Role of the GALT in Scrapie Agent Neuroinvasion from the Intestine

Bridget R. Glaysher and Neil A. Mabbott

Following oral exposure, some transmissible spongiform encephalopathy (TSE) agents accumulate first upon follicular dendritic cells (FDCs) in the GALT. Studies in mice have shown that this accumulation is obligatory for the efficient delivery of the TSE agent to the brain. However, which GALTs are crucial for disease pathogenesis is uncertain. Mice deficient in specific GALT components were used here to determine their separate involvement in scrapie agent neuroinvasion from the intestine. In the combined absence of the GALTs and FDCs (lymphotixin (LT)α−/− mice and LTβ−/− mice), scrapie agent transmission was blocked. When FDC maturation was induced in remaining lymphoid tissues, mice that lacked both Peyer’s patches (PPs) and mesenteric lymph nodes (wild-type (WT)→LTα−/− mice) or PPs alone (WT→LTβ−/− mice) remained refractory to disease, demonstrating an important role for the PPs. Although early scrapie agent accumulation also occurs within the mesenteric lymph nodes, their presence in WT→LTβ−/− mice did not restore disease susceptibility. We have also shown that isolated lymphoid follicles (ILFs) are important novel sites of TSE agent accumulation in the intestine. Mice that lacked PPs but contained numerous FDC-containing mature ILFs succumbed to scrapie at similar times to control mice. Because the formation and maturation status of ILFs is inducible and influenced by the gut flora, our data suggest that such factors could dramatically affect susceptibility to orally acquired TSE agents. In conclusion, these data demonstrate that following oral exposure TSE agent accumulation upon FDCs within lymphoid tissue within the intestine itself is critically required for efficient neuroinvasion. The Journal of Immunology, 2007, 178: 3757–3766.

T
ransmissible spongiform encephalopathies (TSEs),3 or “prion diseases,” are subacute neurodegenerative diseases that affect humans and both domestic and free-ranging animals. The neuropathological features within the CNS characteristically include spongiform pathology, neuronal loss, glial activation, and amyloidial aggregations of an abnormally folded host protein. There is little evidence of pathology in other tissues. The host prion protein (PrPc) is widely expressed in both humans and animals, and its expression is crucial for TSE disease susceptibility (1). In TSE-affect ed tissues, the PrP accumulates as an abnormal, detergent-insoluble, relatively proteinase-resistant isoform, termed PrPSc. TSE agent infectivity copurifies with PrPSc (2) and is considered to be a major or possibly sole component of the infectious TSE agent. Indeed, the prion hypothesis argues that PrPSc is itself the infectious agent and facilitates conversion of cellular PrP to PrPSc.

TSE diseases typically have long incubation periods before the onset of clinical signs, which in humans can vary from 1.5 to at least 40 years. Following peripheral exposure, many of the acquired TSE agents accumulate in lymphoid tissues such as the spleen, lymph nodes, tonsils, appendix, and Peyer’s patches (PPs), before spreading to the CNS, a process termed neuroinvasion. Examples include sheep with natural scrapie (3), mule deer with chronic wasting disease (4), and humans with variant Creutzfeldt-Jakob disease (vCJD) (5). Within the lymphoid tissues of both experimentally and naturally affected hosts, early PrPSc accumulation occurs within the germinal centers upon follicular dendritic cells (FDCs) and within tingible body macrophages (4–9). FDCs are a distinct lineage from migratory bone marrow-derived dendritic cells because they are considered to derive from stromal precursor cells, are nonphagocytic, and are nonmigratory (10). In mouse scrapie models, mature FDCs are critical for scrapie agent accumulation in lymphoid tissues, and in their absence, neuroinvasion is significantly impared (11–14). From the lymphoid tissues, translocation to the CNS occurs via the peripheral nervous system (15, 16).

The suggestion that consumption of bovine spongiform encephalopathy-contaminated meat products is the most likely cause of vCJD in humans (17) has focused attention on the gastrointestinal tract as an important portal of TSE entry. Following intragastric or oral inoculation of rodents with scrapie, infectivity and PrPSc accumulate first in PPs, mesenteric lymph nodes (MLNs), and glia of the enteric nervous system long before their detection in the CNS (18, 19). Natural sheep scrapie may also be acquired orally as PrPSc is detected in the GALT before detection within the CNS (6). Likewise, PrPSc is first detected in the GALT following experimental oral inoculation of mule deer fawns (Odocoileus hemionus) with chronic wasting disease (4). The detection of disease-specific PrP within the GALT of a human vCJD patient 8 mo before the onset of clinical signs is also consistent with the transmission of this disease by the oral route (5).
The GALT comprises chiefly of appendix, tonsils, PPs, MLNs, and ILFs, but which if any of these tissues are crucial for the oral pathogenesis of TSEs is unclear. Previous studies have used a variety of immunodeficient mouse lines to study the involvement of FDCs and PPs in oral scrapie pathogenesis, including TNF-α−/− mice, aly/aly mice, β2−/− mice, RAG-1−/− mice, and μMT−/− mice (20–22). However, the individual contributions of the deficiencies in lymphoid tissue, lymphoid tissue microarchitecture, or FDC development were not distinguished in the same mouse strains. In the current study, mouse models were created that lacked specific GALT components (PPs, MLNs, and ILFs) but had mature FDC networks in the remaining lymphoid tissues. The presence of FDCs in the remaining lymphoid tissues ensured that TSE agent accumulation could occur within these tissues if the missing tissues were not critical to disease pathogenesis. Using these mouse models, experiments were designed to address the following questions: first, whether TSE susceptibility is reduced in the absence lymphoid tissue within the intestine itself (e.g., PPs)? Second, whether neuroinvasion occurs from multiple sites such that the lack of one compartment (e.g., PPs) can be compensated for by the presence of another (e.g., MLNs)? Third, whether neuroinvasion can occur via other lymphoid tissues (e.g., spleen) in the absence of the GALT?

Materials and Methods

Mice

LTα−/− mice (23) and LTβ−/− mice (24) were obtained from B&K Universal and were maintained on a C57BL/6 background. Age- and sex-matched C57BL/6 mice were used as immunocompetent wild-type (WT) controls in studies using LTα−/− mice and LTβ−/− mice.

Gamma irradiation and bone marrow reconstitution

Bone marrow from the femurs and tibias of immunocompetent C57BL/6 WT mice was prepared as a single-cell suspension (3 × 10^7−4 × 10^7 viable cells/ml) in HBSS (Invitrogen Life Technologies). Recipient adult (6−8 wk old) LTα−/− mice, LTβ−/− mice, and C57BL/6 mice were gamma irradiated (950 rad) and 24 h later reconstituted with 0.1 ml of bone marrow by injection into the tail vein.

PP-deficient mice

To create progeny mice deficient in PPs, timed pregnant C57BL/6Jk mice were given a single i.v. injection of 100 µg of a fusion protein containing the soluble LTβR domain linked to the Fc portion of human IgG1 (LTβR-Ig: Ref 25) on day 11.5 of gestation (26).

Scrapie agent inoculation

For oral inoculation mice were fed individual food pellets dosed with 50 µl of a 1.0% (w/v) scrapie brain homogenate prepared from mice terminally affected with ME7 scrapie. Where indicated, separate groups of mice were inoculated by intracranial injection with 20 µl of a 1.0% (w/v) scrapie mouse brain homogenate (containing ~1 × 10^5 ID50 units). Following challenge, animals were coded and assessed weekly for signs of clinical disease. Entire small intestines from each mouse were divided into three equal parts, coiled, fixed in paraformaldehyde, and embedded in paraffin wax. For light microscopy, following the addition of primary Abs, biotinylated secondary Abs were applied followed by alkaline phosphatase or HRP coupled to the avidin/biotin complex (Vector Laboratories). Vector Red (Vector Laboratories) and diaminobenzidine were used as substrates, respectively, and sections were counterstained with hematoxylin to distinguish cell nuclei. For fluorescent microscopy, following the addition of primary Abs, secondary Abs were applied followed by alkaline phosphatase or HRP coupled to the avidin/biotin complex. The total number of B lymphocytes-containing ILFs in the entire small intestine of each mouse analyzed was counted microscopically using CD45R expression for identification. The maturity of each ILF was determined according to size and the location and density of component cells as described previously (30). The presence or absence of FDCs (CR2/CR1+CD45R− cells) within each ILF was recorded.

Immunoblot detection of PrPSc

Spleen fragments (~20 mg) or MLNs (approximately half the total from each mouse assayed) were prepared as 10% (w/v) tissue homogenates, and PrPSc was enriched by sodium phosphotungstic acid precipitation (31) and treated in the presence of absence of protease K (40 µg/ml, 60 min, 37°C, VWR). Following enrichment, pellets were resuspended and diluted to 0.5 mg protein/ml, and 10 µl was electroblotted through SDS-PAGE gels (12%) polyacrylamide gels (Invitrogen Life Technologies). Proteins were transferred to polyvinylidene difluoride membranes (Bio-Rad) by semidy blotting. PrP was detected with the PrP-specific mouse mAb 8H4 (32), revealed by HRP-conjugated goat anti-mouse antiserum. Bound HRP activity was detected with Supersignal West Dura Extended Duration Substrate (Pierce).

Statistical analysis

Data are presented as mean ± SE. Significant differences between samples in different groups were sought by one-way ANOVA. Values of p < 0.05 were accepted as significant.

Results

Effect of lymphotixin deficiency on scrapie accumulation in lymphoid tissues

The intestines of LTα−/− mice and LTβ−/− mice lack PPs as LTβR signaling during embryonic development is required for their formation (30, 33, 34). In addition LTα−/− mice also lack the MLNs as LTα deficiency blocks their formation (34). However,
postnatal stimulation via lymphocyte-derived LTα1β2 is critically required to maintain FDCs in their differentiated state (35). As a consequence, the remaining MLNs and spleens of LTβ−/− mice (Fig. 1, A and B, respectively) and the spleens of LTα−/− mice (Fig. 1B) are deficient in FDCs. Because FDCs are critical for the efficient neuroinvasion of the ME7 scrapie agent from the intestine (13), we first investigated scrapie pathogenesis in the combined absence of GALT (MLNs and/or PPs) and FDCs in the remaining lymphoid tissues in LTα−/− and LTβ−/− mice.

In this study, the normal cellular form of the PrP is referred to as PrPc, and two terms (PrPSc or PrPd) are used to describe the disease-specific, abnormal accumulations of PrP that are characteristic of TSE-affected tissues and considered to represent the presence of the TSE agent (2). Disease-specific PrP accumulations are relatively resistant to proteinase digestion, whereas cellular PrPc is destroyed by this treatment. Where we were able to confirm this resistance by proteinase K treatment of samples and analysis by immunoblot, PrPSc is used as a biochemical marker for the presence of the TSE agent. Unfortunately, treatment of tissue sections with proteinase K destroys the microarchitecture. Therefore, tissue sections were fixed and pretreated to enhance the detection of the disease-specific abnormal accumulations of PrP (PrPd), whereas cellular PrPc is denatured by these treatments (7). We have shown in a series of studies that these PrPSc accumulations occur only in the tissues of TSE-affected animals and correlate closely with the presence of the TSE agent (7, 8, 11, 13, 19). Expression levels of cellular PrPc in tissues from uninfected mice were analyzed on acetone-fixed frozen sections. Immunocompetent C57BL/6 WT mice, LTα−/− mice, and LTβ−/− mice were inoculated orally with the ME7 scrapie strain. Within 70 days of oral inoculation of WT mice with the ME7 scrapie agent, strong accumulations of PrPSc and agent infectivity are found within PPs (Ref. 13; N. A. Mabbott, unpublished observations). High levels of proteinase K-resistant PrPSc and agent infectivity are also found within MLNs (Fig. 2A, lanes 2 and 4; Ref. 13; N. A. Mabbott, unpublished observations) and are sustained until the terminal stage of disease (Fig. 2C, lanes 2 and 4). However, in the MLNs of LTβ−/− mice or the mesenteric membranes taken from MLN-deficient LTα−/− mice, PrPSc was undetectable both 70 days (Fig. 2A) and 545 days (Fig. 2C) after inoculation. No PrPSc was detected in any of the spleens from WT mice, LTα−/− mice, and LTβ−/− mice assayed 70 days after inoculation (Fig. 2B). However, strong accumulations of PrPSc were found in the spleens of WT mice taken at the terminal stage of disease (Fig. 2D), but the subsequent accumulation in the spleens of LTα−/− mice and LTβ−/− mice was blocked (Fig. 2D). Thus, in the absence of PPs and FDCs in remaining lymphoid tissues, PrPSc accumulation in MLNs and the spleen is blocked.

**Effect of lymphotxin deficiency on scrapie susceptibility**

We next determined the effect of the combined GALT and FDC deficiency in LTα−/− mice and LTβ−/− mice on scrapie susceptibility. All orally inoculated WT mice succumbed to clinical TSE disease with a mean incubation period of 311 ± 3 days (n = 20; Table I). In contrast, LT deficiency dramatically affected scrapie susceptibility as all LTα−/− mice (n = 13) and LTβ−/− mice (n = 18) remained free of the signs of scrapie up to at least 545 days after oral inoculation (Table I). Characteristic PrPSc accumulation, reactive astrocytes, and spongiform pathology were detected in the brains of all clinically affected WT mice (Fig. 3A). The severity and distribution of the pathological vacuolation within the brains of WT mice was typical for oral infection with the ME7 scrapie strain (Fig. 3B). However, none of the pathological

**Figure 1.** Immunohistochemical detection of FDCs within the MLNs (A) and spleens (B) of WT mice, LTα−/− mice, and LTβ−/− mice. CD21/CD35-expressing (red) FDCs and organized B lymphocyte follicles (CD45R-positive cells; green) were detected in the tissues of WT mice. No FDCs were detected in tissues from LTα−/− mice and LTβ−/− mice. Original magnification: ×200.

**Figure 2.** PrPSc accumulation in the MLNs and spleens of LTα−/− mice and LTβ−/− mice is blocked following oral inoculation with scrapie. A and C, MLNs (or the mesenteric membrane containing the region where MLNs would have been in LTα−/− mice) and spleens (B and D) were collected 70 days after oral inoculation with the scrapie agent (A and B) or at the terminal stage of disease (C and D). Samples were treated in the presence (+) or absence (−) of proteinase K (PK) before electrophoresis. After PK treatment, a typical three-band pattern was observed between molecular mass values of 20–30 kDa, representing unglycosylated, monoglycosylated, and diglycosylated isomers of PrP (in order of increasing molecular mass). dpi, day postinoculation on which the tissues were analyzed; pos, mice that developed clinical signs of scrapie; neg, mice that were free of the signs of scrapie.
characteristics of TSE disease were detected within the brains of any of the surviving LTα−/− mice and LTβ−/− mice (Fig. 3, A and B).

When inoculated with the scrapie agent directly into the CNS (by intracranial injection) WT mice, LTα−/− mice, and LTβ−/− mice developed clinical scrapie with similar incubation periods of 172–175 days (Table I). These data confirm that the apparent resistance of LTα−/− mice and LTβ−/− mice to orally inoculated scrapie agent could not be attributed to a role for LTβR signaling in the development of pathology within the CNS.

FIGURE 3. Immunohistochemical and pathological analysis of brain tissue from terminally scrapie-affected mice and mice that remained free of the signs of disease at the end of the experiment. A and B, Brains from WT mice, LTα−/− mice, and LTβ−/− mice inoculated orally with the scrapie agent. C and D, Brains from WT→WT mice, WT→LTα−/− mice, and WT→LTβ−/− mice inoculated orally with the scrapie agent. Large PrP accumulations (brown; upper rows), reactive astrocytes expressing high levels of GFAP (red; middle rows), and spongiform pathology (lower rows) were detected in the hippocampi of all clinically scrapie-affected WT mice (A) and WT→WT mice (C), but not in the brains clinically negative LTα−/− mice and LTβ−/− mice (A), and WT→LTα−/− mice and WT→LTβ−/− mice (C). All sections were counterstained with hematoxylin (blue). Original magnification: ×200. dpi, day postinoculation on which the tissues were analyzed; pos, mice that developed clinical signs of scrapie; neg, mice that were free of the signs of scrapie. B and D, Pathological assessment of the spongiform change (vacuolation) in brains from terminally scrapie-affected mice and mice that remained free of the signs of disease at the end of the experiment. Vacuolation was scored on a scale of 0–5 in the following gray matter (G1–G9) areas: G1, dorsal medulla; G2, cerebellar cortex; G3, superior colliculus; G4, hypothalamus; G5, thalamus; G6, hippocampus; G7, septum; G8, retrosplenial and adjacent motor cortex; G9, cingulate and adjacent motor cortex. Each point represents mean vacuolation score ± SE for groups of 6–20 mice.
Reconstitution of LT-deficient mice with WT bone marrow induces FDC development in remaining lymphoid tissues but not the development of missing lymphoid tissues

Next, the effects of GALT deficiency, but not FDC deficiency, on scrapie pathogenesis were investigated. Adult WT mice, LTα/− mice, and LTβ/− mice were reconstituted with LT-expressing WT bone marrow (termed WT→WT mice, WT→LTα/− mice, and WT→LTβ/− mice, respectively). Within 35 days of WT bone marrow transfer, FDC networks were induced in the remaining lymphoid tissues of LTα/− mice and LTβ/− mice (Fig. 4A), but such treatment did not induce the development of missing lymphoid tissues (Table II). Expression of the cellular form of the PrP, PrPc, upon FDCs within the MLNs (where present) and spleens of WT→LTα/− mice and WT→LTβ/− mice appeared similar to that in tissues from WT→WT mice (Fig. 4B).

Scrapie pathogenesis in the absence of MLNs and/or PPs

Groups of WT→WT mice, WT→LTα/− mice, and WT→LTβ/− mice were inoculated orally with scrapie 35 days after reconstitution with WT bone marrow. Strong accumulations of PrPd were observed within the PPs of WT→WT mice within 70 days of inoculation (Fig. 5A) and were maintained until the terminal stage of disease (Fig. 5B). The distribution of the PrPd within PPs was consistent with accumulation upon FDCs (8, 13). However, PrPd accumulation within the intestines of WT→LTα/− mice and WT→LTβ/− mice was blocked (Fig. 5).

In the MLNs, PrPSc was undetectable in tissues from WT→WT mice, WT→LTα/− mice, and WT→LTβ/− mice assayed 70 days after inoculation (Fig. 6A), although PrPSc was detected in one of the spleens from a WT→WT mice taken at this time (Fig. 6B, lane 2). At the terminal stage of disease strong accumulations of PrPSc were found in the MLNs and spleens of WT→WT mice (Fig. 6, C and D). However, the accumulation of PrPSc in the MLNs (where present) and spleens of WT→LTα/− mice and WT→LTβ/− mice remained undetectable (Fig. 6, C and D).

We next determined the effect of MLN and/or PP deficiency on disease susceptibility. All orally inoculated WT→WT mice succumbed to clinical TSE disease with a mean incubation period of $337 \pm 4$ days ($n = 8$, Table II). In contrast, in the absence of both PPs and MLNs, scrapie susceptibility was dramatically affected as all orally inoculated WT→LTα/− mice ($n = 8$) remained free of the signs of scrapie up to at least 503 days after inoculation (Table II). Furthermore, in the absence of PPs alone, scrapie susceptibility was also dramatically affected as all WT→LTβ/− mice ($n = 7$) remained free of clinical scrapie (Table II). Typical neuropathological characteristics of TSE infection were detected within the brains of all WT→WT animals that developed clinical signs of scrapie (Fig. 3, C and D). None of these characteristics were detected within the brains of any of the surviving WT→LTα/− mice and WT→LTβ/− mice (Fig. 3, C and D).

In this study, a highly sensitive immunoblot method was used to detect PrPSc in our tissue samples (31). Therefore, we are confident that in this study the combined absence of 1) PrPSc in the GALT and spleen, 2) PrPc and neuropathological signs within the CNS, and 3) clinical signs of TSE disease, is convincing evidence that transmission was blocked in scrapie-inoculated LTα/− mice, LTβ/− mice, WT→LTα/− mice, and WT→LTβ/− mice.

Table II. Reconstitution of LT-deficient mice with WT bone marrow induces FDC maturation in remaining lymphoid tissues but does not restore susceptibility to orally inoculated scrapie agent

Mature ILFs contain FDCs

Novel lymphoid clusters termed ILFs have been identified along the antimesenteric wall of the mucosa of the intestine (36). The maturity of ILFs has previously been defined according size and the location and density of component cells (30). Whereas immature ILFs (iILFs) comprise loosely clustered CD45R/B220 cells located at the base of villi (Fig. 7A), mature ILFs (mILFs) are organized nodular structures, of width greater than one villus and comprise a single B lymphocyte follicle (Fig. 7A) with an overlying M cell-containing epithelium similar to the follicle associated epithelium of PPs (Fig. 7D). Using these criteria, double immunostaining for B lymphocytes (CD45R/B220 cells) and FDCs (CR2/CR1/CD45R cells) on the same tissue section revealed that the presence of FDCs could also be reliably used to distinguish ILF

![FIGURE 5](http://www.jimmunol.org/)

**FIGURE 5.** Detection of PrP<sup>d</sup> in the intestines of WT→WT mice, WT→LT<sup>α−/−</sup> mice, and WT→LT<sup>β−/−</sup> mice following oral inoculation with the scrapie agent. Small intestines were collected (A) 70 days after oral inoculation or (B) at the terminal stage of disease. Adjacent sections were stained with CD45R-specific antiserum B220 to detect B lymphocytes (red), CD21/35-specific antiserum to detect CR2/CR1-expressing FDCs (red), and PrP-specific antiserum 1B3 (red). Strong PrP<sup>d</sup> staining colocalized with CD21/35 expressing FDCs in the PPs and the few mILFs of WT→WT mice 70 days after oral inoculation (A) and at the terminal stage of disease (B). PrP<sup>d</sup> was not detected in the mILFs of scrapie-inoculated WT→LT<sup>α−/−</sup> mice or WT→LT<sup>β−/−</sup> mice. dpi, day postinoculation on which the tissues were analyzed; pos, mice that developed clinical signs of scrapie; neg, mice that were free of the signs of scrapie. maturation status. In this study, >1000 ILFs were analyzed, and our data showed that all mILFs consistently possessed large networks of immune complex-trapping FDCs (Fig. 7, A and B). FDCs were never detected in iILFs (Fig. 7, A and C). Like PPs, ILFs lack afferent lymphatics, but LYVE-1-expressing cells were observed in close association with ILFs, indicating the presence of efferent lymphatics (Fig. 7E). S-100-expressing nerve fibers and supportive cells were detected within the gut wall and in close association with mILFs (Fig. 7F).

Involvement of mILFs in scrapie agent neuroinvasion from the intestine

Having demonstrated that mILFs contain large FDC networks we next determined whether scrapie agent neuroinvasion from the intestine could also occur from mILFs. Stimulation via LT/H9252R is also important for the development of ILFs as these structures are absent in LT-deficient mice (30, 36). However, unlike PPs, ILF formation occurs postnatally, and their development in LT-deficient

mice can be restored by reconstitution with WT bone marrow (30, 36). In the experiments described above (Table II), no FDC-containing mILFs were present within the intestines of WT→WT mice, WT→LTα−/− mice, and WT→LTβ−/− mice at the time of scrapie inoculation, as these structures take much longer than 35 days to develop after WT bone marrow transfer (∼8–12 wk; Refs. 30 and 37). The numbers of mILFs in the intestines of immunocompetent control mice in our specific pathogen-free colony are extremely low or absent (typically 0–6 mILFs/mouse). However, in the absence of PPs, LTβR stimulation substantially increases the number of mILFs in the intestine (30). We therefore created mice that lacked PPs but contained numerous mILFs in their intestines through treatment of pregnant C57BL/Dk mice with LTβR-Ig (26, 30). As expected, PP formation in the progeny mice was blocked (termed PP-deficient mice), but the development of a significantly greater number of FDC-containing mILFs was induced when compared with untreated C57BL/Dk (control) mice (p < 0.001; Table III).

Control and PP-deficient mice (81–110 days old) were inoculated orally with the scrapie agent. Strong accumulations of PrPSc were observed upon FDCs within GALT MLNs (A and C) and spleens (B and D) were collected 70 days after oral inoculation with the scrapie agent (A and B) or at the terminal stage of disease (C and D). Samples were treated in the presence (+) or absence (−) of proteinase K (PK) before electrophoresis. Lane M contained molecular mass markers. dpi, day postinoculation on which the tissues were analyzed: pos, mice that developed clinical signs of scrapie; neg, mice that were free of the signs of scrapie.

and possibly also capture and transport by migratory bone marrow-derived dendritic cells (42). In the current study, any potential effects on dendritic cell migration to the spleen, due to a lack of LTα,β expressing B lymphocytes (43), were restored by WT bone marrow reconstitution. However, our data cannot exclude the possibility that the lack of M cells within the follicle associated epithelia of LTα−/− mice, LTβ−/− mice, WT→LTα−/− mice, and WT→LTβ−/− mice at the time of inoculation also contributes to their resistance to orally inoculated scrapie agent.

The inability of the MLNs or spleen to compensate for the absence of the PPs is unlikely to be due to fundamental differences in the nature of the FDCs at each of these sites as no significant differences between the function of FDCs from these tissues has been described, and each population appears to express similar levels of PrPc and CR1/CR2. Following oral inoculation, the TSE agent accumulates first in PPs and is subsequently distributed via the lymph and/or blood-stream to the MLNs and spleen (Ref. 13 and current study). In the absence of the PPs, our data show that this down-stream distribution is blocked.

Diet (e.g., consumption of TSE agent-contaminated food) and PrP genotype (44, 45) are important risk factors that affect TSE susceptibility, but others remain to be determined. Recent studies suggest that inflammation may be another factor, either enhancing agent uptake from mucosal sites (46), or expanding the tissue distribution of these agents (47–49). For example, the induction of FDC networks within the ectopic germinal centers of chronically inflamed kidneys enables the accumulation of high levels of PrPSc in this tissue and excretion of low levels of infectivity in urine (47, 48). Likewise, natural chronic inflammatory conditions can expand the deposition of PrPSc in TSE-affected animals, such as to inflamed mammary glands of scrapie-affected sheep (49).

ILFs are recently identified lymphoid structures distributed throughout the intestines of rodents (36, 50–52) and humans (53) with features similar to PPs. Although the small intestine of an adult mouse may contain as many as 100 ILFs, data from the current study and others (30, 37) show that mILFs are highly infrequent (typically <5 per mouse) in tissues from unmanipulated immunocompetent control mice in a specific pathogen-free colony.

Stimulation via LT immunocompetent control mice in a specific pathogen-free colony. frequent (typically adult mouse may contain as many as 100 ILFs, data from the

The temporary depletion of FDCs for 21–28 days blocks TSE agent transmission from the intestine (13), suggesting this time interval is sufficient to allow clearance of the remaining inoculum. In the current study, no mILFs were detected in the small intestines of WT→LTα−/− mice and WT→LTβ−/− mice at the time the mice were inoculated with the scrapie agent (5 wk after bone marrow reconstitution) as their formation occurs between 8 and 12 wk after WT bone marrow reconstitution (30, 37). Therefore, by the time the mILFs had eventually developed in the intestines of WT→LTα−/− mice and WT→LTβ−/− mice, sufficient time will have elapsed to allow clearance of the remaining inoculum, preventing PrPc accumulation upon the FDCs within them and subsequent neuroinvasion.

In conclusion, our data demonstrate the crucial importance of TSE agent accumulation upon FDCs within the GALT for efficient neuroinvasion following oral exposure. Current evidence suggests vCJD shares a similar requirement for accumulation upon FDCs before neuroinvasion (5). Thus, our data imply that neuroinvasion of the vCJD agent might also occur soon after accumulation within the GALT before the agent has disseminated to other lymphoid tissues. Our data also identify mILFs as a novel and important site of TSE agent accumulation within the small intestine. As the formation and maturation status of ILFs is strongly influenced by commensal and pathogenic microorganisms (30, 38, 39), factors that stimulate mILF development are likely to dramatically enhance susceptibility to orally acquired TSE agents.

Acknowledgments

We thank Karen Brown, Claudine Raymond, Simon Cumming, Rebecca Greenan, and Irene McConnell (Institute for Animal Health, Neuropathogenesis Unit, Edinburgh, U.K.) for excellent technical support; Christine Farquhar (Institute for Animal Health) for provision of pAb 1B3; and Man-Sun Sy (Case Western Reserve University School of Medicine, Cleveland, OH) for provision of 8H4 mAb. LTβR-Ig was provided by Jeffrey Browning (Biogen, Cambridge, MA), and requests for this reagent should be addressed to Jeff_Browning@biogen.com.
