Edited by Tom C. Lubensky, University of Pennsylvania, Philadelphia, PA, and approved October 28, 2014 (received for review August 15, 2014)

It is widely believed that the swimming speed, \(v\), of many flagellated bacteria is a nonmonotonic function of the concentration, \(c\), of high-molecular-weight linear polymers in aqueous solution, showing peaked \(v(c)\) curves. Pores in the polymer solution were suggested as the explanation. Quantifying this picture led to a theory that predicted peaked \(v(c)\) curves. Using high-throughput methods for characterizing motility, we measured \(v\) and the angular frequency of cell body rotation, \(\Omega\), of motile *Escherichia coli* as a function of polymer concentration in polyvinylpyrrolidone (PVP) and Ficoll solutions of different molecular weights. We find that nonmonotonic \(v(c)\) curves are typically due to low-molecular-weight impurities. After purification by dialysis, the measured \(v(c)\) and \(\Omega(c)\) relations for all but the highest-molecular-weight PVP can be described in detail by Newtonian hydrodynamics. There is clear evidence for non-Newtonian effects in the highest-molecular-weight PVP solution. Calculations suggest that this is due to the fast-rotating flagella seeing a lower viscosity than the cell body, so that flagella can be seen as nano-rheometers for probing the non-Newtonian behavior of high polymer solutions on a molecular scale.

**Significance**

The way microorganisms swim in concentrated polymer solutions has important biomedical implications, i.e., how pathogens invade the mucosal lining of mammal guts. Physicists are also fascinated by self-propulsion in such complex non-Newtonian fluids. The current standard model of how bacteria propelled by rotary helical flagella swim through concentrated polymer solutions postulates bacteria-sized pores, allowing them relative easy passage. Our experiments using high-throughput methods overturn this standard model. Instead, we show that the peculiarities of flagellated bacteria locomotion in concentrated polymer solutions are due to the fast-rotating flagellum, giving rise to a lower local viscosity in its vicinity. The bacterial flagellum is therefore a nano-rheometer for probing flows at the molecular level.

\( \Omega(\omega) \) in the same range of \( \omega \) (Fig. S1), which is inconsistent with the data of BT, who observed a monotonic decrease.

We therefore performed a fresh experimental study of *E. coli* motility using the same polymer (PVP) as SD, but varying the molecular weight, \( M \), systematically. High-throughput methods for determining \( \omega \) and \( \Omega \) enabled us to average over \( \sim 10^4 \) cells at each data point. Using polymers as purchased, we indeed found peaked \( \omega(c) \) curves at all \( M \) studied. However, purifying the polymers removed the peak in all but a single case. Newtonian hydrodynamics can account in detail for the majority of our results, collapsing data onto master curves. We show that the hydrodynamics can account in detail for the majority of our results, collapsing data onto master curves. We show that the ratio \( \omega(c)/\Omega(c) \) is a sensitive indicator of non-Newtonian effects, which we uncover for 360-kDa PVP. We argue that these are due to shear-induced changes in the polymer around the flagella.

Below, we first give the necessary theoretical and experimental background before reporting our results.

**Theoretical Groundwork: Solving Purcell's Model**

Purcell's widely used "model *E. coli*" has a prolate ellipsoidal cell body bearing a single left-handed helical flagellum at one pole (18). Its motion is described by three kinematic parameters: the swimming speed, \( v \), the flagellum angular speed, \( \omega_0 \), and the body angular speed, \( \Omega \),

\[
v(0,0,0), \quad \omega(0,0,0), \quad \Omega(0,0,0),
\]

with \( (v, \omega, \Omega) > 0 \). The drag forces and torques \((\overline{F}, \overline{N})\) on the body (subscript \( b \)) and flagellum (subscript \( f \)) are given by

\[
\overline{F}_b = -\left( A_0 \quad 0 \quad D_0 \right) \begin{pmatrix} v \\ \Omega \end{pmatrix},
\]

\[
\overline{F}_f = -\left( A B \quad B D \quad 0 \right) \begin{pmatrix} \omega \end{pmatrix},
\]

where \( A_0, D_0, A, B, D \propto \eta_r \), the solvent viscosity. Requiring the body and flagellum to be force and torque free, we find

\[
\Omega = \frac{D_0(A_0 + A) - B^2}{D_0(A_0 + A) - \omega \equiv \beta \omega}, \quad \omega \equiv \gamma \omega,
\]

where \( \beta \) and \( \gamma \) are viscosity-independent geometric constants. Eqs. 4 and 5 predict that

\[
\Omega = R_1 \omega, \quad \text{with} \quad R_1 = \beta/\gamma,
\]

but underdetermine \((v, \Omega, \omega)\). Closure requires experimental input, in the form of the relationship between the torque developed by the motor, \( N \), and its angular speed, \( \omega_m \), where

\[
\omega_m = \Omega + \omega = (1 + \beta \omega) \Omega
\]

Measurements have repeatedly shown (19) that \( N(\omega_m) \) displays two regimes (Fig. 1), which we model as

\[
\omega \leq \omega_m : N = N_0
\]

and

\[
\omega > \omega_m : N = \alpha \omega_m^\alpha \omega_m^{\alpha - \omega_m}
\]

where \( \alpha = |\text{d}N/\text{d}\omega_m| = N_0/(\omega_m^\alpha - \omega_m^\alpha) \) is the absolute slope of \( N(\omega_m) \) when \( \omega_m < \omega < \omega_m^\alpha \). For our purposes later, it is important to realize that Eq. 7 implies an equivalent \( N(\Omega) \) relation, with associated \( \Omega^\alpha \) and \( \Omega^{\alpha - \omega_m^\alpha} \).

**Experimental Groundwork: Characterizing Polymers**

SD used "PVP K-90, molecular weight 360,000" (14), which, according to current standards (20), has a number averaged molecular weight of \( M_n \sim 360 \) kDa, and a weight-average molecular weight of \( M_w \approx 10^7 \) kDa. We show in SI Text that SD's polymer probably has somewhat lower \( M_n \) than the current PVP 360 kDa. We used four PVPs (Sigma Aldrich) with stated average molecular weights of \( M_w \approx 360 \) kDa (K-90), 40 kDa (K-30), 160 kDa (K-60), and 360 kDa (K-90). Measured low-shear viscosities, which obeyed a molecular weight scaling consistent with good solvent conditions, yielded (see SI Text for details) the overlap concentrations (17), \( c_r = 0.55 \pm 0.01, 1.4 \pm 0.02, 3.8 \pm 0.1, \) and \( 9.5 \pm 0.5 \) wt.%. In order of decreasing \( M_w \), Fig. S2 and Table S1). Static light scattering in water gave \( M_w \approx 840 \) kDa for our PVP360k, well within the expected range (20), and \( \omega = 56 \) nm (Table S2). We also used Ficoll with \( M_w \approx 70 \) kDa and 400 kDa from Sigma Aldrich (F70kF, F400k).

**Results**

We measured the motility of *E. coli* in polymer solutions using two new high-throughput methods (Materials and Methods and SI Text). Differential dynamic microscopy (DDM), which involves correlating Fourier-transformed images in time, delivers, inter alia, the mean swimming speed \( \bar{v} \) (21, 22). In dark-field flicker microscopy (DFM), we average the power spectrum of the flickering dark-field image of individual swimmers to obtain the mean body angular speed, \( \bar{\omega} \).
Cells suspended in a phosphate motility buffer were mixed with polymer solution in buffer to reach final desired concentrations and loaded into sealed capillaries for DDM and DFM. The concentrations of cells were low enough to avoid any cell-cell interaction, including polymer-induced depletion aggregation (23)—the absence of the latter being confirmed by microscopy. Separate experiments confirmed that oxygen depletion is negligible over the duration of the measurements.

Native Polymer. The measured \( \bar{\nu}(c) \) curves for all four PVP (Fig. S3) and Ficoll (Fig. S4) solutions are all nonmonotonic. The peak we see in PVP360k (Fig. S3) is somewhat reminiscent of SD’s observation (14) for E. coli (Fig. 2A). Interestingly, all \( \bar{\mu}(c) \) are also nonmonotonic except for PVP360k (Fig. S3).

Dialyzed Polymers. The initial rise in \( \bar{\nu} \) and \( \bar{\omega} \) on addition of native polymers (Figs. S3 and S4) are somewhat reminiscent of the way swimming speed of E. coli rises on adding small-molecule carbon sources (see the example of glycerol in Fig. S5), which cells take up and metabolize to increase the proton motive force. PVP is highly efficient in complexing with various small molecules (20). We therefore cleaned the as-bought, native polymers by repeated dialysis using membranes that should remove low-molecular-weight impurities (Materials and Methods) and then repeated the \( \bar{\nu}(c) \) and \( \bar{\omega}(c) \) measurements (Fig. 2), now reported in normalized form, \( \bar{\nu}/\bar{\nu}_0 \) and \( \bar{\omega}/\bar{\omega}_0 \), with \( \bar{\nu}_0 \) and \( \bar{\omega}_0 \) values at \( c = 0 \) (buffer).

The prominent broad peaks or plateaus seen in the data for native PVP40k and PVP160k have disappeared (the same is true for Fi70k and Fi400k; Fig. S6). A small bump (barely one error bar high) in the data for PVP10k remains. Given the flatness of the measured SD peak we see in PVP360k (Fig. S3) is somewhat reminiscent of the way swimming speeds from SD (14) normalized to the values at their lowest polymer concentration.

Newtonian Propulsion. To observe \( \bar{\nu}(c)/\bar{\nu}_0 = \bar{\omega}(c)/\bar{\omega}_0 \) (Fig. 2 B–D) we require \( \nu \propto \Omega \), i.e., that Eq. 6 should be valid. This proportionality is directly confirmed by Fig. 3: data for PVP10k, 40k, and 160k collapse onto a single master proportionality at all concentrations. Data for two dialyzed Ficolls also fall on the same master line. The good data collapse shows that there is only limited sample-to-sample variation in the average body and flagellar geometry, which are the sole determinants of \( R_1 \) in Eq. 6. The slope of the line fitted to all of the data gives \( R_1 \approx 9.6 \, \mu \text{m}^{-1} \) (compare \( \approx 7 \, \mu \text{m}^{-1} \) in ref. 24). The constancy of the ratio \( R_1 = \bar{\nu}/\bar{\omega} \) is also seen from the strongly peaked distribution of this quantity calculated from all individual pairs of \( \bar{\nu}(c) \) and \( \bar{\omega}(c) \) values except those for PVP360k (Fig. 3, Inset). Physically, \( R_1 \) is an inverse cell body processivity, i.e., on average a bacterium swims forward a distance \( R_1^{–1} \approx 0.1 \, \mu \text{m} / \text{body revolution} \).

The implication of Fig. 3 is that swimming E. coli sees all our polymer solutions except PVP360k as Newtonian fluids. Interestingly, BT cited the proportionality between \( \Omega \) and \( \eta^{-1} \) (rather than \( \Omega \) and \( \nu \)) as evidence of Newtonian behavior in Ficoll. We show the dependence of body rotation speed normalized by its value at no added polymer, \( \bar{\omega}/\bar{\omega}_0 \), on the normalized fluidity \( \eta/\eta_0 \) (where \( \eta_0 \) is the viscosity of the solvent, i.e., buffer) for our four PVPs and two Ficolls in Fig. 4, together with the lines used by BT to summarize their MC and Ficoll data. Our data and BT’s MC results (which span \( 0.2 < \eta/\eta_0 < 1 \)) cluster around a single master curve, which, however, is not a simple proportionality. Eqs. 10a and 10b together predict such nonlinear data collapse, provided that the cell body geometry, \( (a, b) \), and the motor characteristics, \( (N_0, \Omega_0, \Omega_0^{\max}) \), remain constant between datasets. The larger data scatter in Fig. 4 compared with Fig. 3 suggests somewhat larger variations in motor characteristics than in geometry between samples.*

![Fig. 2. (A–D) Normalized swimming speed \( \bar{\nu}/\bar{\nu}_0 \) (black circles) and body angular speed \( \bar{\omega}/\bar{\omega}_0 \) (red squares) vs. dialyzed PVP concentration (in weight percent) at four molecular weights, with \( \bar{\nu}_0 = 15 \, \mu \text{m} / \text{s} \) and \( \bar{\omega}_0 = 20 \, \text{Hz} \). Top axis: PVP concentration normalized to \( c^* \). The blue stars in A are the swimming speeds from SD (14) normalized to the values at their lowest polymer concentration.](image-url)

*Note, however, that this refers to the fictitious effective motor powering the single effective flagellum in Purcell’s E. coli model, so that in reality, the variability may reflect differing number and spatial distribution of flagella as much as individual motor characteristics.
and torque balance now read

\[ \Omega = \frac{\Omega}{v} = \frac{\pi}{\tau} \left( \frac{n}{\eta} \right) \left[ \frac{a_0 + a}{b} \right]^{-b^2} \tag{13} \]

Eq. 11 makes an interesting prediction. If we take \( \eta'(c) = \eta \), and use previously quoted flagellum dimensions for E. coli (24) to calculate \( (a_0, a_1, a_2, b, d) \), it predicts nearly perfectly the observed nonlinear \( \Omega(\tau) \) relationship for PVP360k (Fig. 3). Details are given in SI Text, where we also predict the observed peak in \( \tau(c) \) (Fig. 2 and Fig. S7). To check consistency, we proceed in reverse and treat the flagellum as a nano-rheometer. Given the measured \( \tau(c) \) in PVP360k, we deduce the viscosity seen by the flagellum, \( \eta'(c) \), at shear rate \( \dot{\gamma} \approx 10^4 \text{ s}^{-1} \) (SI Text and Fig. 6). In Fig. 6 we also show the low-shear viscosity of PVP360k solutions measured using conventional rheometry. Indeed, over most of the concentration range, we find \( \eta' \approx \eta \). (Note that the highest c data points are subject to large uncertainties associated with measuring very low swimming speeds.) Thus, our data are consistent with the flagellum seeing essentially just the viscosity of the pure solvent (buffer). Macroscopically, this corresponds to extreme shear thinning. Is this a reasonable interpretation?

For a helical flagellum of thickness \( d \) and diameter \( D \) rotating at angular frequency \( \omega \), the local shear rate is \( \dot{\gamma} \approx \omega D/d \) (we neglect translation because \( v \ll \omega D \)). For an E. coli flagellar bundle, \( a \approx 40 \text{ nm}, D \approx 550 \text{ nm}, \text{ and } \omega \approx 2 \times 115 \text{ rad/s} \) (24), giving \( \dot{\gamma} \approx 10^4 \text{ s}^{-1} \) in the vicinity of the flagellum. The Zimm relaxation time of a polymer coil is \( \tau_c \approx 4 \pi \eta_D r_0^2 / k_BT \), where \( k_BT \) is the thermal energy. Using \( \eta_D = 10^{-2} \text{ Pa} \cdot \text{s} \) and \( r_0 \approx 60 \text{ nm}, we find \( \tau_c \approx 1 \text{ ms} \) for our PVP360k at room temperature. Because \( \Omega^2 \gg \dot{\gamma} \), the cell body does not perturb significantly the polymer conformation. However, \( \dot{\gamma} \ll 0.1 \pi \), so that the polymer may be expected to shear thin in both dilute (\( c < c^* \)) (25) and semidilute (\( c \gtrsim c^* \)) (26) solutions. Low-shear rate data collected using rheometry and high-frequency rheocytological data collected using 1-\( \mu \)m beads and interpreted using the Cox-Merz rule (27) (see SI Text for details) show that there is indeed significant shear thinning of our PVP360k polymer (Fig. 6 and Fig. S8), although not as extreme as thinning down to \( \eta \).

**Non-Newtonian Effects and Flagella Nano-Rheology.** Given the above conclusion, the nonlinear \( \Omega(\tau) \) for PVP360k (Fig. 3) suggests a non-Newtonian response at the flagellum. In a minimal model, the flagellum “sees” a different viscosity, \( \eta'(c) \), than the cell body, which simply experiences the low-shear viscosity of the polymer solution, \( \eta(c) \). Making explicit the viscosity dependence of the resistive coefficients in Eqs. 2 and 3 by writing \( A = a \eta \), etc., force and torque balance now read

\[ \eta \dot{a}_0 v = \eta' \left( -\dot{a} + \dot{b} \right) \tag{11} \]

\[ \eta \dot{a}_0 \Omega = \eta' \left( -\dot{b} + \dot{a} \right) \tag{12} \]

Solving these gives

Of all of the polymers contributing to Fig. 4, PVP360k gave the most extensive coverage over the whole range of fluidity (Fig. 5). Eqs. 10a and 10b apply to the low and high fluidity regimes of these data, respectively. Eq. 10a depends on a single motor parameter, \( N_0 \), and predicts a strict proportionality. Our lowest fluidity data points suggest that at the highest polymer concentrations reached, we are indeed operating in this regime. Using \( a = 1.2 \mu \text{m} \) and \( b = 0.43 \mu \text{m} \) (average values from microscopy) to fit Eq. 10a to the lowest fluidity data gives \( N_0 = 1.450 \pm 50 \text{ pNnm} \) (Fig. 5, blue), which agrees well with previously measured stall torque (19).

The majority of the data away from the lowest fluidities are clearly nonlinear and need to be fitted with Eq. 10b. Doing so with the above value of \( N_0 \) gives \( \Omega^2 / 2 \pi \approx 6.9 \pm 0.5 \text{ s}^{-1} \) and \( \Omega^2 / 2 \pi \approx 20.5 \pm 0.5 \text{ s}^{-1} \) (Fig. 5, pink). Given that \( \Omega \approx a_0 \eta \) (Eq. 7), we expect \( \Omega^2 \approx a_0^2 \eta^2 \). Our ratio of \( \Omega^2 / 2 \pi \approx 3.1 \) compares reasonably with \( a_0^2 \eta^2 / c \approx 2.3 \) for a different strain of E. coli at the same temperature (22 °C) (19).

Thus, Eqs. 10a and 10b give a reasonable account of the data in Fig. 5. We conclude that PVP360k solution is Newtonian as far as body rotation is concerned.

---

1To reach lower fluidity, or higher viscosity, required progressively more polymer (by mass). To recover enough polymer after dialysis becomes more challenging as the molecular weight decreases.
Anisotropic elastic stresses (9–11, 13) and shear thinning (28, 29) have been proposed before as a possible cause of non-
Newtonian effects in biological swimmers. However, in
the usual sense, these are continuum concepts arising from experiments
on the millimeter (rheometry) or micrometer (micro rheology) scale.
Neither is obviously applicable to an ~40-nm segment of flagellum
moving through a somewhat larger polymer coils (r2 ~ 60 nm).
One of the very few explorations of the property of polymers is
important to note here: the polymer coils in its vicinity are
effectively carves out an anisotropic reaction rate that is dependent
to time. This is well known from experiments on the micrometer scale.

**Fig. 6.** Viscosities of PVP360k solutions: low-shear values from rheometry (filled circle); micro rheology data obtained using 980-nm beads at 10 Hz (red square); and η deduced from swimming data (green triangle). Lines are best fits (SI Text). (Inset) Schematic showing three snapshots of a section of a flagellum (sphere, r ~ 40 nm) cutting through a solution of polymer coils (r2 ~ 120 nm) with a circular path. Coils, which are initially in the path of the flagellum section (gray), become stretched out (red), leaving a coil-sized channel of solvent.

Shear thinning is not the only possible effect in the vicinity of a flagellum creating local deformation rates of ~10^4 s⁻¹. Higher-
molecular-weight polymers that are more viscoelastic than PVP
360 kDa will show significant elastic effects. Interestingly, it is
known that double-stranded DNA could be cut at a significant
rate at ~10⁴ s⁻¹ (35). An E. coli swimming through a high-
molecular-weight DNA solution should therefore leave behind
a trail of smaller DNA and therefore of lower-velocity motion,
making it easier for another bacterium to swim in the wake. The
latter may have important biomedical implications: the mucosal
lining of normal mammalian gastrointestinal tracks and of
diseased lungs can contain significant amounts of extracellular
DNA. Exploration of these issues will be the next step in
seeking a complete understanding of flagellated bacterial mo-
tility in polymeric solution.

**Materials and Methods**

**Cells.** We cultured K12-derived WT E. coli strain AB1157 as previously detailed (21, 22). Briefly, overnight cultures were grown in Luria-Bertani (LB) broth using a shaking incubator at 30 °C and shaking speed of 200 rpm. A fresh culture was inoculated as 1:100 dilution of overnight grown cells in 35 mL tryptone broth (TB) and grown for 4 h (to late exponential phase). Cells were washed three times with motility buffer (MB, pH = 7.0, 6.2 mM K₂HPO₄, 3.8 mM KH₂PO₄, 67 mM NaCl, and 0.1 mM EDTA) by careful filtration (0.45-μm HAT filter; Millipore) to minimize flagellar damage and were resuspended in MB to variable cell concentrations.

**Polymer stock solutions were prepared and diluted with MB.**

**Dialysis.** The polymer stock solutions were dialyzed in tubes with 14-mm-diameter and 12-kDa cutoff (Medicell International) against double-distilled water. The dialysis was performed over 10 h with daily exchange of the water. The final polymer concentration was determined by measuring the weight loss of a sample during drying in an oven at 55 °C and subsequent vacuum drying.

**Summary and Conclusions**

We measured the average swimming speed and cell body rotation
rate in populations of E. coli bacteria swimming in different
concentrations of solutions of the linear polymer PVP (nominal
molecular weights of 10, 40, 160, and 360 kDa, respectively). For low-shear values from rheometry, the branch polymer Ficoll
(70 and 400 kDa). We dialyzed each polymer to remove small-
molecular impurities that can be metabolized by the cells to in-
crease their swimming speed. The collapse of data for all polymers
except PVP360k onto a single proportionality relationship be-
tween swimming speed and body rotation rate, Ω(τ) (Fig. 3),
demonstrates that these solutions behave as Newtonian fluids as
far as E. coli propulsion is concerned.

**Shear thinning** is not the only possible effect in the vicinity of a flagellum creating local deformation rates of ~10⁴ s⁻¹. Higher-
molecular-weight polymers that are more viscoelastic than PVP
360 kDa will show significant elastic effects. Interestingly, it is
known that double-stranded DNA could be cut at a significant
rate at ~10⁴ s⁻¹ (35). An E. coli swimming through a high-
molecular-weight DNA solution should therefore leave behind
a trail of smaller DNA and therefore of lower-velocity motion,
making it easier for another bacterium to swim in the wake. The
latter may have important biomedical implications: the mucosal
lining of normal mammalian gastrointestinal tracks and of
diseased lungs can contain significant amounts of extracellular
DNA. Exploration of these issues will be the next step in
seeking a complete understanding of flagellated bacterial mo-
tility in polymeric solution.
treatment for 6 h. Polymer solutions at several concentrations were prepared by dilution using MB.

**Motility Measurement.** Bacterial suspensions were gently mixed with the polymer solutions to a final cell density of \(5 \times 10^9\) cells/mL. An \(400-\mu\)m-deep flat glass sample cell was filled with \(\approx 150 \, \mu\)L of suspension and sealed with petroleum jelly to prevent drift. Immediately after, two movies, one in phase-contrast illumination (\(\sim 40 \mu\)s, Nikon Plan Fluor 10xPh1 objective, NA = 0.3, Ph1 phase-contrast illumination plate at 100 frames and 500\(^2\) pixels) and one in dark-field illumination (\(\sim 10 \, \mu\)s, Nikon Plan Fluor 10xPh1 objective, NA = 0.3, Ph3 phase-contrast illumination plate, either 500 or 1,000 frames, 500\(^2\) pixels) were consecutively recorded on an inverted microscope (Nikon TE300 Eclipse) with a Mikrotron high-speed camera (MC 1362) and frame grabber (Inspector S, 1-Gb memory) at room temperature (\(\pm 1\) °C). We image at 100 μm away from the bottom of the capillary to avoid any interaction with the glass wall.

We measured the swimming speed from the phase contrast movies using the method of DDFM as detailed previously (21, 22). The dark field movies were analyzed to measure the body rotation speed using the method of DFM, in which we Fourier transform the power spectrum of the flickering image of individual cells, and identify the lowest frequency peak in the average power spectrum (Fig. 59) as the body rotation frequency as in previous work (24, 36); the difference here is that DFM is a high-throughput method (SI Text).

**Rheology.** We measured the low-shear viscosity \(\eta\) of polymer solutions using a TA Instruments AR2000 rheometer in cone-plate geometry (60 cm, 0.5°). Passive microrheology was performed using diffusing wave spectroscopy in transmission geometry with 5-mm-thick glass cuvettes. The setup (LS Instruments) uses an analysis of the measured mean square displacement (MSD) of tracer particles as detailed previously (37). Tracer particles (980-nm-diameter polystyrene) were added to the samples at 1 wt% concentration. The transport mean free paths of the samples were determined by comparing the static transmission to a reference sample (polystyrene with 980 nm diameter at 1 wt% in water). The shear rate-dependent viscosity \(\eta\) was obtained from the frequency dependent storage and loss moduli using the Cox–Mezrue rule (27).

**ACKNOWLEDGMENTS.** This work was funded by the UK Engineering and Physical Sciences Research Council (EP/D071070/1, EP/I004262/1, and EP/ J007404/1), EU 7th Framework Programme (PIF-GA-2010-276190), European Soft Matter Infrastructure (263248), European Research Council (AdG 340877 PHYSAPS), Swiss National Science Foundation (PBFRP2-127867), and the Rowland Institute at Harvard.

S1 Text

Predictions from Magariyama and Kudo. We calculated the predicted dependence of swimming velocity on polymer concentration using the theory of Magariyama and Kudo (1) (Fig S1) and show that, as they claimed, there is a peak. However, we also show a calculation that they did not report, namely, the predicted dependence of body rotation frequency as a function of polymer concentration. The latter is a rapidly increasing function, which is clearly unphysical and contradicts the observation by BT (2), as well as data shown here (Fig. 4).

Characterizing the PVP. Intrinsic viscosity and overlap concentration. The viscosity of a polymer solution at low concentrations can be written as a virial expansion of \( \eta \) in \( c \)

\[
\eta = \eta_i \left(1 + [\eta]c + k_H \eta_i^2 c^2 + \ldots \right),
\]

[S1]

where \([\eta] \) and \( k_H \) are the intrinsic viscosity and the Huggins coefficient, respectively, and \( \eta_i \) is the viscosity of the solvent, which here is motility buffer. The linearity at low \( c \) can be expressed in two different ways

\[
\frac{\eta - \eta_i}{\eta_i c} = [\eta] + k_H \eta_i^2 c \quad (\text{Huggins}),
\]

[S2]

\[
\frac{\ln((\eta/\eta_i) c)}{c} = [\eta] + \left(k_H - \frac{1}{2}\right) \eta_i^2 c \quad (\text{Kraemer}).
\]

[S3]

These two linear plots should extrapolate to \([\eta] \) at \( c = 0 \). The intrinsic viscosity measures the volume of a polymer coil normalized by its molecular weight, so that \( c^* = [\eta]^{-1} \). A modern text names this as the best experimental method for estimating the overlap concentration (3).

We first regraph the \( \eta(c) \) data given by SD (4) as HK plots (Fig. S2A). For here and below, concentrations in wt% and grams per deciliter are interchangeable at the sort of concentrations we are considering. It is clear that their lowest \( c \) data point must be inaccurate. Discarding this point gives the expected linear dependence in both plots and a uniquely extrapolated value of \([\eta] = 1.055 \) at \( c = 0 \), giving \( c^* = 0.95 \text{ g/dL} \). Reference to our \( c^* \) values below suggests that SD’s PVP360k has somewhat lower molecular weight than our material with the same label.

According to current industry standards (5), PVP360k should have viscosities of 3–5 and 300–700 mPa s at 1 and 10 wt. % in water, respectively. SD’s reported viscosities at 1 and 10 wt. % at 2.5 and 249 Pa s, respectively, are lower than these values, again consistent with their material having lower molecular weight than our PVP360k.

We characterized all four PVPs used in this work by measuring their low-shear viscosity in motility buffer as a function of concentration. For PVP360k (K-90) at 1 and 10 wt. %, we found \( \eta \approx 4 \) and 370 mPa s, agreeing well with the published standards (5). We now graph the measured viscosities of our four PVPs at low concentrations as HK plots (Fig. S2 B-E). In each case, the expected behavior is found; the extrapolated values of \([\eta] \) and the overlap concentrations calculated from these are given in Table S1. The scaling of \([\eta] \) vs. \( M \) is consistent with a power law (Fig. S2F)

\[
[\eta] \sim M^a, \quad \text{with} \quad a = 0.781.
\]

Because \([\eta] \approx r^3/M, \quad r \sim M^{1/3} \) with \( \nu = (1+a)/3 \). We find \( \nu = 0.593 \), which is consistent with the renormalization group value of \( \nu = 0.588 \) for a linear polymer in a good solvent.

Coil radii, second virial coefficient, and molecular weight. We performed static and dynamic light scattering (SLS and DLS, respectively) experiments to measure the radius of gyration, \( R_g \), the molecular weight, \( M_o \), the second virial coefficient, \( A_2 \), and the hydrodynamic radius, \( R_h \), of PVP-360k in water and motility buffer (6). \( R_h \) was measured by DLS, and \( R_g, M_o, \) and \( A_2 \) were measured using the Zimm plot of SLS data. Results are summarized in Table S2. The positive \( A_2 \) is consistent with our conclusion above that water is a good solvent for PVP. There may be a mild degree of aggregation in motility buffer (larger radii and slightly smaller \( A_2 \)).

Native Polymer Results. Fig. S3A shows \( \eta \) and \( \Omega \) vs. polymer concentration, \( c \), for as-bought, or native, PVP360k. Although \( \Omega(c) \) decays monotonically, a peak is observed in \( \eta \) at \( c = 0.5 \text{ wt. %} \), or roughly \( c^* \) for this molecular weight. The latter ostensibly reproduces SD’s observations (4); their data are also plotted in Fig. S3A. In native PVP-160k (Fig. S3B), the peak in \( \eta(c) \) broadens, and now there is a corresponding broad peak in \( \Omega(c) \) as well. These peaks broaden out into plateaus for native PVP40k and PVP10k (Fig. S3 C and D). We also performed experiments with native Ficoll with the manufacturer-quoted molecular weights of 70k and 400k and observed similar nonmonotonic, broadly peaked responses in both \( \eta(c) \) and \( \Omega(c) \) (Fig. S4).

The Effect of Small-Molecule Energy Sources. Here we show \( \eta(c) \) for E. coli swimming in glycerol solutions of a range of concentrations (Fig. S5). The plot is indeed reminiscent of what is seen for native PVP10k and PVP40k. Indeed, we suggest that the increases at low concentrations in all four polymers have the same origin as the increase observed at low glycerol concentration: the availability of a small-molecule energy source. The decrease at high glycerol is an osmotic effect (as observed for other small molecules, e.g., sucrose) (7), whereas that seen in the 10k, 40k, and 160k polymers can be entirely accounted for by low-Re Newtonian hydrodynamics (polymeric osmotic effects at our concentrations are negligible).

Dialyzed Ficoll Results. Swimming speed and body rotation frequency as a function of concentration are shown for two purified Ficolls in Fig. S6.

Shear-Thinning Calculations. Predicting \( \Omega(\nu) \) for flagellum experiencing buffer viscosity. Here we outline the procedure used to calculate the rotation rate of the cell body for a bacterium swimming in shear-thinning PVP-360k solution as a function of the swimming speed. We assume that the flagellum sees a viscosity \( \eta' \) that is different from the low-shear-rate viscosity \( \eta \) experienced by the bacterial body. This assumption is partly motivated by bulk and microrheological measurements (Fig. 6), showing that at the shear rates generated by the flagellum, shear thinning can be expected at least down to the micrometer scale. Empirically, the low- and high-shear viscosities plotted in Fig. 6 can be fitted by

\[
\begin{align*}
\eta_{\text{low-shear}} &= -5.32 + 6.33 \exp(0.39c) \quad \gamma \to 0 \text{ s}^{-1}, \\
\eta_{\text{high-shear}} &= 0.96 + 0.69c + 0.44c^2 \quad \gamma \approx 10^4 \text{ s}^{-1},
\end{align*}
\]

[S4]

where \( c \) is in wt% and \( \eta \) in centipoise (cP).
In this two-viscosity model, the force and torque balance equations solve to Eq. 13

$$\frac{\omega}{\nu} = \frac{d}{\nu} (\frac{n}{\eta}) [a_0 + a] - \frac{b^2}{\nu},$$

[S5]

The friction coefficients in Eq. S5 are given by (8)

$$\dot{a} = k_n L \sin \psi \tan \psi (1 + \gamma \cot^2 \psi),$$

[S6]

$$\dot{b} = k_n L \frac{\lambda}{2\pi} \sin \psi \tan \psi (1 - \gamma),$$

[S7]

$$\dot{d} = k_n L \left(\frac{\lambda}{2\pi}\right)^2 \sin \psi \tan \psi (1 + \gamma \cot^2 \psi),$$

[S8]

$$\dot{a}_0 = \frac{4\pi b}{\ln 2b - 1/2},$$

[S9]

$$\dot{d}_0 = \frac{16\pi}{3} a^2 b,$$

[S10]

where

$$k_n = \frac{8\pi}{2 \ln c^2 + 1},$$

[S11]

$$k_i = \frac{4\pi}{2 \ln c^2 + 1},$$

[S12]

and $\gamma = k_i/k_n$. Here, $L = 7 \mu m$ and $\lambda = 2 \mu m$ are the total length and pitch of the flagellum, respectively, $\psi = 41^\circ$ is the angle made by the flagellar filament with the flagellar axis, $r = 20 \text{ nm}$ is the estimated radius of the composite filament in a flagella bundle, and $c = 2.4$ is the Lighthill constant. All parameters are taken from a previous experimental paper (8), where this set of parameters was shown to be consistent with the Purcell model.

Using the measured values of $\Omega(c)$ for PVP360k, $\eta' = \eta_r$, $\eta = \eta_{\text{low-shear}}$, and Eq. S5 is sufficient to calculate the corresponding $\Omega$. Results show good agreement with the measured values (Fig. 3), thus predicting a peak in the swimming velocity on an increase in the viscosity of the polymer solution. For a better illustration, we compare the predicted and measured values of $\Omega$ as a function of the viscosity experienced by the body ($\eta_{\text{low-shear}}$) in Fig. S7. Our theory is successful in predicting a peak in the swimming velocity in the right position and of the right shape.

Deducing the viscosity the flagellum sees from measurements. Now we relax our previous assumption that $\eta'$ is equal to the viscosity of the solvent, and use Eq. S5 to extract the viscosity of the fluid surrounding the flagellar filament. Using the measured values of $\Omega(c)$ and $\Omega(c)$, Eq. S5 can be solved for $\eta'$. The results are shown in Fig. 6. Indeed, for most of the concentration range studied, $\eta' \approx \eta_r$.

Dark-field Flicker Microscopy. Under dark-field illumination, the image of a swimming bacterium appears to flicker. By calculating the power spectrum of the spatially localized time-dependent intensity fluctuations of low-magnification images of a quantized pixel box (containing approximately one cell) and then averaging over all cells in the images, we are able to measure the body rotational frequency $\Omega/2\pi$ averaged over ~$10^4$ cells based on a $\approx 10$-s movie. This method is similar to what was done by Lowe et al. (9), who measured the power spectrum of single swimming cells. However, here we use low-magnification dark-field imaging, which allows high-throughput measurement of $\Omega/2\pi$.

Dark-field movies were recorded (Nikon Plan Fluor 10xPh1 objective, NA = 0.3, Ph3 phase-contrast illumination plate) at either 500 or 1,000 Hz on an inverted microscope (Nikon TE300 Eclipse) with a Mikrotron high-speed camera (MC 1362) and frame grabber (Inspecta 5, 1-Gb memory) at room temperature ($\Omega = 1^\circ$). The images correspond to an area of $\approx 720 \times 720 \mu m$, containing around $10^3$ bacteria. Approximately 4,000 frames were captured, at a resolution of 512 $\times$ 512 pixels.

To process a video sequence, each frame was divided into square tiles of side length $l$ (typically five pixels), and the pixel values in each tile were summed to give a single number. This process was repeated for every frame in the video sequence, yielding intensity as a function of time for each tile. The power spectrum of these data was calculated for each tile separately, before averaging over all tiles to give smoothed data for the whole video sequence. The power spectrum is then normalized by the frequency squared to remove any contribution from Brownian motion due the nonmotile cells, inherently present in the bacterial suspensions. An example is shown in Fig. S9. We identify the first peak as the body rotational frequency $\Omega/2\pi$ in line with previous studies (9).

Viscosity Measurements. The viscosity of PVP360k measured using conventional rheometry and DWS micro rheology (Materials and Methods) at different concentrations is shown in Fig. S8. There is reasonable overlap between the two methodologies at intermediate shear rates.

Fig. S1. Normalized swimming speed $v/v_0$, body rotational speed $\Omega/\Omega_0$, and flagella rotational speed $\omega/\omega_0$ vs. viscosity according to Magariyama and Kudo (1).

Fig. S2. (A–E) Huggins and Kraemer representation: (red circles) $(\eta - \eta_s)/\eta_c$ and (black squares) $\ln(\eta/\eta_s)/c$ vs. polymer concentration. Lines are linear fits to the data using Eqs. S2 and S3 simultaneously. Both quantities should be linear and extrapolate to a unique intrinsic viscosity $[\eta]$ at $c=0$. (A) From the PVP viscosity data of Schneider and Doetsch. Discarding the lowest-$c$ point gives $[\eta] = 1.05 \pm 0.02$. (B–E) Our PVP at four different molecular weights. (F) The scaling of intrinsic viscosity, $[\eta]$, with molecular weight, $M$, for our PVPs.
(A–D) Swimming speed $v$ (black circles) and body rotation frequency $\Omega = 2\pi$ (red squares) of *E. coli* vs. concentration (in weight percent) of native PVP of four molecular weights. Top axis: PVP concentration normalized to the overlap concentration $c^*$ (see Table S1). The stars (blue) in A are results for swimming speed from SD (4).

Fig. S4. Speed $v$ (red symbols) and body rotation frequency $\Omega$ (black symbols) given in absolute (Upper) and normalized values (Lower) as functions of concentration for native Ficoll of two molecular weights: (A and B) $M = 70k$ (one dataset) and (C and D) $M = 400k$ (four datasets). Lines are guides to the eye.

Fig. S5. Swimming *E. coli* in glycerol. Speed $v$ as a function of glycerol concentration.
Fig. S6. Speed $\nu$ (red circles) and body rotation frequency $\Omega$ (black squares) given in absolute (Upper) and normalized values (Lower) as functions of concentration for dialyzed Ficoll of two molecular weights: (A and B) $M = 70k$ and (C and D) $M = 400k$. Lines are guides to the eye.

Fig. S7. Speed $\nu$ vs. viscosity from experiments (black dots) and our theory (red diamonds) as discussed in SI Text.

Fig. S8. Viscosity of PVP360k as a function of shear rate obtained from bulk rheology (open symbols) and DWS microrheology (filled symbols) for several polymer concentrations (see legend in weight percent).
Fig. S9. Typical example of the power spectrum of the flickering dark-field image of individual cells averaged over \( \approx 10^4 \) cells based on an \( \approx 10\)-s dark-field movie (Materials and Methods). The power spectrum is normalized by the frequency square to remove contribution from Brownian motion due to the inherent presence of nonmotile cells in the suspension. The black line corresponds to a two-peak fit using Lognormal distribution.
