Comprehensive Comprehensions

Comprehensions with ‘Order by’ and ‘Group by’

Simon Peyton Jones
Microsoft Research

Philip Wadler
University of Edinburgh

Abstract

We propose an extension to list comprehensions that makes it easy to express the kind of queries one would write in SQL using ORDER BY, GROUP BY, and LIMIT. Our extension adds expressive power to comprehensions, and generalises the SQL constructs that inspired it. It is easy to implement, using simple desugaring rules.

Categories and Subject Descriptors D.3.3 [Language Constructs and Features]: Data types and structures; H.2.3 [Languages]: Query languages

General Terms Languages, Theory

Keywords list comprehension, SQL, query, aggregate

1. Introduction

List comprehensions are a popular programming language feature. Originally introduced in NPL (Darlington 1977), they now appear in Miranda, Haskell, Erlang, Python, Javascript, and Scala.

List comprehensions have much in common with SQL queries (Trinder and Wadler 1989), but SQL also provides heavily-used features not found in list comprehensions. Consider this SQL:

```
SELECT dept, SUM(salary)
FROM employees
GROUP BY dept
ORDER BY SUM(salary) DESCENDING
LIMIT 5
```

The GROUP BY clause groups records together; the ORDER BY sorts the departments in order of salary bill; and the LIMIT clause picks just the first five records. We propose an extension to list comprehensions that makes it easy to express the kind of queries one would write in SQL using ORDER BY, GROUP BY, and LIMIT. Here is how we would render the above query:

```
\[ (\text{the } \text{dept}, \text{sum } \text{salary}) \\
| (\text{name}, \text{dept}, \text{salary}) <- \text{employees} \\
, \text{group by dept} \\
, \text{order by Down } (\text{sum } \text{salary}) \\
, \text{using take 5} \]
```

(We’ll explain this in detail later.) Moreover, our extensions generalise the corresponding SQL features.

We make the following contributions.

- We introduce two new qualifiers for list comprehensions, order and group (Section 3). Unusually, group redefines the value and type of bound variables, replacing each bound variable by a list of grouped values. Unlike other approaches to grouping (as found in Kleisli, XQuery, or LINQ), this makes it easy to aggregate groups without nesting comprehensions.
- Rather than having fixed sorting and grouping functions, both order and group are generalised by an optional using clause that accept any function of types

\[
\forall a. (a \rightarrow \tau) \rightarrow [a] \rightarrow [a]
\]

respectively (Sections 3.2 and 3.5). Polymorphism guarantees that the semantics of the construct is independent of the particulars of how comprehensions are compiled.

- We present the syntax, typing rules, and formal semantics of our extensions, explaining the role of parametricity (Section 4). Our semantics naturally accommodates the zip comprehensions that are implemented in Hugs and GHC (Section 3.8).
- We show that the extended comprehensions satisfy the usual comprehension laws, plus some new specific laws (Section 5).

Other database languages, such as LINQ and XQuery, have similar constructs, as we discuss in Section 7. However, we believe that no other language contains the same general constructs.

2. The problem we address

List comprehensions are closely related to relational calculus and SQL (Trinder and Wadler 1989). Database languages based on comprehensions include CPL (Buneman et al. 1994), Kleisli (Wong 2000), Links (Cooper et al. 2006), and the LINQ features of C# and Visual Basic (Meijer et al. 2006). XQuery, a query language for XML, is also based on a comprehension notation, called FLWOR expressions (Boog et al. 2007). Kleisli, Links, and LINQ provide comprehensions as a flexible way to query databases, compiling as much of the comprehension as possible into efficient SQL; and LINQ can also compile comprehensions into XQuery.

Similar ideas have been embedded into general-purpose functional languages. Haskell DB (Leijen and Meijer 1999) is a library that compiles Haskell Monad comprehensions into database queries, and Erlang Mnesia (Mattsson et al. 1999) is a language extension that translates list comprehensions into database queries.

Many SQL queries can be translated into list comprehensions straightforwardly. For example, in SQL, we can find the name and salary of all employees that earn more than 50K as follows.

```
SELECT name, salary 
FROM employees
```
WHERE salary > 50

As a list comprehension in Haskell, assuming tables are represented by lists of tuples, this looks very similar:

\[
\{ (name, salary) \\
| (name, salary, dept) <- employees \\
, salary > 50 \}
\]

Here we assume that employees is a list of tuples giving name, salary, and department name for each employee.

While translating SELECT-FROM-WHERE queries of SQL into list comprehensions is straightforward, translating other features, including ORDER BY and GROUP BY clauses, is harder. For example, here is an SQL query that finds all employees paid less than 50K, ordered by salary with the least-paid employee first.

\[
SELECT name \\
FROM employees \\
WHERE salary < 50 \\
ORDER BY salary
\]

The equivalent in Haskell would be written as follows.

\[
map (\lambda (name,salary) \rightarrow name) \\
\{ (name,salary) \\
\rightarrow elements \\
| (name, salary, dept) <- employees \\
, salary < 50 \}
\]

Since we cannot sort within a list comprehension, we do part of the job in a list comprehension (filtering, and picking just the name and salary fields), before reverting to conventional Haskell functions to first sort, and then project out the name field from the sorted result.

The function sortWith is defined as follows:

\[
sortWith :: \text{Ord} \ b \Rightarrow (a \rightarrow b) \rightarrow [a] \rightarrow [a] \\
\]

\[
\text{sortWith } f \ x s = \\
\text{map } f s = \\
\text{sortBy} (\lambda x y \rightarrow \text{compare} (\text{snd} x) (\text{snd} y)) \\
\{ (x, f x) \mid x \in s \}
\]

The function argument is used to extract a sort key from each element of the input list. This uses the library function

\[
sortBy :: (a \rightarrow a \rightarrow \text{Ordering}) \rightarrow [a] \rightarrow [a]
\]

which takes a function to compare two elements.

Translating GROUP BY is trickier. Here is an SQL query that returns a table showing the total salary for each department.

\[
SELECT dept, sum(salary) \\
FROM employees \\
GROUP BY dept
\]

An equivalent in Haskell is rather messy:

\[
\text{let} \\
\text{depts} = \\
\text{nub [ dept } \\
\text{| (name,dept,salary) <- employees ]} \\
\text{in} \\
\{ (dept, sum [ salary \\
\text{| (name,dept',salary) <- employees \\
, dept == dept']) \\
\text{| dept <- depts ]}
\]

This uses the library function

\[
nub :: \text{Eq} a \Rightarrow [a] \rightarrow [a]
\]

which removes duplicates in a list. Not only is the code hard to read, but it is inefficient too: the employees list is traversed once to extract the list of departments, and then once for each department to find that department’s salary bill. There are other ways to write this in Haskell, some with improved efficiency but greater complexity. None rivals the corresponding SQL for directness and clarity.

It is tantalising that list comprehensions offer a notation that is compact and powerful—and yet fails to match SQL. Furthermore, ORDER BY and GROUP BY are not peripheral parts of SQL: both are heavily used. Thus motivated, we propose extensions to list comprehensions that allows such queries to be neatly expressed. For example, with our extensions the two queries above can be written like this:

\[
\{ \text{name} \\
| (\text{name,salary,dept}) <- \text{employees} \\
, \text{salary} < 50 \\
, \text{order by salary} \}
\]

\[
\{ \text{(the dept, sum salary)} \\
| (\text{name,salary,dept}) <- \text{employees} \\
, \text{group by dept} \}
\]

Just as comprehensions are explained currently, our extensions can be explained by a simple desugaring translation. Furthermore, they embody some useful generalisations that are not available in SQL.

3. The proposal by example

We now explain our proposal in detail, using a sequence of examples, starting with order by and moving on to group by. We use informal language, but everything we describe is made precise in Section 4. To avoid confusion we concentrate on one particular set of design choices, but we have considered other variants, as we discuss in Section 6.

We will use a table listing the name, department, and salary of employees as a running example.

\[
\text{employees} :: [(\text{Name}, \text{Dept}, \text{Salary})] \\
\]

\[
\text{employees} = \{ (\text{"Dilbert"}, \text{"Eng"}, 80) \\
, (\text{"Alice"}, \text{"Eng"}, 100) \\
, (\text{"Wally"}, \text{"Eng"}, 40) \\
, (\text{"Catbert"}, \text{"HR"}, 150) \\
, (\text{"Dogbert"}, \text{"Con"}, 500) \\
, (\text{"Ratbert"}, \text{"HR"}, 90) \}
\]

3.1 Order by

The SQL query

\[
\text{SELECT name, salary} \\
\text{FROM employees} \\
\text{ORDER BY salary}
\]

is expressed by the following comprehension

\[
\{ \text{name} \\
| (\text{name,dept,salary}) <- \text{employees} \\
, \text{order by salary} \}
\]

which returns

\[
\{ (\text{"Wally"}, 40) \\
, (\text{"Dilbert"}, 80) \\
, (\text{"Ratbert"}, 90) \\
, (\text{"Alice"}, 100) \\
, (\text{"Catbert"}, 150) \\
, (\text{"Dogbert"}, 500) \}
\]

The sort key (written after the keyword by) is an arbitrary Haskell expression, not just a simple variable. Here, for example, is a rather silly comprehension, which sorts people by the product of their salary and the length of their name:

\[
\{ \text{name} \\
| (\text{name,dept,salary}) <- \text{employees} \\
, \text{order by name*dept} \}
\]

which returns

\[
\{ (\text{"Dilbert"}, 1920) \\
, (\text{"Wally"}, 440) \\
, (\text{"Ratbert"}, 870) \\
, (\text{"Alice"}, 1000) \\
, (\text{"Catbert"}, 2250) \\
, (\text{"Dogbert"}, 2400) \}
\]
However, this generality has less frivolous uses. We can readily sort by multiple keys, simply by sorting on a tuple:

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by } (\text{salary, name})
\end{align*}
\]

But suppose we want the highest salary first? SQL uses an additional keyword, DESCENDING:

\[
\text{SELECT name, salary FROM employees ORDER BY salary DESCENDING name ASCENDING}
\]

We can use the power of Haskell to express this, simply by using a different key extractor:

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by } (\text{Down salary, name})
\end{align*}
\]

where Down is defined thus:

\[
\text{newtype Down a = Down a deriving(Eq)}
\]

\[
\text{instance Ord a => Ord (Down a) where compare (Down x) (Down y) = y 'compare' x}
\]

Since Down is a newtype, it carries no runtime overhead; it simply tells Haskell how to build the ordering dictionary that is passed to the sorting function.

### 3.2 User-defined ordering

Another useful way to generalise order is by allowing the user to provide the sorting function. For instance, if the sort keys are integers, it may be preferable to use a radix sort rather than the general-purpose sort provided by the library. We therefore generalise order to take an (optional) user-defined function:

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by } f \text{ using sortWith }
\end{align*}
\]

where sortWith is as defined in Section 2.

Furthermore, there is nothing that requires that the user-supplied function should do sorting! Suppose, for example, that we want to extract all employees with a salary greater than 100, highest salary first. In SQL, we could do so as follows:

\[
\text{SELECT name, salary FROM employees WHERE salary > 100 ORDER BY salary DESCENDING}
\]

This translates to the comprehension

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by Down salary, order by Down salary}
\end{align*}
\]

which returns

\[
[\langle \text{"Dogbert", 500} \rangle, \langle \text{"Catbert", 150} \rangle]
\]

However, we might want to write this differently, to first sort the list and then only take elements while the salary is above the limit.

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by Down salary, order by Down salary}
\end{align*}
\]

This uses the standard library function to extract the initial segment of a list satisfying a predicate.

\[
\text{takeWhile :: } (a \rightarrow \text{Bool}) \rightarrow [a] \rightarrow [a]
\]

In general, we can write

\[
\text{order by } p \text{ using } \text{filter}
\]

whenever \( p \) has type \( \tau \) and \( f \) has type

\[
\forall \tau. (a \rightarrow \tau) \rightarrow [a] \rightarrow [a].
\]

We require \( f \) to be polymorphic in the element type \( a \), which guarantees that it gives uniform results regardless of the type of tuple we present, but we do not require it to be polymorphic in the key type \( \tau \). Intuitively, the user-supplied function will be passed a list of records whose exact shape (which fields, in which order) is a matter for the desugaring transformation. So the desugaring transform supplies the function \( f \) with a function used to extract a key from each record. This key has a type \( \tau \) fixed by the sorting function (not the desugaring transform). We return to the question of polymorphism in Section 4.4.

Note that a traditional guard on a predicate \( p \) is equivalent to order by \( p \) using filter.

### 3.3 Dropping the by clause in ordering

The ability to process the record stream with a user-defined function, rather than with a fixed set of functions (sort ascending, sort descending, etc) is a powerful generalisation that takes us well beyond SQL. Indeed, another apparently-unrelated SQL construct, LIMIT, turns out to be expressible with order. Suppose we want to find the three employees with the highest salary. In SQL, we would use the LIMIT notation:

\[
\text{SELECT name, salary FROM employees ORDER BY salary DESCENDING LIMIT 3}
\]

We can do this using a trivial variant of order that drops the "by" clause:

\[
\begin{align*}
& \langle \text{name, salary} \rangle \\
& \langle \text{name, dept, salary} \rangle \leftarrow \text{employees} \\
& \text{order by Down salary}
\end{align*}
\]

which returns

\[
[\langle \text{"Dogbert", 500} \rangle, \langle \text{"Catbert", 150} \rangle, \langle \text{"Alice", 100} \rangle]
\]

The effect of omitting the by clause is simply that the supplied function is used directly without being applied to a key-extractor function.

As a second (contrived) example, we could sort into descending salary order by first sorting into ascending order and then reversing the list:

\[
\langle \text{name, salary} \rangle
\]

63
In general, we can write

\[
\text{order using } f
\]

whenever \( f \) is an arbitrary Haskell expression with type \( \forall a. [a] \rightarrow [a] \).

Again, we require \( f \) to be polymorphic in the element type \( a \).

However, omitting "by" is mere convenience, since

\[
\text{order using } f \equiv \text{order by } () \text{ using } \lambda x. f
\]

where \( x \) does not appear in \( f \).

3.4 Group by

Having described how order by works, we now move on to group by. As an example, the SQL query

\[
\begin{align*}
\text{SELECT dept, SUM(salary)} \\
\text{FROM employees} \\
\text{GROUP BY dept}
\end{align*}
\]

translates to the comprehension

\[
[ (\text{the dept, sum salary}) \\
| (\text{name, dept, salary}) \leftarrow \text{employees} \\
, \text{group by dept} ]
\]

which returns

\[
[ ("Con", 500) \\
, ("Eng", 220) \\
, ("HR", 240) ]
\]

The only new keywords in this comprehension are group by. Both the and sum are ordinary Haskell functions. The Big Thing to notice is that group by has changed the type of all the variables in scope: before the group by each tuple contains a name, a department and a salary, while after each tuple contains a list of names, a list of departments, and a list of salaries! Here is the comprehension again, decorated with types:

\[
[ (\text{the dept::[Dept]}, \text{sum (salary::[Salary])}) \\
| (\text{name::Name, dept::Dept, salary::Salary}) \leftarrow \text{employees} \\
, \text{group by (dept::Dept)} ]
\]

Hence we find the sum of the salaries by writing \text{sum salary}.

Function \text{the} returns the first element of a non-empty list of equal elements:

\[
\text{the} :: \text{Eq a} \Rightarrow [a] \rightarrow a \\
\text{the} (x:xs) | \text{all (x ==) xs} = x
\]

Thanks to the group by all values in the dept list will be the same, and so we extract the department name by writing the dept. (We could use head, but the makes clear the intended invariant on its argument.)

Unlike SQL, which always returns a flat list, we can use comprehensions to compute more complex structures. For example, to find the names of employees grouped by department, we could write

\[
[ (\text{the dept, name}) \\
| (\text{name, dept, salary}) \leftarrow \text{employees} \\
, \text{group by dept} ]
\]

which returns

\[
[ ("Con", [ "Ratbert" ] ) \\
, ("Eng" [ "Dilbert", "Alice", "Wally"] ) \\
, ("HR", [ "Catbert", "Ratbert" ] ) ]
\]

Or if we want to pair names with salaries, we could write

\[
[ (\text{the dept, namesalary}) \\
| (\text{name, dept, salary}) \leftarrow \text{employees} \\
, \text{order by salary} \\
, \text{let namesalary} = (\text{name, salary}) \\
, \text{group by dept} ]
\]

which returns

\[
[ [ ("Con", [ ("Ratbert", 500) ] ) \\
, ("Eng" [ ("Wally", 40) \\
, ("Dilbert", 80) \\
, ("Alice", 100) ] ) \\
, ("HR", [ ("Ratbert", 90) \\
, ("Catbert", 150) ] ) ]
\]

As above, the type of namesalary is changed by the group qualifier. Before the group qualifier namesalary has type \((\text{Name,Salary})\), but after it has type \([\text{Name,Salary}]\). In Section 4 we make precise what "before" and "after" mean, and we also formalise the usual let notation for Haskell list comprehensions used in this example.

3.5 User-defined grouping

Just as with order, we can generalise group to take an (optional) user-defined function. The default grouping function is \text{groupWith}, which first sorts on the group key:

\[
\text{groupWith} :: \text{Ord b} \Rightarrow (a \rightarrow b) \rightarrow [a] \rightarrow [[a]]
\]

\[
\text{groupWith} f = \text{groupRun} f \cdot \text{sortWith} f
\]

It is defined in terms of a function \text{groupRun}, that groups adjacent elements with the same key:

\[
\text{groupRun} :: \text{Eq b} \Rightarrow (a \rightarrow b) \rightarrow [a] \rightarrow [a]
\]

\[
\text{groupRun} f xs = \\
\text{map f} \\
(\text{groupBy} (\lambda x y \rightarrow \text{compare} (x) (\text{snd} x) (\text{snd} y)) \\
[ (x, f x) | x \leftarrow xs])
\]

This in turn uses the library function

\[
\text{sortBy} :: (a \rightarrow a \rightarrow \text{Bool}) \rightarrow [a] \rightarrow [a]
\]

which takes an equivalence relation over elements.

For example, we may find the length and average of adjacent runs of trades on a given stock with the following, which uses \text{groupRun} in place of \text{groupWith}:

\[
[ (\text{the stock, length stock, average price}) \\
| (\text{stock, price}) \leftarrow \text{trades} \\
, \text{group by stock using} \text{groupRun} ]
\]

If trades is the list

\[
[ ("MSFT", 80.00) \\
, ("MSFT", 70.00) \\
, ("GOOG", 100.00) \\
, ("GOOG", 200.00) \\
, ("GOOG", 300.00) \\
, ("MSFT", 20.00) ]
\]

this returns

\[
[ ("MSFT", 2, 75.00) \\
, ("GOOG", 3, 200.00) \\
, ("MSFT", 2, 55.00) ]
\]

In general, we can write

\[
\text{group by } c \text{ using } f
\]
whenever $e$ has type $\tau$ and $f$ has type $\forall a. [a] \rightarrow [[a]]$.

As before, we require $f$ to be polymorphic in the element type $a$. The only difference between sort by and group by is that the former takes a list to a list, while the latter takes a list to a list of lists.

### 3.6 Dropping the by clause in grouping

It is also possible to drop the “by” clause in a group. For example, the following function breaks a stream into successive runs of a given length.

```haskell
runs :: Int -> [a] -> [[a]]
runs n = [ take n xs | xs <- iterate tail , order by length xs >= n using takeWhile ]
```

For example, one can compute a running average over the last three trades for a given stock as follows.

```haskell
[ average price | (stock, price) <- trades , stock == "MSFT" , group using runs 3 ]
```

For the data above, this returns

```
[ 60.00, 40.00 ]
```

(since $60 = (80 + 70 + 30) / 3$ and $40 = (70 + 30 + 20) / 3$).

In general, we can write

```
    group using f
```

whenever $f$ has type $\forall a. [a] \rightarrow [[a]]$

Again, we require $f$ to be polymorphic in the element type $a$. As before, omitting “by” is mere convenience, since

```
    group using f = group by () using \x. f
```

where $x$ does not appear in $f$.

### 3.7 Having

In SQL, while one filters rows with WHERE, one filters groups with HAVING. Here is our original grouping query, modified to consider only employees with a salary greater than 50K, and departments having at least ten such employees.

```sql
SELECT dept, SUM(salary) FROM employees WHERE salary > 50 GROUP BY dept HAVING COUNT(name) > 10
```

In our notation, both the WHERE and HAVING clauses translate into guards of the comprehension.

```haskell
[ (the dept, sum salary) | (name, dept, salary) <- employees , salary > 50 , group by dept , length name > 10 ]
```

Rebinding variables to lists leads naturally to guards that follow group serving the same purpose as HAVING clauses.

### 3.8 Zip

GHC and Hugs have for some time supported an extension to list comprehensions that makes it easy to draw from two lists in parallel. For example:

```haskell
[ x+y | x <- [1..3] | y <- [4..6] ]
```

Here we draw simultaneously from the two lists, so that the comprehension returns $[5,7,9].$ Of course there can be multiple qualifiers in each of the parallel parts. For example:

```haskell
[ x+y | x <- [1..3], order by Down x | y <- [4..6] ]
```

Here we sort the first list in reverse order, so that the comprehension returns $[7,7,7].$

### 3.9 Parenthesised qualifiers

With the new generality of qualifiers, it makes sense to parenthesise qualifiers. For example, consider

```haskell
p1 = [ (x,y,z) | x <- [1,2] | y <- [3,4] , z <- [5,6] ]
```

Here we draw from the first two lists in parallel, and then take all combinations of such pairs with elements of the third list, so that the comprehension returns

$[(1,3,5), (1,3,6), (2,4,5), (2,4,6)].$

It would mean something quite different if we wrote

```haskell
p2 = [ (x,y,z) | x <- [1,2] | ( y <- [3,4] , z <- [5,6] ) ]
```

Here we take all combinations of elements from the last two lists, and draw from that list and the first list in parallel. There are four elements in list of combinations, but only two in the first list, so the extra ones are dropped, and the comprehension returns

$[(1,3,5), (2,3,6)].$

(The parentheses on the qualifiers are redundant in this second example, because we take comma to bind more tightly than bar.)

Similar considerations apply to order and group. Consider

```haskell
p3 = [ (x,y) | ( x <- [1..3] , y <- [1..3] ) , order by x >= y using takeWhile ]
```

and

```haskell
p4 = [ (x,y) | x <- [1..3], ( y <- [1..3] , order by x >= y using takeWhile ) ]
```

which differ only in how the qualifiers are parenthesised. The first returns

```
[ (1,1) ]
```

while the second returns

```
[ (1,1), (2,1), (2,2), (3,1), (3,2), (3,3) ].
```
Similarly, parentheses can be used to control exactly how group works. Consider

\[ p5 = \{(x, y, \text{the } b) \mid (x \leftarrow [1..3]), (y \leftarrow [1..3]), \text{let } b = (x \geq y)\} \]

and

\[ p6 = \{(x, y, \text{the } b) \mid x \leftarrow [1..3], (y \leftarrow [1..3]), \text{let } b = (x \geq y), \text{group by } b\} \]

which differ only in how the qualifiers are parenthesised. The first returns

\[ \{(1, 2, 3, 3, 3), (1, 1, 2, 1, 2), (2, 3, 3, 3, 3), (1, 1, 2, 1, 2), (2, 3, 3, 3, 3), (3, 1, 2, 3, 3), (3, 1, 2, 3, 3), (3, 1, 2, 3, 3), (3, 1, 2, 3)\} \]

while the second returns

\[ \{(1, 1, 1, 1), (1, 2, 1, 2), (2, 1, 1, 2), (2, 1, 1, 2), (2, 1, 1, 2), (2, 1, 1, 2), (2, 1, 1, 2), (2, 1, 1, 2)\} \]

Not only the answers are different, but even the types of the answers. Since \( x \) is in scope of the group in \( p6 \), it is bound to a list of integers in the result, while since \( x \) is not in scope of group in \( p6 \) comprehension, it is bound to an integer in the result.

If no parentheses are used, both order and group scope as far to the left as possible, so that

\[ p3' = \{(x, y) \mid x \leftarrow [1..3], y \leftarrow [1..3], \text{order by } x \geq y \text{ using takeWhile}\} \]

behaves the same as example \( p3 \). As we shall see in the next section, the syntax ensures that there is always a qualifier to the left of an order or group.

All of this may seem a little tricky, but the good news is that parentheses are never required. Instead, one can simply use a nested comprehension, at some modest cost in duplicated variable bindings. For example, \( p4 \) can be written:

\[ p4' = \{(x, y) \mid x \leftarrow [1..3], y \leftarrow [1..3], \text{order by } x \geq y \text{ using takeWhile}\} \]

### 4. Semantics

We now explain the semantics of extended comprehensions, looking at the syntax, the type rules, the translation into a language without comprehensions, and the role of parametricity.

#### 4.1 Syntax

The syntax of comprehensions is given in Figure 1. We let \( x, y, z \) range over variables, \( e, f, g \) range over expressions, \( w \) range over patterns, and \( p, q, r \) range over qualifiers. A comprehension consists of an expression and a qualifier. There are two qualifiers that bind a single pattern (generators and \( \text{let} \)), two that bind no variables (guards and empty qualifiers), two that combine two qualifiers (cartesian product and zip), and two that modify a single qualifier (order and group). In a generator the expression is list-valued, while

![Figure 1: Syntax of list comprehensions](image)

![Figure 2: Typing of list comprehensions](image)
in a guard the expression is boolean-valued. Generators and let contain patterns, which consist (for now) of variables and tuples.

The generator, let, guard, and cartesian product qualifiers are found in Haskell 98 (with cartesian product restricted to disallow nesting), and the zip qualifier is found in GHC (with zip restricted to disallow nesting, see Section 7.3.4 of the GHC manual). The generator let \( w = d \) is equivalent to \( w \leftarrow [d] \). The empty qualifier is not much use in practical programs, but can be useful when manipulating comprehensions using laws.

The grammar explicitly indicates that parentheses may be used with qualifiers. The order and group constructs extend as far to the left as possible, comma binds more tightly than bar, and we assume comma and bar associate to the left. (In fact, our semantics will make both comma and bar associative.)

In order and group, either the by clause or the using clause may be optionally omitted, but not both. A missing using clause expands to invoke the default functions sortWith and groupWith as defined in Sections 2 and 3.5:

- \( q \), order by \( e \), order by \( e \) using sortWith
- \( q \), group by \( e \), group by \( e \) using groupWith

A missing by clause expands as described in Sections 3.3 and 3.6:

- \( q \), order using \( f \), order by \( () \) using \( \lambda x. f \)
- \( q \), group using \( f \), group by \( () \) using \( \lambda x. f \)

where \( x \) does not appear in \( f \).

4.2 Types

The type rules for comprehensions are given in Figure 2. We let \( \tau \) range over types, \( \alpha \) range over type variables, and \( \Gamma \) and \( \Delta \) range over environments mapping variables to types. The typing judgement \( \Gamma \vdash e : \tau \) indicates that in environment \( \Gamma \) the term \( e \) has type \( \tau \). We only give here the rule for comprehensions (rule COMP).

The typing judgement \( \Gamma \vdash w : \tau \Rightarrow \Delta \) indicates that pattern \( w \) of type \( \tau \) binds variables with typings described by \( \Delta \). A variable yields a single binding (rule VAR), while a tuple yields the union of its bindings (rule TUP).

The typing judgement \( \Gamma \vdash q : \Delta \) indicates that in environment \( \Gamma \) the qualifier \( q \) binds variables with typings described by \( \Delta \). A guard and the empty qualifier yield no bindings (rules GUARD and UNIT), while a generator and a let binding yield a binding for each variable in \( w \) (rules GEN and LET).

A cartesian product and a zip yield the bindings introduced by their contained qualifiers (rules COMMA and BAR). However these two rules are not identical: in the cartesian product all bindings introduced by the qualifier on the left \( p \) are in scope for the qualifier on the right \( q \), while this is not the case for a zip.

The rules for order and group require that \( f \) has a polymorphic type and, in the case where there is a by clause, the return type \( \tau \) of \( f \)'s argument function must match the type of \( e \) (rules ORDER1 and GROUP1). The typing rules for group also indicate that the type of the bound variables changes to contain lists of the previous type (rules GROUP1 and GROUP2). If \( \Delta \) is the environment

\[
x_1 : \tau_1, \ldots, x_n : \tau_n
\]

then \([\Delta]\) is the environment

\[
x_1 : [\tau_1], \ldots, x_n : [\tau_n].
\]

Note that in an order or a group, the bindings yielded by the contained qualifier \( q \) are in scope for the expression \( e \) in the by clause, but not in scope for the expression \( f \) in the using clause.

4.3 Translation

We define the dynamic semantics of comprehensions by giving a translation into a simpler, comprehension-free language. The translation is given in Figure 3. It is specified in terms of two operations on qualifiers. If \( q \) is a qualifier, then

- \( \{q\} \) is a tuple of the variables bound in \( q \).
- \([q]\) is the list of tuples computed by \( q \).

In general, if \( q : \tau \) then \([q] : [\tau] \). For example, for the qualifier

\[
x = [1, 2, 3], y \leftarrow ['a', 'b']
\]

then

\[
q_n : \text{[Int,Char]} = ((x,y), [(1,'a'),(1,'b'),(2,'a'),(2,'b'),(3,'a'),(3,'b')])
\]

The top-level translation for comprehensions is given by

\[
[ e \mid q ] = \text{map} (\lambda q. e) [q]
\]

Figure 3: Translation of comprehensions

\[
\begin{align*}
(p,q) & = p \otimes q_v \\
(p \mid q) & = p \otimes q_v \\
[p,q] & = \text{concatMap} (\lambda p. \text{map} (\lambda q. p_v \otimes q_v) [q]) [q] \\
[p \mid q] & = \text{zipWith} (\lambda p. \text{unzip} p_v, p_v \otimes q_v) [q] [q]
\end{align*}
\]

Figure 4: Translation of comprehensions with tuple concatenation

The definition of \( q_n \), the tuple of variables bound by \( q \), is straightforward (Figure 3). A generator or let binds the variables in the pattern, a guard or empty qualifiers binds no variables, a cartesian product or zip binds a pair consisting of the bound variables of the
After applying `groupWith` implements `unzip` tions 2 and 3.5 respectively, while the standard Prelude function

The functions `groupWith` and `sortWith` were introduced in Sections 2 and 3.5 respectively, while the standard Prelude function

```
unzip3 :: [(a,b,c)] -> ([a], [b], [c])
```

and `sortWith` were introduced in Section 4.4 Parametricity

The type rules for order and group require the supplied function to have a universally quantified type. Here, for instance, is the rule for order:

```
Γ ⊢ q : σ → τ 
Γ ⊢ e : σ 
Γ ⊢ f : ∀a. (a → τ) → [a] → [a] 
Γ ⊢ q, order by c using f ⇒ Δ 
```

Finally, mapping over this list gives the desired result

```
map (\(\text{name,dept,sal} \rightarrow (\text{the dept, sum sal})\))
\text{employees})
```

implies `unzip3(name,dept,sal)`. Let us follow how this works in detail. Here is the original list of employees:

```
employees
= [ ("Dilbert", "Eng", 80) 
, ("Alice", "Eng", 100) 
, ("Wally", "Eng", 40) 
, ("Catbert", "HR", 150) 
, ("Dogbert", "Con", 500) 
, ("Ratbert", "HR", 90) ]
```

After applying `groupWith` we get

```
groupWith (\(\text{name,dept,sal} \rightarrow \text{dept}\))
\text{employees}
= [ [ ("Dogbert", "Con", 500) ] 
, [ ("Dilbert", "Eng", 80) ] 
, [ ("Alice", "Eng", 100) ] 
, [ ("Wally", "Eng", 40) ] 
, [ ("Catbert", "HR", 150) ] 
, [ ("Ratbert", "HR", 90) ] ]
```

Arguably, we might instead have chosen `f` to have a more general type:

```
f : \forall a. (a → b) → [a] → [a]
```

Or a more specific one:

```
f : (σ → τ) → [σ] → [σ]
```

where `σ` is the tuple type `(τ₁, ..., τₙ)` when `Δ` is `x₁ : τ₁, ..., xₙ : τₙ`. Why do we choose to universally quantify one argument but not the other?

We do not choose the more general type because it is too general. The choices we have seen for `f` include the following.

```
sortWith : \forall a. \text{Ord} b ⇒ (a → b) → [a] → [a] 
\text{takeWhile} ⇒ (a → \text{Bool}) → [a] → [a]
```

If we required `f` to have the more general type, then we could not instantiate `f` to either of these functions. So we need a more specific type.
Similarly, we do not choose the more specific type because it is too specific; it requires us to fix details of how tuples of bound variables are encoded. Indeed, the nested encoding of tuples in the preceding section does not quite match the flat encoding of environments given above. For example, recall that the qualifier
\[ q = (x \leftarrow xs, y \leftarrow ys), z \leftarrow za \]
yields the tuple of bound variables \( q_v = ((x, y), z) \), whereas to use the more specific type given above we would need to choose \( q_v = (x, y, z) \). So we need a more general type.

Using a universally quantified type not only ensures that the function has the right type to work with arbitrary encodings of tuples, but also ensures that changing the encoding will not change the semantics. This follows because semantic parametricity (sometimes called ‘theorems for free’), which ensures universally quantified functions satisfy certain properties (Reynolds 1983; Wadler 1989).

In particular, the type
\[ f : \forall a. (a \rightarrow \tau) \rightarrow [a] \rightarrow [a] \]
has the following free theorem
\[ \text{map } h \cdot f (g \cdot h) = f g \cdot \text{map } h \]
and this is exactly what is required to ensure that \( f \) gives the same result for different ways of encoding the environment. For example, we can relate the operation of \( f \) on the two different encodings of tuples discussed above by choosing
\[ h (x, (y, z)) = (x, y, z). \]
This has the consequence—which is exactly what we would expect and hope for!—that the meaning of a comprehension is independent of precise details of how binding tuples are encoded. For instance, Figure 4 shows how to modify Figure 3 to use a 
\[ -\text{tuple and yields an} -\]
while with the new translation (Figure 4), this yields the tuple of bound variables
\[ ((x, y, z)) \]
and this is exactly what is required to ensure that
\[ (x, y, z) \]
we have
\[ \left[ \begin{array}{l} (x, y, z) = (x, y) \\ (x, y) = (x, y) \end{array} \right. \]
and similarly when \( n = 0 \) or \( n = 1 \).

For instance, consider the qualifier \( q \) given above. With the old translation (Figure 3), this yields the tuple of bound variables \( q_v = ((x, y), z) \) while with the new translation (Figure 4), this yields the tuple of bound variables \( q_v = (x, y, z) \) The definition of \( [g] \) is changed correspondingly. Thanks to our requirement of universally quantified types for \( \text{order and group} \), we can guarantee that both choices of translation yield the same results.

4.5 Another translation

The style of translation given here differs from that in, say (Wadler 1987), in that qualifiers \( q \) are translated separately into tuples of bound variables \( q_v \) and lists of bindings \([q] \). Figure 5 gives an alternative, and more conventional translation, where qualifiers translate directly to binding constructs. It is easy to check that the translations of Figures 3 and 5 are equivalent. In particular, this means that the new definitions of the traditional qualifiers (generator, let*, guard, empty qualifier, and cartesian product) coincide with the traditional definitions, and hence that the new definition is a conservative extension of the old.

We choose the formulation of Figure 3 partly on aesthetic grounds, because it gives a direct, compositional translation to qualifiers themselves rather than only to qualifiers embedded in a comprehension. Furthermore, for group and order the translation is somewhat more compact and efficient, because it does not require the construction of nested comprehensions.

4.6 General patterns in generators

Thus far, the syntax in Figure 1 and semantics in Figure 3 permits only variable and tuple patterns in generators, a choice we made to reduce clutter and focus attention on order and group.

However, in Haskell a generator can use an arbitrary pattern, where a pattern that can fail to match acts as an implicit filter. For example:
\[ f :: [Maybe Int] \rightarrow \text{Int} \]
\[ f \text{ xs} = \text{sum} [x \mid \text{Just } x \leftarrow \text{xs}] \]

Here, only the elements of \( \text{xs} \) that match the pattern \( (\text{Just } x) \) are chosen from \( \text{xs} \). It is easy to accommodate general patterns in generators, as we show in Figure 6.

5. Laws

The semantics we have given validates a number of laws. We begin with a number of laws that carry over unchanged from the usual treatment of comprehensions (Wadler 1992). It is a significant feature of the new formulation that it does not violate any of these laws.

The most significant law is the nesting law (which also appears as a line in Figure 5):
\[ [e \mid p, q] = \text{concat} \{ [e \mid q] \mid p \} \]
This is easily checked, as the left and right sides yield to the same term using the translation of Figure 3.

We also have a flattening law:
\[ [e \mid p, x \leftarrow [f \mid q], r] = [e[x := f] \mid p, q, r[x := f]] \]
This is an immediate consequence of nesting and the following simpler law:
\[ [e \mid x \leftarrow [f \mid q]] = [e[x := f] \mid q] \]

The simpler law is an immediate consequence of the translation and the map composition law:
\[ \text{map } f \cdot \text{map } g = \text{map } (f \cdot g) \]
(Wadler (1992) suggests the use of induction over the structure of comprehensions to prove the flattening law, but this is not necessary.)

A special case of the flattening law is:
\[ q = q_v \leftarrow [q_v \mid g] \]

Among other things, this law can be used to make clear grouping without using parentheses, as we saw in Section 3.9.
Cartesian product is associative with the empty qualifier as unit:
\[
\begin{align*}
[e \mid (p, q), r] &= [e \mid (p, q, r)] \\
[e \mid p, O] &= [e \mid p] \\
[e \mid O, p] &= [e \mid p]
\end{align*}
\]
This is easily checked, using the fact that concat and unit are natural transformations and form a monad (where unit \( x = \{x\} \)):
\[
\begin{align*}
\text{map } f \cdot \text{concat} &= \text{concat} \cdot \text{map} \, (\text{map } f) \\
\text{map } f \cdot \text{unit} &= \text{unit} \cdot f \\
\text{concat} \cdot \text{concat} &= \text{concat} \cdot \text{map} \, \text{concat} \\
\text{concat} \cdot \text{unit} &= \text{id} \\
\text{concat} \cdot \text{map} \, \text{unit} &= \text{id}
\end{align*}
\]
Another law relates zip of cartesian product to cartesian product of zip. If \( xs \) and \( ys \) have the same length, and \( uA \) and \( vA \) have the same length, then
\[
\begin{align*}
(x <- xs \mid y <- ys), (u <- uA \mid v <- vA) \\
= (x <- xs, u <- uA) \mid (y <- ys, v <- vA)
\end{align*}
\]
The proof is by induction of \( xs \) and \( ys \), with lemmas proved by inducting over \( uA \) and \( vA \).

We also have some laws specifically applicable to order. Since the default ordering function is a stable sort, sorting on two keys in succession is equivalent to sorting on a pair of keys:
\[
\text{order by } d, \text{order by } e = \text{order by } (d, e)
\]
When there is no by clause, ordering with two functions in succession is equivalent to ordering by the composition of the two:
\[
\text{order using } f, \text{order using } g = \text{order using } (g \cdot f)
\]
Combining by and using is a bit messier:
\[
\text{order by } d \text{ using } f, \text{order by } e \text{ using } g = \text{order by } (d, e) \text{ using } \lambda h. g \cdot (\text{snd} \cdot h) \cdot f \cdot (\text{fst} \cdot h)
\]
The using function takes function \( h \) that extracts a pair of keys, runs \( f \) passing it the extractor function for the first key, and then similarly \( g \) passing it the extractor function for the second key.

However, analogues of the three above laws do not appear to hold for group, since a single group changes all bound variables to lists, while two adjacent groups change all bound variables to lists of lists.

6. Variations on the theme

Thus far we have concentrated on describing a particular design in complete detail. However there are many design choices to be made, and we explore a few of them here, albeit in less detail.

6.1 Concrete syntax

We are unhappy with the use of the keyword order because, with a user-defined function such as take, no reordering at all may be involved. One suggestion is to re-use the keyword “then”, followed immediately by the function to use:
\[
\begin{align*}
[\text{(the dept, sum salary)}] \\
| (\text{name, dept, salary}) <- \text{employees} \\
& \text{, then sortWith by salary} \\
& \text{, then takeWhile by salary < 50} \\
& \text{, then take 5 ]}
\end{align*}
\]
The “by” clause remains optional, but the ordering function is not. (Perhaps it would read better to say “using” instead of “by” in this context.)

6.2 Binding in group

In our main design, group implicitly re-binds all the in-scope variables to lists of their previous type. This implicit re-binding is convenient in small examples, but it is arguably rather surprising—it is certainly unique in Haskell’s design—so it might be worth considering a more verbose but explicit syntax such as:
\[
\begin{align*}
[\text{(the dept, namesalary)}] \\
| (\text{name, dept, salary}) <- \text{employees} \\
& \text{, the dept <- group by dept} \\
& \text{where (name, salary) -> namesalary}
\end{align*}
\]
Here, the group form is extended to bind a fresh variable, the dept, which is of course takes one value for each group. The where clause specifies that the namesalary list is constructed by stuffing all the (name, salary) pairs from a group into a list. In general one could have an arbitrary expression to the left of the “->”.

One could debate the concrete syntax, but the main design question is whether the clumsiness of extra syntax justifies the extra clarity.

6.3 Cubes and hierarchies

Another extension to SQL is the CUBE construct. The main idea is to support multi-level aggregation. For example, suppose we have a relation sales that gives the name, colour, size, and cost, of a number of products. Consider the query
\[
\begin{align*}
\text{SELECT } & \text{size, colour, SUM(cost)} \\
& \text{FROM sales} \\
& \text{GROUP BY CUBE( size, colour )}
\end{align*}
\]
This query might return:
\[
\begin{align*}
& \text{large blue 10} \\
& \text{large red 20} \\
& \text{small blue 30} \\
& \text{small red 40} \\
& \text{large NULL 30} \\
& \text{small NULL 70} \\
& \text{NULL blue 40} \\
& \text{NULL red 60} \\
& \text{NULL NULL 100}
\end{align*}
\]
The special value NULL is used to indicate an aggregated attribute; for instance, the line with size large and colour NULL contains the sum of the entries for the lines with size large and colours blue and red.

To support this kind of multi-level aggregation we need one further generalisation of our notation:
\[
\begin{align*}
[\text{(sc, sum cost)}] \\
| (\text{size, colour, cost}) <- \text{sales} \\
& \text{, sc <- hgroup by [size,colour] using groupCube ]}
\end{align*}
\]
The construct is introduced by a new keyword hgroup, and the user-supplied grouping function groupCube has type
\[
\text{groupCube ::} \\
(\text{a -> [String]}) -> [([\text{Maybe String}], [\text{a}])]
\]
Here, the key-extractor function returns a list of strings (size and colour in this case), which groupCube uses to make groups under various combinations of this list (as above). It differs from the previous group by construct, because the grouping function must return a list of pairs: the first component records which subset of the key list identifies this group, while the second component holds the members of the group. Corresponding to the previous result, the query might return
\[
\begin{align*}
& [\text{(Just "large", Just "blue", 10)}] \\
& [\text{(Just "large", Just "red", 20)}] \\
& [\text{(Just "small", Just "blue", 30)}] \\
& [\text{(Just "small", Just "red", 40)}]
\end{align*}
\]
6.4 Implicit result concatenation

In a breadth-first search over a tree, one might write this:

```plaintext
concat [ [t1,t2] | Node _ t1 t2 <- trees ]
```

or alternatively

```plaintext
[ t | Node _ t1 t2 <- trees, t <- [t1,t2] ]
```

Neither is very appealing. A simple possibility, suggested to us by Koen Claessen, is to allow the programmer to write a comma-separated list of values before the initial vertical bar of the comprehension, thus:

```plaintext
[ t1, t2 | Node _ t1 t2 <- trees ]
```

The semantics is given by:

```plaintext
[ e1, ..., en | q ] = concatMap (λq. [e1, ..., en]) [q]
```

This proposal is orthogonal to the rest of this paper.

7. Related work

We now consider how we would express the two SQL queries from the introduction in XQuery and LINQ. Recall the queries are

- **SELECT** name
  FROM employees
  WHERE salary < 50
  ORDER BY salary

- **SELECT** dept, SUM(salary)
  FROM employees
  GROUP BY dept

7.1 XQuery

We assume that the XQuery variable $employees is bound to a sequence of employee elements, where each employee element contains a name, dept, and salary element.

In XQuery, we would write the first query above as

```plaintext
<query1>{
  for $employee in $employees
  where $employee/salary > 50
  order by $employee/salary
  return $employee/name
}</query1>
```

XQuery is based on a notion of comprehension (called a FLWOR expression), which includes an order by clause similar to the one described here, added precisely in order to make it easy to parallel the behaviour of SQL. Unlike our extension to Haskell, uses of order by are limited to sorting, with options for multiple keys each in ascending or descending order.

We would write the second query as:

```plaintext
<query2>{
  for $d in fn:distinct-values($employees/dept)
  let $g = $employees[dept = $d]
  return <group>(
    $dept, 
    <sum>{ fn:sum($g/salary) }<sum>
  )</group>
}</query2>
```

This is similar to the technique used for Haskell of writing nested comprehensions, but slightly smoother because the XPath subset of XQuery provides compact notation for extracting elements from a sequence or filtering on the value of an element. XQuery has no construct that parallels GROUP BY directly.

Two proposals to add grouping constructs to XQuery have been put forward by others. The first of these, Beyer et al. (2005) resembles ours in that the grouping construct changes the sequence of bindings, but it has explicit constructs to bind values that index groups (such as dept) and values aggregated within groups (such as salary). Here is how the running example would look:

```plaintext
<query2>{
  for $e in $employees
  group by $e/dept into $dept
  nest $e/salary into $salaries
  return <group>(
    $dept, 
    <sum>{ fn:sum($salaries) }<sum>
  )</group>
}</query2>
```

The second proposal, Kay (2006) uses a predicate on adjacent elements to decide where a break between groups should occur (similar to groupBy in the current Haskell library), whereas our construct looks at individual bindings. Neither proposal supports user-defined functions for grouping or ordering.

7.2 LINQ

Using the LINQ features of C# 3.0, the first query is written as

```csharp
from e in employees
where e.salary < 50
orderby e.salary
select e.name
```

As with XQuery, this is easy to write because comprehensions are extended with an orderby construct that parallels the behaviour of SQL, and is limited to sorting, again with options for multiple keys each in ascending or descending order.

We would write the second query as:

```csharp
from e in employees
  group e by e.dept into g
  select new { g.Key, g.Sum( e => e.salary ) }
```

This is shorthand for a nested comprehension

```csharp
from g in
  from e in employees
  group e by e.dept
  select new { g.Key, g.Sum( e => e.salary ) }
```

LINQ can return nested structures, whereas SQL can only return flat relations. The group operation always returns a collection of items belonging to a group type, where a group consists of a key and a collection. Nested constructs are used to explicitly loop over the groups.
LINQ differs from our proposal, in that it is tied to a specific grouping function and a group data type, and it requires a separate nested loop over groups.

LINQ queries are also general in a way that ours are not: LINQ queries operate over any arbitrary container type that implements a particular interface. One reason for this generality is to support meta-programming, so that a query generates a so-called expression tree that can (in many cases) be translated to SQL. It is natural to ask whether our extensions could similarly extend to an arbitrary monad, a direction we have not yet investigated.

8. Conclusion and further work

List comprehensions are a very modest language construct: they provide syntactic sugar, but offer no new expressive power. Nevertheless, syntactic sugar can be important and, in the Darwinian process of language evolution, list comprehensions have prospered. It therefore seems productive to consider extensions of this syntactic sugar that share the modest cost of existing comprehensions while extending their power.

In this paper we have presented extensions to Haskell list comprehensions that parallel the ORDER BY and GROUP BY clauses of SQL. Constructs that parallel ORDER BY are also found in XQuery, LINQ, and Links, but not in (unextended) Haskell, CPL, Erlang, or Kleisi. A construct that parallels GROUP BY is found in LINQ, and proposed for extensions to XQuery, but does not appear in any other language so far as we know.

The new constructs proposed here are more general than the constructs in the other languages, because they work with any function of a given type, rather than being limited to specific functions. Parametricity of these functions plays an important role in ensuring the semantics of such constructs is independent of particular details of how tuples of bindings are represented.

The grouping construct is also unusual in that it rebinds each variable in scope, from a single value to a list of values. This seems close in spirit to the behaviour of GROUP BY in SQL, but is arguably more uniform. The separate WHERE and HAVING clauses are subsumed by comprehension guards, and the same construct supports both aggregation and nested lists.

We have implemented a simple prototype of the translation given here to confirm its correctness. We plan to implement the new construct both in the GHC compiler for Haskell and in the Edinburgh implementation of Links, and look forward to feedback from their use. Links uses comprehensions to write queries that access a database, and the compiler converts as much of these as possible into SQL. The new constructs should allow us to compile into queries that use SQL GROUP BY and aggregate functions where appropriate.

It may be possible to generalize the ideas presented here. Since group and order seem so similar, it is natural to wonder whether there might be a more general construct of which these two are a special case. The type of the function $f$ could be generalised to

$$f :: \forall a. (a \rightarrow \tau) \rightarrow [\alpha] \rightarrow [C \ a]$$

where $C : * \rightarrow *$. For order, $C$ is the identity function on types, while for group $C$ is the list type constructor $\left[\right]$. In this more general setting we must be able to derive from $C$ a canonical unzipping function $\text{unzip}^C : C(a, b) \rightarrow (C a, C b)$. There seem to be two difficulties with such a generalisation: finding $C$ might be hard (in general, higher order unification is undecidable); and even given $C$ it may not be clear what the canonical $\text{unzip}^C$ should be. It may also be possible to generalise from lists to monads. This seems relatively straightforward, modulo the difficulty of generalizing unzip. However, it is not clear whether either generalization would be sufficiently useful to justify the increase in complexity.

Lastly, in view of the generality of the new constructs, we wonder whether they might also constructively feed back into the design of new database programming languages.

Acknowledgements

Many thanks to Erik Meijer, who prodded us to find comprehension equivalents for ‘order by’ and ‘group by’, and to Michael Adams, David Balaban, Botje, Koen Claessen, Ezra Cooper, Gavin Bierman, Falcon, Fanf, Sam Lindley, Neil Mitchell, Tom Schrijvers, Jerome Simeon, Ganesh Sittampalam, Dan Suciu, Don Syme, Sjoerd Visscher, for their helpful feedback.
