Abstract

The Discrete Element Method (DEM) has been employed to simulate vertical one-dimensional compression of an idealized soil. Direct measurement of the full stress tensor was possible and the results show that $K_0$ (the ratio of horizontal to vertical effective stresses) increases with void ratio, which is consistent with previous experimental studies. The anisotropic fabric induced during compression was quantified by considering the orientations and magnitudes of the normal contact forces. For the denser samples there was a definite bias towards more vertically-oriented contacts, resulting in lower stresses being transmitted in the horizontal direction for a given vertical stress. In contrast, the contacts were oriented more isotropically in the looser samples, allowing more similar stresses to be transmitted in the horizontal and vertical directions.

Keywords: Discrete-element modelling; fabric/structure of soils; particle-scale behaviour
1. Introduction

The coefficient of lateral earth pressure at rest ($K_0$), defined as the ratio of horizontal effective stress ($\sigma'_{h}$) to vertical effective stress ($\sigma'_{v}$) measured under zero lateral strain conditions, is an important parameter used for the design of geotechnical structures. Measurement of horizontal effective stresses is non-trivial and so practising engineers tend to use the formula put forward by Jaky (1944), which correlates $K_0$ to the angle of shearing resistance:

$$K_0 = 1 - \sin \phi'$$ \hspace{1cm} (1)

Where $\phi'$ is the effective angle of shearing resistance which is often taken as the angle of shearing resistance at the critical state ($\phi'_{cr}$) (Jaky, 1944; Mesri & Hayat, 1993). This definition implies that there is a unique $K_0$ value for a given soil type and that $K_0$ is independent of initial state (i.e., packing density and stress level). The angle of shearing resistance at the peak stress ($\phi'_{p}$) is sometimes used in equation (1) (Mesri & Vardhanabhuti, 2007; Talesnick, 2012; Lee et al, 2013). $\phi'_{p}$ depends on the material state (Been & Jefferies, 1985); thus if $\phi'_{p}$ is used in Equation (1), at a given stress level $K_0$ will increase with increasing void ratio. While Jaky’s equation has been successfully applied in a large range of engineering applications, it may fail to predict the measured $K_0$ as it does not consider certain factors in the granular materials that may affect the $K_0$ value. $K_0$ experiments conducted by Chu & Gan (2004) and Wanatowski & Chu (2007) found relatively high $K_0$ values and a marked sensitivity of the $K_0$ response to the initial void ratio ($e_0$) for loose sand samples; for denser sands the $K_0$ values were lower and less sensitive to variations in packing density. Similar observations were reported by Okochi & Tatsuoka (1984), Mesri & Vardhanabhuti (2007), Northcutt & Wijewickreme (2013) and Lee et al (2013). In contrast, Talesnick (2012) reported higher $K_0$ values for dense states than for loose ones. It is worth mentioning that the differences in the experimental procedures, testing devices, sample preparation techniques and data acquisition methods between the studies likely influence any variation in the observed $K_0$– void ratio dependency.

Differences in size, shape or roughness of particles also influence the measured $K_0$ values. Lee et al (2013) measured higher values of $K_0$ for non-etched glass beads than for etched glass beads. Furthermore, sub-angular and angular particles showed lower values of $K_0$ than glass beads. Changes in particle shape and hence in the connectivity of particles affect the fabric of granular materials which is closely related to the $K_0$ values (Guo & Stolle, 2006; Northcutt & Wijewickreme, 2013).

Lee et al (2013) attributed the low values obtained for $K_0$ of dense materials to the development of strong force chains in the vertical direction, leading to less stress transmission in the horizontal direction. However, Talesnick (2012) attributed the high $K_0$ values for dense materials to the dilatant
nature of dense soils: it is difficult to accept this explanation as dilation is suppressed during one-dimensional compression. This contribution aims to develop a science-based, fundamental understanding of the dependency of $K_0$ on void ratio. Discrete Element Method (DEM) simulations of one-dimensional compression tests were performed; the stresses could be directly calculated from the contact forces and so the vertical and horizontal stresses could be quantified accurately which is difficult to achieve in physical experiments.

2. DEM Simulations

This study used a modified version of the open-source code LAMMPS (Plimpton, 1995). Three-dimensional numerical samples were created as a representative volume element consisting of 22,312, initially non-contacting, spherical particles enclosed by periodic boundaries. These boundary conditions eliminate inhomogeneities (Thornton, 2000; Huang et al, 2014a). The particle size distribution (PSD) used for all simulations is representative of Toyoura sand (Figure 1). A simplified Hertz-Mindlin contact model was used. The input parameters were a shear modulus ($G$) of 29 GPa, particle Poisson’s ratio ($\nu$) of 0.12, particle density ($\rho$) of 2650 kg/m$^3$ and local damping coefficient of 0.1. Initially, the periodic cell was deformed until the system reached an isotropic stress state with an initial mean effective stress ($p'_0$) of 25 kPa. After reaching the desired $p'_0$, the system was subjected to numerical cycling until $p'$ and the number of contacts became constant indicating equilibrium. Ten samples were created and the initial void ratio of each sample was controlled using different inter-particle friction coefficients ($\mu$) during the isotropic compression stage, as indicated in Table 1.

Once the isotropic compression stage had been finished, $\mu$ was set to 0.25 (Huang et al, 2014b). One-dimensional compression was then simulated by deforming the periodic cell: the top boundary was moved at a constant velocity in the vertical direction while the horizontal and bottom boundaries were maintained in a fixed position. The velocity chosen was sufficiently small to ensure that the system was maintained in the quasi-static regime (i.e., inertial number ($I$) $\leq$ 2.5$\times$10$^{-3}$) (MiDi, 2004; da Cruz, 2005). The stresses in the periodic cell were determined using the particle and contact force data (Bagi, 1996; Potyondy & Cundall, 2004). Ten triaxial tests were carried out to define the $e_0 - \phi'_p$ relationship and obtain $\phi'_cv$ for the simulated sand. Details of the triaxial simulations and corresponding results are shown in Table 2.

3. Results

3.1. Macro response

Results from six representative one-dimensional compression tests are plotted in Figure 2. The initial void ratios at the start of compression ranged from $e_0 = 0.544$ as the densest sample to $e_0 = 0.664$ corresponding to the loosest of these six samples. Tests were terminated at mean effective stress ($p'$)
values between 750 and 950 kPa. Referring to Figure 2(a), the effective stress ratio \((q/p')\) decreased as \(e_0\) increased. Figure 2(b) indicates that the axial strain level \((\varepsilon)\) at which a given value of \(q\) was reached increased with \(e_0\). For the densest sample \((e_0 = 0.544)\), \(q = 100\) kPa was achieved at \(\varepsilon \approx 0.07\%\), while for the loosest sample \(e_1\) exceeded 0.25% at the same \(q\) level. Figure 2 also includes results from laboratory tests from Chu & Gan (2004) and Wanatowski & Chu (2007), which indicate that the observations from the simulations are qualitatively consistent with the experimental data.

The horizontal stresses were calculated as the mean value of \(\sigma'_{x}\) and \(\sigma'_{y}\). Figure 3(a) illustrates the variation of \(K_0\) with effective vertical stress \((\sigma')\), while Figure 3(b) illustrates the variation in \(K_0\) with the major principal strain \((\varepsilon)\) (i.e., the vertical strain); both sets of data illustrate a clear dependency of \(K_0\) upon \(e_0\). Generally, loose samples attained higher \(K_0\) values than denser samples, in line with previous experimental observations by Chu & Gan (2004), Wanatowski & Chu (2007) and Okochi & Tatsuoka (1984) that are included in Figure 3 for comparison. Interestingly, while different preparation methods were used in the experimental studies, i.e., as air pluviation (Okochi & Tatsuoka, 1984) or moist tamping (Chu & Gan, 2004, Wanatowski & Chu, 2007) and different initial stress conditions were applied, the trend is more or less the same for all the experiments and DEM simulations. Note that \(K_0\) did not reach a constant value when plotted either against either \(\sigma'\) or \(e_1\) but decreased continuously for all samples, indicating that \(K_0\) depends on \(\sigma'\) and \(e_1\).

Figure 4(a) shows the variation of \(K_0\) with initial void ratio at three discrete values of \(\sigma'\) while Figure 4(b) gives \(K_0\) at three discrete \(e_1\) values. For each value of \(\sigma'\) or \(e_1\) considered, the relationship between \(K_0\) and void ratio can be represented by a power law equation. Laboratory data in terms of \(K_0\) and \(e_0\) were collected and plotted in Figure 4 for comparison. The dashed lines correspond to Jaky’s equation used by Wanatowski & Chu (2007) from plane-strain and triaxial tests. Generally, \(K_0\) values obtained in the DEM simulations and laboratory tests increase with increasing \(e_0\). A power law relationship between \(K_0\) and \(e_0\) is identified for numerical data. This relationship differs from the linear \(K_0 e_0\) relationship observed and proposed by Chu & Gan (2004) and Wanatowski & Chu (2007) for loose marine sand samples prepared by moist tamping (MT) and water sedimentation (WS) methods. Results from Hendron (1963) indicate a gentler linear increase of \(K_0\) with \(e_0\) for rounded Minnesota sand. A steeper response was found for Toyoura sand as reported by Okochi & Tatsuoka (1984). The \(K_0\) values for Toyoura sand are closer to those from the numerical tests than other types of sand. Figure 4(a) illustrates a similar dependency of \(K_0\) on \(\sigma'\), observed by Okochi & Tatsuoka (1984). The differences between the magnitudes of \(K_0\) for the physical sands tested and for the numerical simulations can be attributed to particle size, shape (perfect spheres, angular and sub-angular sands) and differences in initial anisotropies (Guo & Stolle, 2006). It is important to note, however, that in the current study the structural anisotropy is induced entirely by the strain path.
imposed, while in the experimental studies, there will be an initial anisotropic structure as a consequence of gravity deposition during sample preparation.

Figure 4(c) compares the measured $K_o$ values with the predicted $K_o$ from Jaky’s equation using $\phi’_p$, $\phi’_{cv}$ and the angle of shearing resistance mobilized during the 1D compression tests ($\phi’_{mob}$), calculated from $\sin \phi’_{mob} = (\sigma’_v - \sigma’_h)/(\sigma’_v + \sigma’_h)$ at the same discrete values of $\sigma’_v$ where $K_o$ was directly measured. From the triaxial results shown in Table 2, an exponential relationship between $\phi’_p$ and $e_o$ as observed by Wanatowski & Chu (2006) is evident and thus the $K_o$–$e_o$ relationship is established. For the case of $\sigma’_v = 700$ kPa, Jaky’s equation overestimates the $K_o$ values for dense samples ($e_o < 0.65$) by as much as 0.12 considering $\phi’_p$ as input for Jaky’s formula, while for looser samples ($e_o > 0.65$), $K_o$ is underestimated by up to 0.05 when $\phi’_{cv}$ is used. Similar findings are presented by Wanatowski & Chu (2007) as indicated in Figure 4(a) which are consistent with how Jaky (1944) derived Equation (1), by considering a normally consolidated mass of soil in a loose condition and thus giving better predictions for loose states when considering $\phi’_{cv}$. The data points calculated for $K_o$ using $\phi’_{mob}$ in Jaky’s equation are located above those measured in the numerical simulations. Considering that the ratio of horizontal to vertical stresses can be expressed as $(1 - \sin \phi’_{mob})/(1 + \sin \phi’_{mob})$, applying $\phi’_{mob}$ in Jaky’s equation would displace the predicted values from those measured. The variance of the numerical $K_o$ is in line with those reported from laboratory experiments. This can be observed in Figure 5 which shows $K_o$ against $\phi’_{cv}$ for a range of soils including sands and clays as summarized by Wood (1990) based on results from Wroth (1972) and Ladd et al (1977). Jaky’s equation is included in Figure 5 where it can be observed how the experimental results are enclosed between -0.20 and +0.12 from Jaky’s equation with the numerical results also falling between those limits.

3.2 Micro scale analysis

Prior authors have attributed the $K_o$ dependency on void ratio to the different internal fabrics formed during sample preparation (Wanatowski & Chu, 2007; Lee et al, 2013). However, these relationships are hypothetical as the material fabric cannot be directly quantified in conventional laboratory tests. The DEM simulation data provide information on the direction of contacts. Satake (1982) proposed quantifying structural (fabric) anisotropy using the fabric tensor, which is defined as:

$$\Phi_F = \frac{1}{N_c} \sum_{i=1}^{N_c} n_i n_j$$

where $N_c$ is the total number of contacts and $n_i$ is the unit contact normal. The largest, intermediate and smallest eigenvalues of the fabric tensor are denoted as $\Phi_1$, $\Phi_2$, and $\Phi_3$ respectively. The ratio between $\Phi_3$ and $\Phi_1$ can be adopted to describe the degree of structural anisotropy: $F = \Phi_3/\Phi_1$, with the condition of $\Phi_3 = \Phi_2$ being closely satisfied. $F$ equalling to zero represents the highest degree of structural anisotropy while $F$ equalling to one indicates an isotropic state. Figures 6(a) and 6(b) show
the evolution of the normalized $F/F_0$ with $\sigma'_{v}$ and $\varepsilon_{l}$, respectively, where $F_0$ is the degree of structural anisotropy after isotropic compression and is in the range of 0.9904 to 0.9961. Figure 6(a) indicates that $F/F_0$ decreases as $\sigma'_{v}$ increases. Dense samples attained lower values of $F/F_0$ than looser samples, and as Figure 6(b) shows, dense samples also showed a more rapid decrease in $F/F_0$ than looser samples during straining. Figure 6(c) plots $K_0$ against $F/F_0$ (up to $\varepsilon_{l} = 0.25\%$), from which it is evident that $K_0$ values increase as $F/F_0$ values increase for all the packing densities considered. In general, while dense samples showed a higher degree of anisotropy, loose samples remained more isotropic. It is also noticeable that while $K_0$ decreases with $\sigma'_{v}$, the degree of structural anisotropy increases with $\sigma'_{v}$.

Rothenburg & Bathurst (1989) analytically showed that the stress ratio is related to different sources of anisotropy, including geometrical anisotropy, normal contact force anisotropy and tangential contact force anisotropy, of which the normal contact force anisotropy ($a_{n}$) dominates. It is worth exploring the $K_0$ - $a_{n}$ relationship for the DEM simulations. The definition of $a_{n}$ follows Rothenburg & Bathurst (1989) and Guo & Zhao (2013) with the average normal contact force expressed by Equation (3) (where $\Phi'_{ij}$ is the deviatoric part of $\Phi_{ij}$) with its probability distribution given by Equation (4) and $a_{n}^{ij} = (15/2)F_{ij}^{n}/j^{ij}$. $F_{ij}^{n}$ is the average normal contact force calculated considering the entire $\Omega$, different from the mean normal contact force averaged over all contacts. $a_{n}$ is related to the second invariant of $a_{n}^{ij}$ as $a_{n} = \sqrt{(3/2)a_{n}^{ij}a_{n}^{ij}}$.

\[ F_{ij}^{n} = \frac{1}{4\pi} \int_{\Omega} f_{n}(\Omega)n_{x}n_{y}d\Omega = \frac{1}{N_{c}} \sum_{i=1}^{N_{c}} \frac{f_{n}(\Omega)n_{x}n_{y}}{[1+(15/2)\Phi'_{ij}n_{x}n_{y}]} \]  
\[ f_{n}(\Omega) = j^{ij}[1+a_{n}^{ij}] \]  

Figures 7(a) and 7(b) indicate the evolution of $a_{n}$ with $\sigma'_{v}$ and $\varepsilon_{l}$, respectively. There is a clear influence of the initial void ratio with denser samples attaining higher values of $a_{n}$ than looser ones. Figure 7(b) shows that all samples have attained an almost constant value of $a_{n}$ after 0.05% of $\varepsilon_{l}$. Figure 7(c) plots $K_0$ against $a_{n}$, where a similar path is noticed for all the samples.

The relationships between $K_0$ and $F/F_0$ at different values of $\sigma'_{v}$ and $\varepsilon_{l}$ are presented in Figure 8(a) and 8(b). In both cases, and for all stages, a linear relationship can be found between $K_0$ and $F/F_0$ in which higher values of $K_0$ are always related to higher $F/F_0$. The relationships between $K_0$ and $a_{n}$ at different values of $\sigma'_{v}$ and $\varepsilon_{l}$ are presented in Figure 8(c) and 8(d). Regardless of stress or strain levels, the relationship between $K_0$ and $a_{n}$ can be represented by a single line that shows lower values of $K_0$ at higher $a_{n}$.

For a clearer illustration of the influence of structural anisotropy and normal contact force anisotropy, Figures 9(a) and 9(b) present the contact rose diagrams for a dense (test K0-1) sample and a loose
(test K0-9) sample at the same level of $\sigma'$, considering the projections onto the x-z vertical plane using an angular increment of 10 degrees. The radial length of each bin indicates the number of contacts oriented within the angle defining the bin. The colour of each bin is proportional to the sum of the normal contact forces that are present in that bin. For the dense sample, the stronger contacts that carry higher forces are preferentially aligned in the loading (i.e., vertical) direction, while the weaker contacts (transmitting lower force) tend to be oriented orthogonal to the loading direction. A larger number of contacts are present in the vertical direction than in the horizontal direction leading to lower values of $F$. More stress is transmitted in the vertical direction than in the horizontal direction, resulting in a larger value of $\sigma'_v$ and a smaller value of $\sigma'_h$. The loose sample presents a more isotropic distribution of both contact direction and force magnitude, yielding higher values of $F$. Moreover, contact forces transmitted in the horizontal direction are closer in magnitude to those transmitted in the vertical direction, making the values of $\sigma'_v$ and $\sigma'_h$ more alike. This explains why $K_0$ values decrease with increasing packing density.

4. Conclusions

One-dimensional tests on initially isotropic samples with a range of void ratios have been simulated using DEM. The resulting dependency of $K_0$ on void ratio qualitatively agrees with previously published laboratory tests, i.e., $K_0$ increases as void ratio increases. A power-law relationship between $K_0$ and $e_0$ was observed and this relationship depends on the stress level and vertical strain. Three definitions of $\phi'$ were considered when applying Jaky’s expression ($\phi_{mob}^{'}$, $\phi_p^{'}$ and $\phi_{cv}^{'}$) and compared to the measured $K_0$. While the use of $\phi_p^{'}$ gave the best match at lower void ratios and $\phi_{cv}^{'}$ reported fair predictions for looser samples, none of these expressions gave a good match with the measured $K_0$ values for the entire range of void ratio and stress levels considered. Micro-scale analysis revealed that the variation of $K_0$ with void ratio is related to the degree of both structural anisotropy and normal contact force anisotropy. $K_0$ decreases linearly with increasing structural anisotropy quantified using the ratio of major and minor principal values of the fabric tensor, $F$. The $K_0-F$ relationship was seen to depend on stress and strain level while a unique relationship, independent of stress or strain level, was found between $K_0$ and $a_w$. Dense samples had higher degrees of structural and normal contact force anisotropy at all test stages while loose samples remained more isotropic with lower normal contact force anisotropy. Loose samples were found to transmit similar stresses in all directions, while for dense samples, stress transmission coincides preferentially with the vertical loading direction. Therefore, $K_0$ values for dense samples are smaller than those of loose samples. The results of this study support the hypothesis of Lee et al (2013) and Wanatowski & Chu (2007) that $K_0$ values are related to the internal structure.
