Y)
- Restrict the arc relation to arcs bounded by (X’, Y’)
- (use an index that supports range searches)
- Perform the query on the restricted relation (main memory evaluation should be possible)

5 Some saving in space could be achieved by having a separate relation for the timed nodes.
6 This computation is based on the version of Switchboard data that is marked with time information at turn boundaries only. Given an n-word turn, the size of the transitive precedence relation is approximately n^2 / 2.

7. Conclusions

Like semistructured data, annotation graphs have a natural representation in terms of nodes and arcs. A key feature of annotation graphs is that the arcs are organized into a quasi-linear flow in the horizontal direction. As in the case of semistructured data, we seek a natural query language for accessing and transforming this data.

This paper has described progress on a query language for annotation graphs. Path patterns and some abbreviation devices provide a convenient way to express a wide range of queries. We exploit the quasi-linearity of annotation graphs by partitioning the precedence relation, and we believe that this will enable efficient temporal indexing of the graphs.

In ongoing work we are exploring hybrid structures and languages which would permit both the vertical and horizontal perspectives on semistructured data to co-exist. On this view, a horizontal path expression could be embedded inside a vertical path expression, or vice versa.
