We have investigated random telegraph noise (RTN) observed in individual metallic carbon nanotubes (CNTs). Mean lifetimes in high- and low-current states, \( \tau_{\text{high}} \) and \( \tau_{\text{low}} \), have been studied as a function of bias-voltage and gate-voltage as well as temperature. By analyzing the statistics and features of the RTN, we suggest that this noise is due to the random transition of defects between two metastable states, activated by inelastic scattering with conduction electrons. Our results indicate an important role of defect motions in the 1/f noise in CNTs. © 2014 AIP Publishing LLC.

The switching of resistance between two discrete values, referred to as random telegraph noise,† has been observed in a variety of mesoscopic systems such as submicron metal-oxide-semiconductor field-effect-transistors (MOSFETs),‡,§ metallic nanobridges,† and small tunnel junctions.† Although microscopic details differ from one system to another, the observed switching of resistance is an apparent signature of an underlying two-level fluctuator (TLF), which consists of two energy wells separated by a barrier. The presence of a large number of TLF’s, with a wide distribution of fluctuation rates, is generally believed to be responsible for the 1/f noise, frequently observed in various materials and systems. 1/f noise has also been widely studied in carbon nanotubes,§–13 and the random telegraph signal has been reported for carbon nanotubes (CNT)-FETs14–16 and CNT film-silicon Schottky junctions.17 These random telegraph noises (RTNs) were attributed to charge traps in dielectric materials or in the interface.

In this Letter, we report extensive observations of RTN in individual metallic CNTs. The noise behavior is distinguished from the RTN observed in semiconducting CNT-FETs.14,15 By analyzing the statistics and features of the current switching, we attribute the RTN to the defect motions between two metastable states. The activation energy for this transition is evaluated from the bias-voltage dependence of the RTN.

Experiments have been carried out on individual metallic single-walled carbon nanotubes (SWNTs) dispersed on Si/SiO₂ substrates. The heavily doped Si was used as a back-gate and the thickness of the oxide layer was 300 nm. For electrical contacts, Ti/Au (5 nm/15 nm) electrodes were deposited on SWNTs using conventional e-beam lithography (Figure 1(c)). Low temperature measurements were performed both in a Janis variable temperature cryogenic system and in a simple liquid He bath. The samples were biased at a constant voltage and the current fluctuations were monitored with either a preamplifier (Ithaco 1211) or a semiconductor characterization system (Keithley 4200). In general, the RTN can be characterized by three parameters, namely the RTN amplitude (\( \Delta I_{ds} \)) and the mean lifetimes of the high-current state (\( \tau_{\text{high}} \)) and the low-current state (\( \tau_{\text{low}} \)). To obtain reasonable statistical values of these parameters, 5000 to 20000 current points were registered for a fixed drain-source bias-voltage (\( V_{ds} \)). The observation window of \( \tau_{\text{high}} \), \( \tau_{\text{low}} \), lies between 0.1 s and 1000 s.

In Figs. 1 and 2, we present typical results of two-probe measurements from a representative sample. Figure 1(a) shows time-traces of the drain-source currents (\( I_{ds} \)) for five different \( V_{ds} \), at \( T = 4.2 \text{ K} \). Current switching between two discrete values is clearly observable in a particular range of \( V_{ds} \), 75 \( \leq V_{ds} \leq 180 \text{ mV} \), and the magnitude of the current fluctuation reaches 30% of the total current. The fluctuation rate becomes faster with increasing \( V_{ds} \) and the switching becomes faster than the experimental bandwidth for \( V_{ds} > 180 \text{ mV} \). Values of \( \tau_{\text{high}} (\ast) \) and \( \tau_{\text{low}} (\bigcirc) \), obtained from nine different \( V_{ds} \), are shown in Fig. 1(b). It demonstrates that the \( \tau_{\text{high}} \) and \( \tau_{\text{low}} \) increase exponentially with respect to the inverse \( V_{ds} \). To investigate the effect of gate-voltage (\( V_{g} \)) on the RTN, we checked the current fluctuation as we swept \( V_{g} \) by 20 µV/s in the range of 1 V while keeping \( V_{ds} = 100 \text{ mV} \). Figure 2(a) shows the measured currents as a function of gate-voltage. The two current levels are clearly distinguishable in the Coulomb oscillations. In Fig. 2(b), the noise amplitude \( \Delta I_{ds} \) was estimated by taking the difference of the two discrete current-curves in Fig. 2(a). The peak positions of \( \Delta I_{ds} \) match with those of \( I_{ds} \). The result is consistent with the reported 1/f noise characteristics of a SWNT single-electron-transistor (SET),§ where peaks of both the current and the current noise coincide.

What is the origin of the RTN we have observed in metallic SWNTs? At first, we checked the effect of tunnel conductance fluctuations across the contact barrier, which can possibly cause the RTN, assuming two kinds of contact configurations with different tunnel barriers. To test this, a four-probe measurement was introduced with the electrode configuration shown in Fig. 1(c). We simultaneously measured the RTN in both four- and two-probe configurations, i.e.,

†Author to whom correspondence should be addressed. Electronic mail: shjang@konkuk.ac.kr
measuring the $I_{ds}$ and $V_{ds}$ between the outer two electrodes (two-probe) and at the same time measuring the voltage drop between the inner two electrodes (four-probe) of the same sample. Figure 3 shows that both the two- and four-probe resistance switch at the same time, which rules out the role of contact barriers in the RTN.

As a second candidate, we can possibly think about the effect of charge traps in dielectric materials which could explain the RTN in MOSFETs\(^2,3\) and CNT-FETs\(^14–16\). Since our experiments have been performed for similar FET structures. However, our results of the RTN in metallic SWNTs are different from those observed in the semiconductors. The same experiment as in Fig. 2(a), performed on a submicron MOSFET in the Coulomb-blockade regime at $T = 4.2$ K, showed two discrete $I_{ds}-V_{g}$ curves that exhibited the same Coulomb oscillations but were shifted relative to one another along the horizontal axis ($V_{g}$)\(^18\). This is because the trapped charge affects the potential of the dot. In our RTN data, however, no horizontal shift is observed as shown in Fig. 2(a).

Furthermore, the noise peaks, shown in Fig. 2(b), occur at the zero-gain points, ($\partial I_{ds}/\partial V_{g} = 0$), where the current is a maximum. If the noise is caused by charge fluctuations, the noise peak should occur at the point of maximum gain, that is, at $V_{g}$ where $I_{ds}$ is most sensitive to slight fluctuations in gate-voltage\(^7,19\). Second, $\tau_{\text{high}}$ and $\tau_{\text{low}}$ showed no gate-voltage dependence in the range of $V_{g}$ = 16 to 16 V (data not shown). However, a negatively charged trap in an oxide layer is more likely to emit its charge at $V_{g} < 0$ and to maintain it at $V_{g} > 0$. Note that the RTNs in CNT-FETs are observed only in a limited range of the gate-voltage\(^14,15\). Therefore, the lack of a gate-voltage dependence of $\tau_{\text{high}}$ and $\tau_{\text{low}}$ indicates that the RTN is not due to charge fluctuations. Finally, to rule out the effect of traps in the substrate, we prepared a SWNT suspended over the SiO\(_2\) substrate\(^20\). The RTN still appeared in the suspended SWNT at $T = 1.8$ K (data not shown). Therefore, we conclude that it is necessary to consider another source of the RTN.

Regarding the RTN to be due to intrinsic fluctuations, we now turn our attention to the defects in metallic SWNTs. Considering the high current density ($\sim 10^{10}$ A/cm\(^2\) at 10 nA) flowing through the surface of a 1 nm-sized carbon tube, a defect in a SWNT could transfer between two metastable positions, activated by inelastic scattering with conduction electrons. The reversible motion of a defect, inducing different electrical properties at each metastable position, could produce the observed telegraphic current fluctuations. We note that RTN in metallic nanobridges has been successfully explained in terms of similar defect motion\(^4,21–23\). This noise mechanism is consistent with our typical observation of electromigration of defects, which appears as an irreversible current change in time as $V_{ds}$ is further increased.

For the analysis of our results, we adopt the model\(^21,23\) used to describe RTN in metallic nanobridges. The temperature of a defect is usually identical to the lattice temperature. However, in CNTs and metallic nanobridges, the defect
temperature $T_d$ is expected to be much higher than the lattice temperature because of the inelastic scattering with conduction electrons as well as the poor energy relaxation to the lattice. With $T_d$ depending on the bias voltage, the model could explain the exponential dependence of the mean lifetimes as a function of $V_{ds}^{-1}$ observed at large bias-voltages.\textsuperscript{31,23,24} Note that we found a similar dependence in Fig. 1(b).

Following the approach of Ref. 21, where they calculated $T_d$ in equilibrium with ballistic electrons (treating the defect as a harmonic oscillator), Holweg \textit{et al.} derived the relation $k_B T_d = \zeta e |V_{ds}|$ with $\zeta = 5/16$ for high bias-voltage and low lattice temperature.\textsuperscript{23} With a modification term due to the electromigration force, the thermally activated behavior of the mean lifetime $\tau$ either in the high- or low-current state was expressed by

$$\tau = \tau_0 \exp \left( \frac{E_B - \zeta V_{ds}}{2 \zeta e |V_{ds}|} \right),$$

with $\tau_0$ the attempt time, $E_B$ the activation energy, and $\zeta$ the electromigration parameter. From the slope of Fig. 1(b), the activation energy $E_B$ of TLF1 in Fig. 1(a) is estimated (with $\zeta = 5/16$) to be 140 meV for $\tau_{\text{high}}$ and 160 meV for $\tau_{\text{low}}$. However, here we point out that for some TLF, the rate becomes independent of $V_{ds}$ at low bias-voltage as shown in Fig. 4. Also, the temperature dependence of the RTN, displayed in the inset of Fig. 4, shows that the fluctuation rate is nearly independent of temperature at $T \leq 20$ K, indicating that tunnelling between the two metastable states, rather than thermal activation, is dominant in this temperature range. Based on these observations, we assume that $T_d = \zeta e |V_{ds}|/k_B$ is equal to 20 K at $V_{ds} = 19.5$ V$^{-1}$ where the fluctuation rate becomes saturated at low bias-voltage. Thus, we obtain $\zeta \approx 0.034$ for the TLF2 in Fig. 4. This value is an order of magnitude smaller than $\zeta = 5/16$ suggested by the theory for metallic nanobridges. The voltage drop at the contact between the SWNT and the electrodes could be responsible for the reduced value of $\zeta$, together with the effect of energy relaxation to the lattice, which is not accounted for in the above theory. Also, the small $\zeta$ parameter reflects our diffusive SWNT device, allowing an electron to scatter off defects several times while traversing the tube.

In Table I, the magnitude of the current fluctuation and the estimated activation energy (with experimentally determined $\zeta$) are summarized for three different TLF’s. The measured $\Delta I_{ds}/I_{ds} \sim 0.1$–0.3 is two to four orders of magnitude larger than that of the metallic nanobridges (diameter $\sim$10 nm).\textsuperscript{4,21–23} This can be attributed to the much narrower current path in the SWNTs. In fact, for atomic-scale metal-constriction, the magnitude of the fluctuation can be as large as the total conductance.\textsuperscript{24} The small activation energy of 15–24 meV is a reflection of our measurement temperature ($T = 4.2$ K), and it is comparable to those of the metallic nanobridges measured at the same temperature. In most systems where RTN was found, the measured activation energy was a strong function of the temperature.\textsuperscript{2,22} This is because only the TLF for which the activation energy corresponds to the measurement temperature can be observable as RTN in the experimental bandwidth. At higher temperatures, the RTN was often observed with several TLF’s acting at the same time. In that case, the frequency dependence of the noise became close to the 1/f spectrum. If we regard the 1/f noise as a superposition of such TLF’s, our results indicate an important role of defect motions in the 1/f noise observed in the CNTs.\textsuperscript{6–12} In many CNT devices, prepared on dielectric substrates, charge traps in the vicinity of CNTs are expected to play a role in the 1/f noise. However, the deviation from the typical gain dependence of the 1/f noise, reported for CNT-SETs,\textsuperscript{7,9} cannot be explained by the charge fluctuations alone and instead can be understood by invoking a noise mechanism due to the defect motions. Also, in the frequency domain, the current power spectral density of the RTN is a Lorentzian given by

$$S_f = \frac{4(\Delta I_{ds}/I_{ds})^2}{T_f^2 (\tau_{\text{high}} + \tau_{\text{low}})(1/\tau_{\text{high}} + 1/\tau_{\text{low}})^2 + (2\pi f)^2)}.$$

With the 1/f$^2$ tail of the Lorentzian, we note that the 1/f$^2$ dependence of the noise (instead of 1/f) observed in free-standing CNTs\textsuperscript{8,11} can be interpreted as due to the presence of RTN, generated by defect motions.

Large RTN amplitude observed for metallic SWNTs suggests the possibility to use RTN measurements as a sensitive probe for characterizing the defects in nanotubes. Also, it is remarkable that, increasing the number of defects on the tubes by Cs ion irradiation, we could sometimes observe more...
current levels appearing in the time traces, which resulted in overall higher resistance fluctuations. With further investigations, RTN approach could be developed into a comparative diagnostic to grade differently prepared nanotubes.

In summary, we have investigated random telegraph noise observed in individual metallic SWNTs. Reversible motion of a defect, activated by inelastic scattering with conduction electrons, is suggested to be responsible for the observed RTN. Regarding the 1/f noise as a superposition of two-level current switchings, our results imply an important role of defect motions as a source of the 1/f noise for the CNTs.
