(Received 23 January 2015; published 24 April 2015)
We present measurements of radio emission from cosmic ray air showers that took place during thunderstorms. The intensity and polarization patterns of these air showers are radically different from those measured during fair-weather conditions. With the use of a simple two-layer model for the atmospheric electric field, these patterns can be well reproduced by state-of-the-art simulation codes. This in turn provides a novel way to study atmospheric electric fields.

DOI: 10.1103/PhysRevLett.114.165001 PACS numbers: 92.60.Pw, 95.85.Ry, 96.50.sd

One of the important open questions in atmospheric physics concerns the physical mechanism that initiates lightning in thunderclouds [1]. Crucial to the answer is knowledge of atmospheric electric fields. Existing in situ measurements, from balloons or airplanes, are limited due to the violent nature of thunderstorms. Furthermore, they are limited to balloon trajectories or perturbed by the presence of the aircraft. Here, we present a new method to probe atmospheric electric fields through their influence on the pattern of polarized radio emission emitted by cosmic-ray-induced extensive air showers.

The main mechanism for driving radio-wave emission from air showers is that the relativistic electrons and positrons in the electromagnetic part of the shower are accelerated in opposite directions by the Lorentz force exerted by Earth’s magnetic field. This produces a short, nanosecond time scale, coherent pulse of radio emission mostly at megahertz frequencies. The emission generated by this geomagnetic mechanism is unidirectionally polarized in the \( \hat{e}_{vxB} \) direction. Here, \( v \) is the propagation velocity vector of the shower and \( B \) represents Earth’s magnetic field [2–4].

A secondary emission mechanism, contributing between \( \sim 3\%–20\% \) to the signal amplitude depending on distance to the shower axis and the arrival direction of the shower [5,6], results from a negative charge excess in the shower front. This consists of electrons knocked out of air molecules by the air shower. This also produces a short radio pulse but now polarized radially with respect to the shower symmetry axis.

The emission from both processes is strongly beamed in the forward direction, due to the relativistic velocities of the particles. Additionally, the nonunity refractive index of the air causes relativistic time-compression effects leading to enhanced emission from parts of the shower seen at the Cherenkov angle [7,8]. Interference between the differently polarized emission from both components leads to a complex and highly asymmetric intensity pattern [9]. In contrast, time-compression effects do not alter the direction of the polarization vector of the emission. The polarization pattern of the radio emission thus points predominantly in the \( \hat{e}_{vxB} \) direction with a minor radial deviation. Strong atmospheric electric fields will influence the motions of the electrons and positrons in air showers. This is expected to be visible in the polarization patterns of the recorded emission [10]. Therefore, we analyze air showers recorded during thunderstorms.

Data for this analysis were recorded with the low-band, 10–90 MHz, dual-polarized crossed dipole antennas located in the inner, \( \sim 2 \) km radius, core of the the LOw-Frequency ARray (LOFAR) radio telescope [11]. These antennas are grouped into circular stations that act as dishes for standard interferometric astronomical observations. For the purpose of air shower measurements, all antennas are equipped with ring buffers that can store up to 5 s of raw voltage data sampled every 5 ns. A dedicated scintillator array, the LOfar Radboud air shower Array (LORA), is located at the center of LOFAR to provide an independent trigger whenever an air shower with an estimated primary energy of \( \geq 2 \times 10^{16} \) eV is detected [12]. When a trigger is received, 2 ms of raw voltage data around the trigger time are stored for every active antenna.

These data are processed in an off-line analysis [13] from which a number of physical parameters are extracted and stored. These include the estimated energy of the air shower (as reconstructed from the particle detector data), the arrival direction of the air shower (as reconstructed from the arrival times of the radio pulses in all antennas), and for each antenna polarization information in the form of the Stokes parameters: \( I \) (intensity), \( Q, U \), and \( V \). The orientation of the polarization vector is reconstructed from Stokes \( Q \) and \( U \) [6].

Over the period between June 2011 and September 2014, LOFAR recorded a total of 762 air showers. The complex radio intensity pattern on the ground of almost all measured showers can be well reproduced by state-of-the-art air shower simulation codes [14]. These codes augment well-tested Monte Carlo air shower simulations with radio emission calculated from first principles at the microscopic level [15,16]. In this analysis, we use the COREAS plug in of CORSIKA [17] with QGSJETII [18] and FLUKA [19] as the hadronic interaction models. It was previously found that the exact shape of the intensity pattern depends on the atmospheric depth where the number of shower particles is largest, \( X_{\text{max}} \), and that the absolute field strength of the radio emission scales with the energy of the primary particle.

The radio footprints of 58 of the 762 air showers are very different from those predicted by simulations. Of these, 27 air showers have a measured signal-to-noise ratio below 10 in amplitude—too low to get a reliable reconstruction. The polarization patterns of the other 31 showers differ significantly from those of “normal” fair-weather air showers. This can be seen in the middle and bottom panels of Fig. 1 where the polarization direction is clearly coherent.
(i.e., nonrandom) over all antennas but no longer in the expected \( \hat{e}_{v \times B} \) direction. In addition, for some of these showers the intensity of the radio signal at low 10–90 MHz frequencies is strongest on a ring around the shower axis with a radius of approximately 100 m (see also Fig. 2). This “ring structure” in the intensity pattern is not present in normal fair-weather air showers that all lack rotational symmetry in the intensity pattern and instead show a single maximum that is displaced in the \( \hat{e}_{v \times B} \) direction from the shower axis [14,20]. Twenty of these 31 showers occur within 2 h of lightning strikes recorded within \( \sim 150 \) km distance from LOFAR by the Royal Dutch Meteorological Institute. Given the similarity of the polarization patterns of the remaining showers where no lightning strikes were

FIG. 1. Polarization as measured with individual LOFAR antennas (arrows) in the shower plane for three measured air showers. LOFAR antennas are grouped into circular stations, of which seven are depicted. The expected polarization direction for fair-weather air showers is indicated with “normal.” The position of the shower axis, orthogonal to the shower plane, is indicated by the intersection of the dashed lines.

FIG. 2 (color online). Radio intensity pattern during a thunderstorm. Top: the circles represent antenna positions. Their color reflects measured pulse power. The best-fitting COREAS simulation is shown in color scale in the background. Where the colors of the circles match the background, a good fit is achieved. Bottom: measured (circles) and simulated pulse power (squares) as a function of distance to the shower axis.
measured, it is plausible that at these times the atmospheric electric field was also strong albeit not strong enough to
initiate lightning. An electric field meter has since been
installed at LOFAR that will provide independent verifi-
cation for future measurements.

For the shower in the middle panel of Fig. 1, recorded
during thunderstorm conditions, the pattern is unidirec-
tional for the entire footprint. A second more complicated
type is depicted in the bottom panel. Here, the pattern is
more “wavy.” The analysis presented here focusses on an
air shower of the first type where also a ring structure is
visible and a strong signal is measured by the LORA
particle detectors. All air showers of this type can be
reconstructed with similar accuracy. For showers of the
wavy type, a more complex analysis is currently being
developed.

We propose that the influence of atmospheric electric
fields on air shower radio emission can be understood in
the following way.

The electric field, in the region of the cloud traversed
by the air shower, can be decomposed into components
perpendicular \( E_\perp \) and parallel \( E_\parallel \) to the shower symmetry
axis. The perpendicular component of the field changes the
net transverse force acting on the particles

\[
F = q(E_\perp + \mathbf{v} \times \mathbf{B}).
\]

This changes both the magnitude and the polarization of the
radiation that follow \( F \).

During shower development, the air shower particles
lose energy. The parallel component of the atmospheric
electric field partially compensates this energy loss.
Therefore, the total number of particles within a given
energy range in the shower increases. Because the frac-
tional gain of energy is greatest for lower energy particles,
these are the most affected. However, low-energy particles
do not contribute much to the total radio emission because
they lag behind the shower front and their emission is not
cohesive for frequencies above 10 MHz. Thus, it is the
perpendicular component of the electric field that deter-
nines the measured intensity and polarization direction.

In order to test these hypotheses, atmospheric electric
fields were inserted into COREAS air shower simula-
tions. By the comparison of fields acting purely parallel and purely
perpendicular to the shower axis it was found that the effect
of \( E_\perp \) on the radio emission is indeed much stronger and
will dominate in most shower configurations where both
components are present. This will be discussed in greater
detail in a forthcoming publication.

Having understood the basic effects of atmospheric
electric fields on air shower radio emission, we proceed
with a full reconstruction of LOFAR measurements. We
follow the method developed by Buitink et al. [14] to fit
COREAS simulations to LOFAR measurements. An atmos-
pheric electric field is inserted into the simulations with the
perpendicular component chosen such that the net force is
in the measured average polarization direction (as indicated
in the middle panel of Fig. 1). The parallel component is set
to zero since its influence on the received radiation intensity
and polarization pattern is negligible.

The simplest electric field configuration that can repro-
duce the main features in both the measured intensity and
polarization patterns is composed of two electric field
layers. The upper layer, with strength \(|E_\perp|\), starts at a
height \( h_U \) above the ground and extends down to a height
\( h_L \) at which the lower layer starts, the direction of the net
force changes by 180°, and the field strength decreases to
\(|E_\parallel|\). Two layers are needed because with one layer the ring
structure seen in the measurements is not reproducible.

In Fig. 2 the reconstruction is shown for the air
shower for which the polarization pattern is depicted in
the middle panel of Fig. 1. The reconstruction is optimal
for \( h_U = 8 \) km, \( h_L = 2.9 \) km, \(|E_\perp| = 50 \text{ kV m}^{-1}\), and
\(|E_\parallel|/|E_\perp| = 0.53\). For these values \( \chi^2/\text{ndf} = 3.2 \) as
obtained for a joined fit to both the radio and particle
data. A perfect fit of \( \chi^2/\text{ndf} \approx 1 \), as is often found for fair-
weather showers, is likely not attainable with a simplified
electric field model. However, all the main features of the
intensity and polarization pattern (namely the overall
polarization direction and ring structure) are already
correctly reproduced.

The fit quality is sensitive to changes in the relative field
strength and \( h_L \) as well as \( X_{\text{max}} \). This can be seen in Fig. 3,
where each parameter is varied while keeping the others
fixed at their optimum values. This fixing is not possible for
\( X_{\text{max}} \) in the CORSIKA software, because it is an outcome of
the simulation rather than an input parameter. Therefore,
simulations were selected where \( X_{\text{max}} \) differs by no more
than \( 20 \text{ g cm}^{-2} \). The fit quality reaches its optimum value
for \( h_U = 8 \) km and is not sensitive to a further increase.
This is expected because above this altitude the air shower
is not yet fully developed and there are relatively few
particles contributing to the emission.

For fair-weather air showers, the measured radio intensity
is related to the simulated values through a constant scaling
factor [14] given the energy of the primary particle. This
energy is derived from the particle density on the ground, as
measured with LORA, combined with the information on
\( X_{\text{max}} \), as determined from the radio fit. For the air shower
measured during thunderstorm conditions, the measured
intensity is higher than the normally expected value, as
the absolute electric field strength influences the radio
intensity. However, the simulated intensity increases only
until the atmospheric electric field strength reaches
\(|E_\perp| \geq 50 \text{ kV m}^{-1}\). When the field strength is increased
further, the radio intensity stays constant. This saturation of
the radio intensity appears to be related to the coherent nature
of the emission but is still under investigation.

Measuring radio emission from extensive air showers
during thunderstorm conditions thus provides a unique new
tool to probe the atmospheric electric fields present in thunderclouds. Unlimited by violent wind conditions and sensitive to a large fraction of the cloud, this technique may help answer the long-standing question “how is lightning initiated in thunderclouds?” It has been suggested by Gurevich et al. [21,22] that cosmic-ray-induced air showers in combination with runaway breakdown may initiate lightning. If this is indeed true then LOFAR with its combination of particle detectors and radio antennas is well positioned to measure it.

The LOFAR key science project cosmic rays acknowledges financial support from NOVA, SNN, and FOM as well as from NWO, VENI No. 639-041-130. We acknowledge funding from an Advanced Grant of the European Research Council (FP/2007-2013)/ERC Grant Agreement No. 227610. We also acknowledge funding from the FOM-project 12PR3041 “Cosmic Lightning”. LOFAR, the Low Frequency Array designed and constructed by ASTRON, has facilities in several countries that are owned by various parties (each with their own funding sources) and that are collectively operated by the International LOFAR Telescope foundation under a joint scientific policy.

FIG. 3 (color online). Sensitivity of the fit quality to variations in the atmospheric depth of shower maximum $X_{\text{max}}$ (left panel), the relative field strength (middle panel), and the field reversal altitude $h_2$ (right panel). The optimal proton simulation is the same for all plots. The electric field strength, in the upper layer, for all simulations is $|E_U| = 50$ kV m$^{-1}$.
