1. Introduction

The first question that someone who creates a new programming language will hear from others inevitably is: Why another programming language? Are there not already enough programming languages out there that you can pick from?

I always wanted a programming language

- in which I can express myself compactly and without jumping through too many hoops,
- that is easy to understand and to learn,
- in which purely functional programming is the default and not the exception,
- that supports exceptions,
- that has pattern matching,
- that has built-in support for laziness and concurrency,
- that has built-in support for purely functional lists, vectors, sets and maps,
- that seamlessly marries structured programming constructs like loops with purely functional programming,
- that supports objects, modules and data encapsulation,
- that has mature implementations for all major modern computing platforms and can (and should!) be used for real-world programming,
- that has a simple mechanized formal semantics,
- that is beautiful.

There is no such language out there. Therefore I decided to create one. When Babel-17 will have reached v1.0 then the above goals will have been achieved. The version described in this document is Babel-17 v0.3.2, so there is still some distance to go.

Babel-17 is not a radically new or revolutionary programming language. It picks those raisins I like out of languages like Standard ML [1], Scala [2], Isabelle [3] (which is not
a language, but a system for interactive theorem proving), Alice ML, Java, Javascript, Erlang, Haskell, Lisp, Clojure and Mathematica, and tries to evolve them into a beautiful new design.

Babel-17 is a functional language. It is not a pure functional language because it contains sources of non-determinism like the ability to pick one of two values randomly. If you take these few sources of non-determinism out of the language, it becomes pure.

In Babel-17, every value has a type. These types are not checked statically, but only dynamically.

Babel-17 is also object-oriented in that many aspects of Babel-17 can be explained in terms of sending messages to objects.

The default evaluation order of Babel-17 is strict. But optional laziness is built into the heart of Babel-17, also, and so is concurrency.

Babel-17 has pattern matching and exception handling. Both are carefully integrated with each other and with the laziness and concurrency capabilities of Babel-17.

Furthermore, Babel-17 establishes the paradigm of purely functional structured programming via the notion of linear scope.

In this document I specify Babel-17 in a mostly informal style: formal notation is sometimes used when it supports clarity.

Not part of this document, but also part of the overall Babel-17 specification is its formal ANTLR v3.0 grammar; and the (small, but growing) set of unit tests that correspond to the different sections of this document. Both artifacts are available at [3].

2. Reference Implementation

At [3] you will find a reference implementation of Babel-17 that fully supports the language as described in this document. There you will also find a Netbeans plugin that has syntax and error-highlighting for Babel-17 programs. As you find your way through this document, it might be helpful to directly try out Babel-17 in Netbeans to see if the interpreter behaves as you would guess from this spec. If you find implausible behavior, email your findings to bugparade@babel-17.com. Preferably you would also send along a unit test that fails because of the observed behavior, but which you think should succeed.

3. Lexical Matters

Babel-17 source code is always written UTF-8 encoded. If it ain’t UTF-8, it ain’t Babel-17.

Constructors are alphanumeric strings which can also contain underscores, and which must start with a capital letter. Identifiers are alphanumeric strings which can also contain underscores, and which must start with a non-capital letter. The distinction between two constructors or two identifiers is not sensitive to capitalization.

These are the keywords of Babel-17:
Note that keywords are written always in lower case. For example, `begin` is not a legal keyword, but it also isn’t an identifier (because of case insensitivity). Also note that `Begin` and `BEGIN` denote the same legal constructor. When we talk about identifiers in the rest of the paper, we always mean identifiers which are not keywords.

You can write down decimal, hexadecimal, binary and octal integers in Babel-17. The following notations all denote the same integer:

\[
15 \quad \text{0xF} \quad \text{0b1111} \quad \text{0o17}
\]

There is also a decimal syntax for floating point numbers in Babel-17:

\[
15.0 \quad 1.5E1 \quad 1.5E+1 \quad \text{150E-1} \quad 15E0
\]

Strings start and end with a quotation mark. Between the quotation mark, any valid UTF-8 string is allowed that does not contain newline, backslash or quotation mark characters, for example:

"hello world"  "$1, 2\%"  "1 <= 4! <= 5^2"

Newline, backslash and quotation mark characters can be written down in escaped form. Actually, any unicode character can be written down in its escaped form via the hexadecimal value of its codepoint:

| String consisting only of a quotation mark | "\" |
| String consisting only of a backslash    | "\\" |
| String consisting only of a line feed    | "\n" |
| String consisting only of a carriage return | "\r" |
| String consisting only of line feed via 16-bit escaping | "\u000A" |
| String consisting only of line feed via 32-bit escaping | "\U0000000A" |

Multi-line comments in Babel-17 are written between matching pairs of `#(` and `)#` and can span several lines. Single-line comments start with `##`.

Pragmas start with `#`, just like comments. There are the following pragmas: `#assert`, `#catch`, `#log`, `#print`, `#profile`.

Finally, here are all ASCII special symbols that can occur in a Babel-17 program:

\[
= \quad == \quad <> \quad < \quad <= \quad > \quad >= \quad + \quad - \quad \ast \quad / \quad \wedge \quad ;
\]

| | & | ! | ++ | -- | ** | // | , | :: | :> | => | ? | ...
| ( | ) | [ | ] | { | } | . | ~ | :> | += | +++ | += |

\[
=++ \quad *= \quad **= \quad *** = \quad *** /= \quad //=/ \quad =/\quad /=\quad ^= \quad =~ ^=\quad
\]

Table 1 lists all other Unicode symbols that have a meaning in Babel-17.

4. Overview of Built-in Types

Each value in Babel-17 has a unique type. All built-in types are depicted in Table 2. Often we use the name of a type to refer to this type in this specification, but the representation of it in actual Babel-17 is given in the type column. The type of a value \( v \) can be obtained via
5. Objects and Functions

All values in Babel-17 are objects. This means that you can send messages to them. Many values in Babel-17 are functions. This means that you can apply them to an argument, yielding another value. Note that for a value to be an object, it does not need to have type \texttt{obj}, and for a value to be a function, it does not need to have type \texttt{fun}.

The result of sending message \texttt{m} to object \texttt{v} is written as

\[ v . m \]

Here \texttt{m} is an identifier.

The result of applying function \texttt{f} to value \texttt{x} is written as

\[ x(f) \]
6. Exceptions

Exception handling in Babel-17 mimicks exception handling mechanisms like those which can be found in Java or Standard ML, while adhering at the same time to the functional paradigm.

There are two types of exceptions: PersistentException and DynamicException. The difference is that a PersistentException can be treated as part of any data structure, and is passed around just like any other value, while a DynamicException can never be part of a data structure and has special evaluation semantics.

Exceptions in Babel-17 are not that special at all but mostly just another type of value. Let us write PersistentException v for a PersistentException with parameter v, and DynamicException v for a DynamicException with parameter v. We also write Exception v for an exception with parameter v. The parameter v is a non-exceptional value; this means that v can be any Babel-17 value except one of type DynamicException. Note that a value of type PersistentException is therefore non-exceptional.

The following deterministic rules govern how exceptions behave with respect to sending of messages, function application, laziness and concurrency:

\[(\text{Exception } v).m \rightsquigarrow \text{DynamicException } v\]
\[(\text{DynamicException } v) x \rightsquigarrow \text{DynamicException } v\]
\[f (\text{DynamicException } v) \rightsquigarrow \text{DynamicException } v\] where f is non-exceptional
\[(\text{PersistentException } v) g \rightsquigarrow \text{DynamicException } v\] where g is non-exceptional
\[\text{exception } v \rightsquigarrow \text{DynamicException } v\]
\[\text{lazcy (Exception } v) \rightsquigarrow \text{PersistentException } v\]
\[\text{concurrent (Exception } v) \rightsquigarrow \text{PersistentException } v\]
\[\text{force } v \rightsquigarrow v\] for all v, including exceptions

Exceptions in Babel-17 are created with the expression exception v. Creating exceptions in Babel-17 corresponds to raising or throwing exceptions in other languages. Catching an exception can be done via match or via try–catch. Both constructs will be described later.

In the next section, we will describe the lazy and concurrent expressions of Babel-17. They are the reason why exceptions are divided into dynamic and persistent ones.
7. Laziness and Concurrency

The default evaluation mechanism of Babel-17 is strict. This basically means that the arguments of a function are evaluated before the function is applied to them. Babel-17 has two constructs to change this default behaviour.

The expression

\texttt{laz}y ~e

is not evaluated until it is actually needed. When it is needed, it evaluates to whatever \texttt{e} evaluates to, with the exception of dynamic exceptions, which are converted to persistent ones.

The expression

\texttt{concurrent} ~e

also evaluates to whatever \texttt{e} evaluates to, again with the exception of dynamic exceptions which are converted to persistent ones. This evaluation will happen concurrently.

One could think that apart from obvious different performance characteristics, the expressions \texttt{laz}y \texttt{e} and \texttt{concurrent} \texttt{e} are equivalent. This is not so. If \texttt{e} is a non-terminating expression then, even if the value of \texttt{concurrent} \texttt{e} is never needed during program execution, it might still lead to a non-terminating program execution. In other words, the behaviour of \texttt{concurrent} \texttt{e} is unspecified for non-terminating \texttt{e}.

Sometimes you want to explicitly force the evaluation of an expression. In those situations you use the expression

\texttt{force} \texttt{e}

which evaluates to \texttt{e}. So semantically, \texttt{force} is just the identity function.

We mentioned before that lazy and concurrent expressions are the reason why exceptions are divided into dynamic and persistent ones. To motivate this, look at the expression

\texttt{fst} \ (0, \ \texttt{laz}y \ (1 \ \texttt{div} \ 0))

Here the function \texttt{fst} is supposed to be a function that takes a pair and returns the first element of this pair. So what would above expression evaluate to? Obviously, \texttt{fst} does not need to know the value of the second element of the pair as it depends only on the first element, so above expression evaluates just to 0. Now, if \texttt{laz}y was semantically just the identity function, then we would have

\begin{align*}
0 &= \texttt{fst} \ (0, \ \texttt{laz}y \ (1 \ \texttt{div} \ 0)) = \texttt{fst} \ (0, \ 1 \ \texttt{div} \ 0) = \texttt{fst} \ (0, \ \texttt{exception} \ \texttt{DomainError}) \\
&= \texttt{fst} \ \texttt{exception} \ \texttt{DomainError} = \texttt{exception} \ \texttt{DomainError}
\end{align*}

Obviously, 0 should not be the same as an exception, and therefore \texttt{laz}y cannot be the identity function, but converts dynamic exceptions into persistent ones. For a dynamic exception \texttt{e} the equation

\begin{align*}
(0, \ e) &= e
\end{align*}

holds. For a persistent exception \texttt{e} this equation does not hold, and therefore the above chain of equalities is broken.
8. Lists and Vectors

For \( n \geq 0 \), the expression
\[
[e_1, \ldots, e_n]
\]
denotes a list of \( n \) elements.

The expression
\[
(e_1, \ldots, e_n)
\]
denotes a vector of \( n \) elements, at least for \( n \neq 1 \). For \( n = 1 \), there is a problem with notation, though, because \((e)\) is equivalent to \(e\). Therefore there is the special notation \((e,)\) for vectors which consist of only one element.

The difference between lists and vectors is that they have different performance characteristics for the possible operations on them. Lists behave like simply linked lists, and vectors behave like arrays. Note that all data structures in Babel-17 are immutable.

Another way of writing down lists is via the right-associative :: constructor:
\[
h::t
\]
Here \( h \) denotes the head of the list and \( t \) its tail. Actually, note that the expression \([e_1, \ldots, e_n]\) is just syntactic sugar for the expression
\[
e_1::e_2::\ldots::e_n:[]
\]
Dynamic exceptions cannot be part of a list but are propagated:
\[
(DynamicException v):t \leadsto DynamicException v
\]
\[
h::(DynamicException v) \leadsto DynamicException v \quad \text{where } h \text{ is non-exceptional}
\]
Note that when the tail \( t \) is not a list, we identify \( h::t \) with \( h::t::[] \).

9. CExprs

A CExpr is a constructor \( c \) together with a parameter \( p \), written \( c \, p \). It is allowed to leave out the parameter \( p \), which then defaults to \( \text{nil} \). For example, \( \text{HELLO} \) is equivalent to \( \text{HELLO nil} \). A constructor \( c \) cannot have a dynamic exception as its parameter, therefore we have:
\[
c (DynamicException v) \leadsto DynamicException v
\]

10. Pattern Matching

Maybe the most powerful tool in Babel-17 is pattern matching. You use it in several places, most prominently in the match expression which has the following syntax:

\[
\text{match } e \\
\quad \text{case } p_1 => b_1 \\
\quad \vdots \\
\quad \text{case } p_n => b_n \\
\text{end}
\]
Given a value \( e \), Babel-17 tries to match it to the patterns \( p_1, p_2, \ldots \) and so on sequentially in that order. If \( p_i \) is the first pattern to match, then the result of match is given by the block expression \( b_i \). If none of the pattern matches then there are two possible outcomes:
(1) If \( e \) is a dynamic exception, then the value of the match is just \( e \).
(2) Otherwise the result is a dynamic exception with parameter NoMatch.

A few of the pattern constructs incorporate arbitrary value expressions. When these expressions raise exceptions, they are propagated up.

So what does a pattern look like? Table 3 and Table 4 list all ways of building a pattern.

In this table of pattern constructions we use the \( \delta \)-pattern \( \delta \). This pattern stands for “the rest of the entity under consideration” and can be constructed by the following rules:

(1) The ellipsis ... is a \( \delta \)-pattern that matches any rest.
(2) If \( \delta \) is a \( \delta \)-pattern, and \( x \) an identifier, then \((x \text{ as } \delta)\) is a \( \delta \)-pattern.
(3) If \( \delta \) is a \( \delta \)-pattern, and \( e \) an expression, then \((\delta \text{ if } e)\) is a \( \delta \)-pattern.

Note that pattern matching does not distinguish between vectors and lists. A pattern that looks like a vector can match a list, and vice versa.

Besides the \texttt{match} construct, there is also the \texttt{try} construct. While \texttt{match} can handle exceptions, most of the time it is more convenient to use \texttt{try} for this purpose. The syntax is

\[
\begin{align*}
\texttt{try} \\
& s_1 \\
& \ldots \\
& s_m \\
\texttt{catch} \\
& \texttt{case } p_1 = : b_1 \\
& \ldots \\
& \texttt{case } p_n = : b_n \\
\texttt{end}
\end{align*}
\]

The meaning of the above is similar to the meaning of

\[
\begin{align*}
\texttt{match} \\
& \texttt{begin} \\
& s_1 \\
& \ldots \\
& s_m \\
& \texttt{end} \\
& \texttt{case } (\text{exception } p_1) = : b_1 \\
& \ldots \\
& \texttt{case } (\text{exception } p_n) = : b_n \\
& \texttt{case } x = : x \\
& \texttt{end}
\end{align*}
\]

except for two differences:

(1) the latter expression might not be legal Babel-17 because of linear scoping violations,
(2) \texttt{try} does not catch persistent exceptions.
### Table 3. General Patterns

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-</td>
<td>the underscore symbol matches anything but a dynamic exception</td>
</tr>
<tr>
<td>$x$</td>
<td>an identifier $x$ matches anything but a dynamic exception and binds the matched expression to $x$</td>
</tr>
<tr>
<td>$(x \text{ as } p)$</td>
<td>matches $p$, and binds the successfully matched value to $x$; the match fails if $p$ does not match or if the matched value is a dynamic exception</td>
</tr>
<tr>
<td>$z$</td>
<td>an integer number $z$, like 0 or 42 or $-10$, matches just that number $z$</td>
</tr>
<tr>
<td>$c \ p$</td>
<td>matches a $\text{CExpr}$ with constructor $c$ if the parameter of the $\text{CExpr}$ matches $p$; instead of $c \ _$ you can just write $c$</td>
</tr>
<tr>
<td>$s$</td>
<td>a string $s$, like &quot;hello&quot;, matches just that string $s$</td>
</tr>
<tr>
<td>$(p)$</td>
<td>same as $p$</td>
</tr>
<tr>
<td>$(p \text{ if } e)$</td>
<td>matches any non-exceptional value that matches $p$, but only if $e$ evaluates to $\text{true}$; identifiers bound in $p$ can be used in $e$</td>
</tr>
<tr>
<td>$(\text{val } e)$</td>
<td>matches any non-exceptional value which is equivalent to $e$; in case an $\text{Unrelated}$-exception is thrown, this pattern just does not match, and does not propagate up the exception</td>
</tr>
<tr>
<td>$(c \ ! p)$</td>
<td>let $v$ be the value to be matched; then the match succeeds if the result $v.\text{destruct_}c$ matches $p$</td>
</tr>
<tr>
<td>$(c \ !)$</td>
<td>short for $(c \ ! _)$</td>
</tr>
<tr>
<td>$(f \ ? p)$</td>
<td>$f$ is applied to the value to be matched; the match succeeds if the result of the application matches $p$</td>
</tr>
<tr>
<td>$(f \ ?)$</td>
<td>short for $(f \ ? \text{true})$</td>
</tr>
<tr>
<td>${m_1 = p_1, \ldots, m_n = p_n}$</td>
<td>matches a value of type $\text{obj}$ that has exactly the messages $m_1,\ldots, m_n$ such that the message values match the given patterns</td>
</tr>
<tr>
<td>${m_1 = p_1, \ldots, m_n = p_n, \delta}$</td>
<td>matches a value of type $\text{obj}$ that has the messages $m_1,\ldots, m_n$ such that the message values match the given patterns</td>
</tr>
<tr>
<td>$\text{nil}$</td>
<td>matches the empty object</td>
</tr>
<tr>
<td>exception $p$</td>
<td>matches any exception such that its parameter matches $p$</td>
</tr>
<tr>
<td>$(p : t)$</td>
<td>matches anything that has (or is auto-convertible to) type $t$ and matches $p$</td>
</tr>
<tr>
<td>$(p : (e))$</td>
<td>matches anything that matches $p$ and is or auto-converts to the type that $e$ evaluates to</td>
</tr>
<tr>
<td>$(t \ p)$</td>
<td>inner-value pattern; see Section 27.2</td>

<td>see section [25]</td>
</tr>
</tbody>
</table>

### 11. Non-Determinism in Babel-17

One source of non-determinism in Babel-17 is probabilistic non-determinism. The expression

\[
\text{random } n
\]

returns for an integer \(n > 0\) a number between 0 and \(n - 1\) such that each number between 0 and \(n - 1\) has equal chance of being returned. If \(n\) is a dynamic exception, then this exception is propagated, if \(n\) is a non-exceptional value that is not an integer \(> 0\) then the result is an exception with parameter DomainError.

Another source of non-determinism is choice. The expression

\[
\text{choose } l
\]

takes a non-empty collection \(l\) and returns a member of the collection. The choice operator makes it possible to optimize evaluation in certain cases. For example, in

\[
\text{choose (concurrent a, concurrent b)}
\]

the evaluator could choose the member that evaluates quicker.

There is a third source of non-determinism which has its roots in the module loading mechanism (see Section \[27\]).

Babel-17 has been designed such that if you take the above sources of non-determinism out of the language, it becomes purely functional. If in your semantics of Babel-17 you
replace the concept of value by the concept of a probability distribution over values and a set of values, you might be able to view Babel-17 as a purely functional language even including random and choose.

12. Block Expressions

So far we have only looked at expressions. We briefly mentioned the term block expressions in the description of the match function, though. We will now introduce and explain block expressions.

Block expressions can be used in several places as defined by the Babel-17 grammar. For example, they can be used in a match expression to define the value that corresponds to a certain case. But block expressions can really be used just everywhere where a normal expression is allowed:

```plaintext
begin
  b
end
```

is a normal expression where \( b \) is a block expression. A block expression has the form

```plaintext
s_1
\vdots
s_n
```

where the \( s_i \) are statements. In a block expression both newlines and semicolons can be used to separate the statements from each other.

Statements are Babel-17’s primary tool for introducing identifiers. There are several kinds of statements. Three of them will be introduced in this section.

First, there is the val-statement which has the following syntax:

```plaintext
val p = e
```

Here \( p \) is a pattern and \( e \) is an expression. Its meaning is that first \( e \) gets evaluated. If this results in a dynamic exception, then the result of the block expression that the val-statement is part of will be that dynamic exception. Otherwise, the result of evaluating \( e \) is matched to \( p \). If the match is successful then all identifiers bound by the match can be used in later statements of the block expression. If the match fails, then the value of the containing block expression is the dynamic exception NoMatch.

Second, there is the def-statement which obeys the following syntax for defining the identifier \( id \):

```plaintext
def id arg = e
```

The \( arg \) part is optional. If \( arg \) is present, then it must be a pattern. Let us call those definitions where \( arg \) is present a function definition, and those definitions where \( arg \) is not present a simple definition.

Per block expression and identifier \( id \) there can be either a single simple definition, or there can be several function definitions. If there are multiple function definitions for the same identifier in one block expression, then they are bundled in that order to form a single function.

The defining expressions in def-statements can recursively refer to the other identifiers defined by def-statements in the same block expression. This is the main difference
Table 5. Legal and illegal definitions

<table>
<thead>
<tr>
<th></th>
<th>val x = y</th>
<th>def x = y</th>
<th>val x = y</th>
<th>def x = y</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>val y = 0</td>
<td>val y = 0</td>
<td>def y = 0</td>
<td>def y = 0</td>
</tr>
</tbody>
</table>

between definitions via `def` and definitions via `val`. Only those `val`-identifiers are in scope that have been defined *previously*, but `def`-identifiers are in scope throughout the whole block expression. Table 5 exemplifies this rule.

Let us assume that a block expression contains multiple function definitions for the same identifier f:

```plaintext
def f p_1 = e_1 
... 
def f p_n = e_n
```

Then this is (almost) equivalent to

```plaintext
def f x =
  match x
  case p_1 => e_1
  ...
  case p_n => e_n
end
```

where x is fresh for the $p_i$ and $e_i$. The slight difference between the two notations is that arguments that match none of the patterns will result in a DomainError exception for the first notation, and in a NoMatch exception for the second.

While definitions only define a single entity per block and identifier, it is OK to have multiple `val`-statements for the same identifier in one block expression, for example like that:

```plaintext
val x = 1
val x = (x, x)
x
```

The above block expression evaluates to (1,1); later `val`-definitions overshadow earlier ones. But note that neither

```plaintext
val x = 1
def x = 1
```

nor

```plaintext
def x = 1
val x = 1
```

are legal.

Another difference between `val` and `def` is observed by the effects of non-determinism:

```plaintext
val x = random 2
(x, x)
```
will evaluate either to (0, 0) or to (1, 1). But

\[
\begin{align*}
\text{def } & \ x = \text{random} \ 2 \\
& (x, x)
\end{align*}
\]

can additionally also evaluate to (0, 1) or to (1, 0) because \(x\) is evaluated each time it is used.

Let us conclude this section by describing the third kind of statement. It has the form

\[
yield \ e
\]

where \(e\) is an expression. There is also an abbreviated form of the \texttt{yield}-statement which we have already used several times in this section:

\[
e
\]

The semantics of the \texttt{yield}-statement is that it appends a further value to the value of the block expression it is contained in. Block expressions have a value just like all other expressions in Babel-17. It is obtained by ”concatenating” all values of the \texttt{yield}-statements in a block expression. The value of

\[
\begin{align*}
\text{begin} \\
\text{yield } a \\
\text{end}
\end{align*}
\]

is \(a\). The value of

\[
\begin{align*}
\text{begin} \\
\text{yield } a \\
\text{yield } b \\
\text{end}
\end{align*}
\]

is the vector \((a, b)\) of length 2 and so on.

In this section we have introduced the notions of block expressions and statements. Their full power will be revealed in later sections of this document.

13. Anonymous Functions

So far we have seen how to define named functions in Babel-17. Sometimes we do not need a name for a certain function, for example when the code that implements this function is actually just as easy to understand as any name for the function. We already have the tools for writing such nameless, or anonymous, functions:

\[
\begin{align*}
\text{begin} \\
\text{def } \text{sqr } x & = x \times x \\
\text{sqr} \\
\text{end}
\end{align*}
\]

is an expression denoting the function that squares its argument. There is a shorter and equivalent way of writing down the above:

\[
x \Rightarrow x \times x
\]

In general, the syntax is
where $p$ is a pattern and $e$ an expression. The above is equivalent to

\[
\begin{align*}
\text{begin} \\
def f \ p = e \\
f \\
\text{end}
\end{align*}
\]

where $f$ is fresh for $p$ and $e$.

There is also a syntax for anonymous functions which allows for several cases:

\[
\left( \text{case } p_1 \Rightarrow b_1 \\
\vdots \\
\text{case } p_n \Rightarrow b_n \right)
\]

is equivalent to

\[
\begin{align*}
\text{begin} \\
def f \ p_1 = \text{begin } b_1 \text{ end} \\
\vdots \\
def f \ p_n = \text{begin } b_n \text{ end} \\
f \\
\text{end}
\end{align*}
\]

where $f$ is fresh for the $p_i$ and $b_i$.

14. Object Expressions

Object expressions have the following syntax:

\[
\begin{align*}
\text{object} \\
s_1 \\
\vdots \\
s_n \\
\text{end}
\end{align*}
\]

The $s_i$ are statements. Those $s_i$ that are def statements define the set of messages that the object responds to. Often you do not want to create objects from scratch but by modifying other already existing objects:

\[
\begin{align*}
\text{object } + \text{parents} \\
s_1 \\
\vdots \\
s_n \\
\text{end}
\end{align*}
\]

The expression parents must evaluate to either a list, a vector or a set. The members of parents are considered to be the parents of the newly created object, in the order induced by the collection. The idea is that the created object not only understands the messages defined by the $s_i$, but also the messages of the parents. Messages defined via $s_i$
shadow messages of the parents. The messages of an earlier parent shadow the messages of a later one.

The keyword this can be used only in def-statements of an object and points to the object that the original message has been sent too. There is also a way to denote record-like objects:

\[
\{ m_1 = v_1, \ldots, m_n = v_n \}
\]

This is equivalent to:

\[
begin \\
val (w_1, \ldots, w_n) = (v_1, \ldots, v_n) \\
object \\
def m_1 = w_1 \\
\ldots \\
def m_n = w_n \\
end \\
end
\]

The empty object is denoted by

nil

which is equivalent to

object end

15. **Boolean Operators**

Babel-17 provides the usual boolean operators. They are just syntactic sugar for certain match expressions; the exact translations are given in Table 6. Furthermore, there is the xor operator which is defined in the usual way. Babel-17 also has if-

---

**Table 6. Boolean Operators**

<table>
<thead>
<tr>
<th>not a</th>
<th>a and b</th>
<th>a or b</th>
</tr>
</thead>
<tbody>
<tr>
<td>match a case true =&gt; match b case true =&gt; true case false =&gt; false case _ =&gt; exception DomainError end</td>
<td>match a case false =&gt; match b case true =&gt; true case false =&gt; false case _ =&gt; exception DomainError end</td>
<td>match a case true =&gt; true case false =&gt; false case _ =&gt; exception DomainError end</td>
</tr>
</tbody>
</table>

| match a case true => false case false => true case _ => exception DomainError end | match a case false => false case true => true case _ => exception DomainError end |

---
expressions with the following syntax:

```plaintext
if \( b_1 \) then \\
\hspace{1em} e_1 \\
elseif \( b_2 \) then \\
\hspace{2em} e_2 \\
\hspace{2em} \vdots \\
elseif \( b_n \) then \\
\hspace{3em} e_n \\
else \\
\hspace{4em} e_{n+1} \\
end
```

The `elseif`-branches are optional. They can be eliminated in the obvious manner via nesting, so that we only need to give the semantics for the expression

```plaintext
if \( b \) then \( e_1 \) else \( e_2 \) end
```

The meaning of above expression is defined to be

```plaintext
match \( b \)
\hspace{1em} case true => \( e_1 \)
\hspace{1em} case false => \( e_2 \)
\hspace{1em} case _ => exception DomainError
end
```

Actually, the `else` branch is also optional. The notation

```plaintext
if \( b \) then \( e \) end
```

is shorthand for

```plaintext
if \( b \) then \( e \) else end
```

16. **Order**

Babel-17 has a built-in partial order which is defined in terms of the operator \( \sim \). The expression \( a \sim b \) returns an `Integer`; the usual relational operators are defined in Table 7.

It is possible to chain relational operators like this:

```plaintext
a \leq b \leq c > d <> e
```

Intuitively, the above means
Note that we always evaluate the operands of relational operators, even chained ones, only once. For example, the precise semantics of \( a \leq b \leq c \leq d \leq e \) is

\[
\begin{align*}
\text{begin} \\
\text{val} & \ t = a \\
\text{val} & \ u = b \\
\text{val} & \ v = c \\
\text{val} & \ w = d \\
\text{begin} \\
\text{val} & \ w = e \\
\text{end} \\
\text{end} \\
\end{align*}
\]

In the above, t, u, v and w are supposed to be fresh identifiers. Also note that if there are operands that are dynamic exceptions, then the result of a comparison is a dynamic exception with the same parameter as the first such operand (from left to right).

It is possible that two values \( a \) and \( b \) are not related with respect to the built-in order. In this case, \( a \sim b \) throws an Unrelated-exception. Taking this into account, the definition of \( a \ op \ b \) for \( op \in \{<, >, \leq, \geq\} \) is

\[
\begin{align*}
\text{match} & \ a \sim b \\
\text{case} & \ (u \text{ if } u \ op 0) =\ true \\
& \ case \ _\Rightarrow \ false \\
\text{end} \\
\end{align*}
\]

The cases \( op \in \{==, <>\} \) do not propagate the Unrelated-exception, and are defined like this:

\[
\begin{align*}
\text{match} & \ a \sim b \\
\text{case} & \ (u \text{ if } u \ op 0) =\ true \\
& \ case \ _\Rightarrow \ false \\
& \ case \ (\text{exception} \ Unrelated) =\ true \ op \ false \\
\text{end} \\
\end{align*}
\]

In principle, two values \( a \) and \( b \) are unrelated if they have different types. This statement is weakened by the existence of automatic type conversion (Section 27.7): if \( a \) and \( b \) have different types, it is checked if \( a \) can be automatically converted to something of type \texttt{typeof } b, or if \( b \) can be automatically converted into something of type \texttt{typeof } a. If so, then one of these conversions is done and the result is compared with the other value.

The built-in partial order has the following properties:

- if \( a \) and \( b \) have the same type, and this type is \texttt{obj} or user-defined (see Section 27.2 for how to define your own types), then \( a \sim b \) is equivalent to

\[
\text{match} \ a.\text{compare} _\ b
\]
case $u : \text{int}$ = $u$
case _ = $\text{exception}$ Unrelated
case (exception _) = $\text{exception}$ Unrelated
end

if $a$ has a $\text{compare}$ message; if not then $a$ and $b$ are compared according to the number, names and contents of their messages

- persistent exceptions are partially ordered by their parameter
- booleans are totally ordered and $\text{false} < \text{true}$ holds
- integers are totally ordered in the obvious way
- reals are partially ordered as described in Section 18
- strings are totally ordered via lexicographic ordering
- lists are partially ordered by the lexicographic ordering
- vectors are partially ordered by the lexicographic ordering
- constructed expressions are partially ordered by representing them by the pair consisting of constructor and parameter
- $f \neq g$ for all values $f$ and $g$ of type $\text{fun}$
- sets are partially ordered by first comparing their sizes, and then their elements
- maps are partially ordered by first comparing their sizes, then their keys, and then their corresponding values
- types are totally ordered by their names
- modules are totally ordered by their names

There are built-in operators $\text{min}$ and $\text{max}$ that compute the minimum and the maximum of a $\text{collection}$ (Section 25 defines what a collection is). For example,

\[
\text{min} (1, 2) == \text{max} (-1, 1, 0) == 1
\]

17. Sets and Maps

Sets and maps are built into Babel-17. For example, the set consisting of 3, 42 and 15 can be written as

\[
\{42, 15, 3\}
\]

Sets are always sorted. The sorting order is Babel-17’s built-in partial order, and every set forms a totally ordered subdomain of this partial order. Future versions of Babel-17 might allow the set order to be different from the built-in partial order. Adding or removing an element $e$ from a set $S$ is only well-defined when the elements of $S$ together with $e$ are totally ordered by the partial order of $S$. The same holds for testing if an element is in a set.

Maps map finitely many keys to values. For example, the map that maps 1 to 2 and 4 to 0 is written as

\[
\{1 -> 2, 4 -> 0\}
\]

The empty map is denoted by

\[
\{\} \quad \text{or} \quad 
\]

Maps also have always a partial order associated with them, in the current version of Babel-17 this is always Babel-17’s built-in partial order. Operations on maps are only
well-defined if all keys of the map together with all other involved keys are totally ordered by the associated order.

Pattern matching is available also for sets and maps. The pattern

\[ \{p_1, \ldots, p_n\} \]

matches a set that has \(n\) elements \(e_1, \ldots, e_n\) such that \(p_i\) matches \(e_i\) and \(e_i < e_j\) for \(i < j\). The pattern

\[ \{p_1, \ldots, p_n, \delta\} \]

matches a set that has \(m \geq n\) elements such that its first \(n\) elements match the patterns \(p_i\), and the set consisting of the other \(m - n\) elements matches the \(\delta\)-pattern.

Similarly, the pattern

\[ \{p_1 \rightarrow q_1, \ldots, p_n \rightarrow q_n\} \]

matches a map consisting of \(n\) key/value pairs such that the key/value pairs match the pattern pairs in order. The pattern \(\{ \rightarrow \}\) matches the empty map. Map patterns can have a \(\delta\) pattern, too.

18. REALS AND INTERVAL ARITHMETIC

Babel-17 is radical in its treatment of floating point arithmetic: there is only interval arithmetic. What that means is that reals are represented in Babel-17 as closed real intervals, i.e. as pairs \([a; b]\) where \(a\) and \(b\) are floating point numbers and \(a \leq b\). The usual floating point numbers \(f\) can then be represented as \([f; f]\). For example, the notation 1.5 is just short for \([1.5; 1.5]\).

The general form of this interval notation is

\([a; b]\)

Its value is formed by evaluating \(a\) and \(b\), resulting in \(\text{reals} \ [a_1; a_2]\) and \(\ [b_1; b_2]\), respectively, and then forming the interval \([\min(a_1, b_1), \max(a_2, b_2)]\). In case the evaluation does not yield reals, a \(\text{DomainError}\)-exception is thrown.

The general rule of interval arithmetic in Babel-17 is as follows: If \(f\) is a mapping from \(\mathbb{R}^n\) to \(\mathbb{R}\), then for its interval arithmetic implementation \(F\) the following must hold for all \(x_i \in \mathbb{R}\) and all reals \(y_i = [u_i; v_i]\) such that \(u_i \leq x_i \leq v_i:\)

\[ f(x_1, \ldots, x_n) \in F(y_1, \ldots, y_n) \]

The built-in order on \(\text{reals}\) is defined such that

\[ [a_1; a_2] \leq [b_1; b_2] \iff a_2 < b_1 \lor (a_1 = b_1 \land a_2 = b_2) \]

Note that certain seemingly obvious inequalities like \([1.0; 2.0] \leq 2.0\) do not hold!

19. SYNTACTIC SUGAR

One of the goals of Babel-17 is that Babel-17 code is easy to read and understand. I have found that allowing arbitrary user-specific extensions to the syntax of code is definitely not helping to achieve this goal. Nevertheless, a bare minimum of syntactic sugar is necessary to support the most basic conventions known from arithmetic; for example, one should be able to write \(3 + 5\) to denote the addition of the integer 3 and the integer 5.
Table 8. Syntactic Sugar

<table>
<thead>
<tr>
<th>Sugared</th>
<th>Desugared</th>
</tr>
</thead>
<tbody>
<tr>
<td>$a + b$</td>
<td>$a$.plus$b$</td>
</tr>
<tr>
<td>$a - b$</td>
<td>$a$.minus$b$</td>
</tr>
<tr>
<td>$a$</td>
<td>$a$.uminus$b$</td>
</tr>
<tr>
<td>$a * b$</td>
<td>$a$.times$b$</td>
</tr>
<tr>
<td>$a / b$</td>
<td>$a$.slash$b$</td>
</tr>
<tr>
<td>$a \div b$</td>
<td>$a$.div$b$</td>
</tr>
<tr>
<td>$a \mod b$</td>
<td>$a$.mod$b$</td>
</tr>
<tr>
<td>$a ^ b$</td>
<td>$a$.pow$b$</td>
</tr>
<tr>
<td>$a ** b$</td>
<td>$a$.plus$b$</td>
</tr>
<tr>
<td>$a -- b$</td>
<td>$a$.uminus$b$</td>
</tr>
<tr>
<td>$a \times b$</td>
<td>$a$.times$b$</td>
</tr>
<tr>
<td>$a // b$</td>
<td>$a$.slash$b$</td>
</tr>
<tr>
<td>$a \to b$</td>
<td>$a$.to$b$</td>
</tr>
<tr>
<td>$a \downarrow b$</td>
<td>$a$.downto$b$</td>
</tr>
<tr>
<td>$f x$</td>
<td>$f$.apply$x$</td>
</tr>
</tbody>
</table>

The programmer can use some of this syntactic sugar when defining her own objects. For example, $3 + 5$ is just syntactic sugar for $3$.plus$5$

Table 8 lists all syntactic sugar of Babel-17 that is also available to the programmer. The availability of syntactic sugar for function application means that you can let your own objects behave as if they were functions.

20. Memoization

Babel-17 supports memoization. In those places where def-statements can be used, memoize-statements can be used, also. A memoize-statement must always refer to def-statements in the same scope. Babel-17 differentiates two kinds of memoization, strong and weak. A memoize-statement has the following syntax:

$$\text{memoize } \text{ref}_1, \ldots, \text{ref}_n$$

The ref_i are either of the form id to indicate strong memoization, or of the form (id) to signal weak memoization. In both cases id refers to the def-statement being memoized. As an example, here is the definition of the weakly memoized fibonacci-sequence:

$$\text{memoize } (\text{fib})$$
$$\text{def } \text{fib } 0 = 0$$
$$\text{def } \text{fib } 1 = 1$$
$$\text{def } \text{fib } n = \text{fib } (n-1) + \text{fib } (n-2)$$

The difference between weak and strong memoization is that strong memoization always remembers a value once it has been computed; weak memoization instead may choose not to remember computed results in certain situations, for example in order to free
memory in low memory situations. Note that all arguments to the same memoized function must be totally ordered by the built-in partial order.

21. Linear Scope

We are now ready to explore the full power of block expressions and statements in Babel-17. We approach the topic of this and the following sections, linear scope, in an example-oriented way. A more in-depth treatment can be found in my paper Purely Functional Structured Programming [4].

First, we extend the syntax of val-statements such that it is legal to leave out the keyword val in certain situations. Whenever the situation is such that it is legal to write

\[ a = expr \]

for a variable identifier \( a \), we say that \( a \) is in linear scope. We call the above kind of statements assignments. A necessary condition for \( a \) to be in linear scope is for \( a \) to be in scope because of a previous val-statement or a pattern match. The idea behind linear scope is that when the program control flow has a linear structure, then we can make assignments to variables in linear scope without leaving the realm of purely functional programming.

The following two expressions are equivalent:

\[
\begin{align*}
&\text{begin} \\
&\quad \text{val} \; x = a \\
&\quad \text{val} \; y = b \\
&\quad \text{val} \; x = c \\
&\quad d \\
&\text{end}
\end{align*}
\]

\[
\begin{align*}
&\text{begin} \\
&\quad \text{val} \; x = a \\
&\quad \text{val} \; y = b \\
&\quad x = c \\
&\quad d \\
&\text{end}
\end{align*}
\]

So far, val-statements and assignments have indistinguishable semantics. The differences start to show when we look at nested block expressions:

\[
\begin{align*}
&\text{begin} \\
&\quad \text{val} \; x = 1 \\
&\quad \text{val} \; y = 2 \\
&\text{begin} \\
&\quad \text{val} \; x = 3 \\
&\quad \text{val} \; y = 4 \ast x \\
&\text{end} \\
&\quad (x, y) \\
&\text{end}
\end{align*}
\]

\[
\begin{align*}
&\text{begin} \\
&\quad \text{val} \; x = 1 \\
&\quad \text{val} \; y = 2 \\
&\text{begin} \\
&\quad \text{val} \; x = 3 \\
&\quad \text{begin} \\
&\quad \text{val} \; x = 3 \\
&\quad \text{val} \; y = 0 \\
&\quad y = 4 \ast x \\
&\text{end} \\
&\quad (x, y) \\
&\text{end} \\
&\quad (x, y)
\end{align*}
\]

\[
\begin{align*}
&\text{begin} \\
&\quad \text{val} \; x = 1 \\
&\quad \text{val} \; y = 2 \\
&\text{begin} \\
&\quad \text{val} \; x = 3 \\
&\quad \text{val} \; y = 0 \\
&\quad y = 4 \ast x \\
&\text{end} \\
&\quad (x, y) \\
&\text{end}
\end{align*}
\]

evaluates to \((1, 2)\) evaluates to \((1, 12)\) evaluates to \((1, 2)\)

The above examples show that the effect of dropping the val in a val-statement is that the binding of an identifier becomes visible at that level within the linear scope where it has last been introduced via a val-statement or via a pattern match.
Linear scope spreads along the statements and nested block expressions of a block expression. It usually does not spread into expressions. An exception are certain expressions that can also be viewed as statements. We call these expressions *control expressions*. For example, in

```
begin
  val x = 1
  x = 2
  val y = a * b
  (x, y)
end
```

the linear scope of $x$ does not extend into the expressions $a$ and $b$, because $a * b$ is not a control expression. Therefore the above expression will always evaluate (assuming there is no exception) to a pair which has 2 as its first element. But for example in

```
begin
  val x = 1
  x = 2
  val y =
    begin
      s_1
    ...
      s_n
    end
  (x, y)
end
```

the linear scope of $x$ extends into $s_1$ and spreads then along the following statements. Therefore the first element of the pair that is the result of evaluating above expression depends on what happens in the $s_i$. Here are three example code snippets that further illustrate linear scope:

<table>
<thead>
<tr>
<th>begin</th>
<th>begin</th>
<th>begin</th>
</tr>
</thead>
<tbody>
<tr>
<td>val x = 1</td>
<td>val x = 1</td>
<td>val x = 1</td>
</tr>
<tr>
<td>val y =</td>
<td>val y = 3 *</td>
<td>val y = 3 *</td>
</tr>
<tr>
<td>begin</td>
<td>begin</td>
<td>begin</td>
</tr>
<tr>
<td>x = 2</td>
<td>x = 2</td>
<td>x = 2</td>
</tr>
<tr>
<td>x+x</td>
<td>x+x</td>
<td>x+x</td>
</tr>
<tr>
<td>(x, y)</td>
<td>(x, y)</td>
<td>(x, y)</td>
</tr>
<tr>
<td>end</td>
<td>end</td>
<td>end</td>
</tr>
</tbody>
</table>

| evaluates to (2, 4) | illegal | evaluates to (1, 12) |

These are the control expressions that exist in Babel-17:

- `begin ... end`
- `if ... end`
- `match ... end`
• try ... catch ... end
• for ... do ... end
• while ... end

The last two control expressions are loops and explained in the next section. The first four have already been treated without delving too much into their statement character. We have already seen how begin ... end is responsible for nesting block expressions, when it is used as a statement. Just as the begin ... end expression may be used as a statement, you can also use all other control expressions as statements, for example:

```plaintext
begin
  val x = random 2
  if x == 0 then
    x = 100
  else
    x = 200
  end
  x + x
end
```

This expression will evaluate either to 200 or to 400.

For if-statements the else-branch is optional, but match-statements throw a NoMatch exception if none of the patterns matches.

22. Record Updates

Linear scope makes it possible to have purely functional record updates in Babel-17. Let us assume you have defined

```plaintext
val u = {x = 10, y = 20, z = -4}
```

and now you want to bind u to another record that differs only in the x-component. You could proceed as follows:

```plaintext
u = {x = 9, y = u.y, z = u.z}
```

but this clearly does not scale with the number of components of u. A more scalable alternative would be to write

```plaintext
u =
object + [u]
def x = 9
end
```

Babel-17 allows to write down the above statement in a more concise form:

```plaintext
u.x = 9
```

In general, for a value u of type obj,

```plaintext
u.m = t
```

is shorthand notation for
u =
  begin
    val evaluated_t = t
    object + [u]
    def m = evaluated_t
  end
end

Actually, there is an exception to the above rule: if u has a message \texttt{m.putback\_t}, then
\[ u.m = t \]
is actually shorthand for
\[ u = u.m\texttt{putback\_t} \]

The reason for this exception is that it allows us to generalize the concept of a purely functional record update to the concept of a \textit{lens}.

### 23. Lenses

Lenses [6] allow us to generalize the thing we did with updating records in a purely functional way. Lenses and linear scope work together well; this is very similar to how lenses and the state monad work together well [7].

A \textit{lens} is basically a pair of functions \((g, p)\), where \(g\) is called the \textit{get} function and \(p\) is called the \textit{putback} function of the lens. In the special case where a lens represents a field \(m\) of a record \(u\), this pair would be defined via
\[
  g\ u = u.m, \quad p\ u\ t = \text{a copy of } u \text{ where the field } m \text{ has been set to } t
\]

Generalizing from this special case, a lens should obey the following laws:
\[
g\ (p\ u\ t) = t, \quad p\ u\ (g\ u) = u
\]

In Babel-17, these laws are just recommendations for how to construct a lens as there are no mechanisms in place to ensure that a lens actually obeys them.

You can define a lens in Babel-17 directly via providing \textit{get} and \textit{putback} explicitly:
\[
def g\ u = u.m
\]
\[
def p\ u = t =\Rightarrow \begin{align*}
  \text{begin } & u.m = t; \ u \text{ end}
\end{align*}
\]
\[
val l = \text{\texttt{lens\_}}(g, p)
\]

The above code constructs a new lens \(l\). Lenses actually form their own type, so we have
\[
\texttt{typeof}\ l == (\text{\_lens}).
\]

What can you do with a lens once you got one? You can apply \(l\) to a value \(u\) via
\[
l\ u
\]

This applies the \textit{get} function of \(l\) to \(u\), so for our specific \(l\) we have that \(l\ u\) is equivalent to \(u.m\). In order to emphasize the aspect that \(l\) can be regarded as a field accessor for \(u\), instead of \(l\ u\) you can also write
\[
u.(l)
\]

This notation has the advantage that it can also be used on the left hand side of an assignment:
Table 9. Modifying Assignment Operators

</tbody>
</table>

val u = \{m = 10, n = 12\}
u.(1) = 23
u == \{m = 23, n = 12\}

The above evaluates to true, because the line u.(1) = 23 is short for u = 1.putback u 23.

Lenses come automatically equipped with a modify operation, 1modify u f is short for 1.putback u (f (1 u)). There is special notation that supports this operation:

val u = \{m = 10, n = 12\}
u.(1) += 2
u == \{m = 12, n = 12\}

This again evaluates to true, because the line u.(1) += 2 is short for

u = 1.modify u (m => m + 2)

The identity lens

val id = lens (x => x, x => y => y)

blurs the distinction between normal assignment and lens assignment, because the meaning of

val x = 10
x = 12

is exactly the same as the meaning of

val x = 10
x.(id) = 12

In particular, our new assignment operators like += and *= also work in the context of normal assignment:

val x = 10
x += 2
x == 12

This evaluates to true. Tables 9 list all modifying assignment operators.

Besides via directly giving the pair of functions that form a lens, a lens can also be defined by its access path. The access path of a lens is basically just how you would write
down the get function of the lens if it could be defined using message passing (possibly with arguments) and lens application only. For example, instead of defining a lens via

```haskell
def g u = u.m
def p u = t => begin u.m = t; u end
val l = lens (g, p)
```
you could just write

```haskell
val l = lens u =>> u.m
```
The identity lens becomes even simpler in this form:

```haskell
val id = lens u =>> u
```

Another valid legal lens definition is:

```haskell
val h = lens x => ((x.mymap.lookup 10) + 40).(l)
```
You could define the above lens directly via a pair of functions as follows:

```haskell
def g x = ((x.mymap.lookup 10) + 40).(l)
def p x = t =>
  begin
    val u1 = x.mymap
    val u2 = u1.lookup 10
    val u3 = u2 + 40
    val new_u3 = l.putback u3 t
    val new_u2 = u2.plus_putback_ 40 new_u3
    val new_u1 = u1.lookup_putback_ 10 new_u2
    val new_x = x
    new_x.mymap = new_u1
    new_x
  end
val h = lens (g, p)
```

The cool thing about lenses is that they are composable. Given two lenses \(a\) and \(b\), we can define a new lens \(c\) via

```haskell
val c = lens x => x.(a).(b)
```

Multiplication of lenses is defined to be just this composition, so we could also just write

```haskell
val c = a * b
```

Here is an example that illustrates composition:

```haskell
val a = lens x => x.a
val b = lens x => x.b

val x = {a = {a = 1, b = 2}, b = {a = 3, b = 4}}
x.(a+b) = 10
x.(b+a) = 20

x == {a = {a = 1, b = 10}, b = {a = 20, b = 4}}
```
This evaluates to \textbf{true}. Note that if the left hand side of an assignment is an access path, then the corresponding lens is automatically constructed. Therefore, in the above context the following five lines have identical meaning:

\begin{align*}
x.(a+b) &= 10 \\
x.(a).(b) &= 10 \\
x.a.b &= 10 \\
x.(a).b &= 10 \\
x.a.(b) &= 10
\end{align*}

24. \textbf{With}

By default, all yielded values of a block expression are collected into a vector which collapses in the case of a single element. The programmer might want to deviate from this default and collect the yielded values differently, for example to get rid of the collapsing behavior. The \textbf{with} expression allows her to do just that. Its syntax is:

\begin{verbatim}
with c do \\
  b \\
end
\end{verbatim}

where \(c\) is a \textit{collector} and \(b\) is a block expression. A collector \(c\) is any object that

\begin{itemize}
  \item responds to the message \texttt{collector\_close\_},
  \item and returns via \texttt{c.collector\_add\_} \(x\) another collector.
\end{itemize}

It is recommended that collectors also support the message \texttt{empty} to represent the empty collector that has not collected anything yet.

Lists, vectors, sets, maps and strings are built-in collectors which the programmer can use out-of-the-box; apart from that she can implement her own collectors, of course.

Here is an example where we use a set as a collector:

\begin{verbatim}
with \{4\} do \\
  yield 1 \\
  yield 2 \\
  yield 1 \\
  10 \\
end
\end{verbatim}

Above expression evaluates to \{1, 2, 4, 10\}.

25. \textbf{Loops}

This is the syntax for the \textbf{while}-loop:

\begin{verbatim}
while c do \\
  b \\
end
\end{verbatim}

Here \(c\) must evaluate to a boolean and \(b\) is a block expression. For example, here is how you could code the euclidean algorithm for calculating the greatest common divisor:
def gcd (a,b) = begin
  while b <> 0 do
    (a, b) = (b, a mod b)
  end
  a
end

There is also the for-loop. It has the following syntax:

for p in C do
  b
end

In the above p is a pattern, C is a collection, and b is a block expression. The idea is that above expression iterates through those elements of the collection C which match p; for each successfully matched element, b is executed.

An object C is a collection if it handles the message iterate_

• by returning () if it represents the empty collection,
• or otherwise by returning (e, C') such that C' is also a collection.

Here is an example of a simple for-loop expression:

begin
  val s = [10, (5, 8), 7, (3,5)]
  with {−> } : for (a,b) in s do
    yield (b,a)
  end
end

evaluates to {8 −> 5, 5 −> 3}.

Using for-loops in combination with linear scope it is possible to formulate all of those fold-related functionals known from functional programming in a way which is easier to parse (and remember) for most people. Let us for example look at a function that takes a list m of integers \([a_0, \ldots, a_n]\) and an integer x as arguments and returns the list

\[
[q_0, \ldots, q_n] \quad \text{where} \quad q_k = \sum_{i=0}^{k} a_i x^i
\]

The implementation in Babel-17 via a loop is straightforward, efficient and even elegant:

m => x =>
  with [] do
    val y = 0
    val p = 1
    for a in m do
      y = y + a*p
      p = p * x
      yield y
    end
  end
The built-in collections that can be used with for-loops are the usual suspects: lists, vectors, sets, maps and strings. Of course you can define your own custom collections. There is even a pattern you can use for matching against an arbitrary collection:

\[
\text{(for } p_1, \ldots, p_n \text{ end)}
\]

and the corresponding \(\Delta\) pattern

\[
\text{(for } p_1, \ldots, p_n, \Delta \text{ end)}
\]

match collections with exactly \(n\) or at least \(n\) elements, respectively.

26. Pragmas

Pragmas are statements that are not really part of the program, but inserted in it for pragmatical reasons. They are useful for testing, debugging and profiling a program. There are currently four different kinds of pragmas available:

- \#log \(e\) evaluates the expression \(e\) and logs it.
- \#print \(e\) evaluates the expression \(e\) such that it has no internal lazy or concurrent computations any more, and then logs it.
- \#profile \(e\) evaluates the expression \(e\), gathers profiling information while doing so, and logs both.
- \#assert \(e\) evaluates the expression \(e\) and signals an error if \(e\) does not evaluate to true.
- \#catch \(p\) try \(e\) evaluates the expression \(e\) and signals an error if \(e\) does not evaluate to an exception with a parameter that matches \(p\).

The Babel-17 interpreter / compiler is free to ignore pragmas, typically if instructed so by the user.

27. Modules and Types

Modules give Babel-17 code a static structure and improve on object expressions by providing more sophisticated encapsulation mechanisms via types. Modules are introduced with the syntax

\[
\text{module } p_1.p_2.\ldots.p_n
\]

\[
\text{\hspace{1cm} } s_1
\]

\[
\text{\hspace{1cm} } \vdots
\]

\[
\text{\hspace{1cm} } s_n
\]

\[
\text{end}
\]

where \(p = p_1.p_2.\ldots.p_n\) is the module path.

The statements \(s_i\) that may appear in modules are basically those that may also appear in object expressions. Additionally, modules can contain type definitions; this is the topic of the next section.

Identifiers introduced via definitions become the messages that this module responds to except when hidden via private.

Modules can be nested. Basically,

\[
\text{module } p_1.p_2.\ldots.p_n
\]

\[
\text{\hspace{1cm} } S_1
\]

\[
\text{\hspace{1cm} } \text{module } q_1.q_2.\ldots.q_m
\]
:  
end
$S_2$
end
means the same as
\[
\text{module } p_1.p_2.\ldots.p_n \\
S_1 \\
\text{end}
\]
\[
\text{module } p_1.p_2.\ldots.p_n.q_1.q_2.\ldots.q_m \\
:  \\
\text{end}
\]

A module cannot access its surrounding scope, with the exception of those identifiers that have been introduced via `import`. So the following is not allowed, because inside module `b` the identifier `u` cannot be accessed:

\[
\text{module } a \\
\text{val } u = 2 \\
\text{module } b \\
\text{def message } = u \\
\text{end} \\
\text{end}
\]

But the following is allowed:

\[
\text{module } a \\
\text{import someCoolModule.importantValue } = u \\
\text{module } b \\
\text{def message } = u \\
\text{end} \\
\text{end}
\]

27.1. **Loading Modules.** Before a module can respond to messages, it must be loaded. A module is in one of the following three states: DOWN, LOADING or UP. There are three things that one might suspect to change the state of the module:

- **A:** the module receives a message `m` that corresponds to a definition inside of it,
- **B:** the module receives a message `m` that corresponds to a submodule `p.m`,
- **C:** the module receives an invalid message `m`.

Of these three things, neither B nor C change the state of the module, so we are looking now only at case A.

In the following we distinguish modules which need initialization from modules which don’t. A module does not need initialization iff it consists only of the following types of statements: `def`, `typedef`, `import`, `private`, `memoize`.

If module `p` needs initialization and is in state DOWN, then sending it a message causes it to go to state LOADING; after `p` has been loaded, that is all statements of the
module have been executed, \( p \) goes from state LOADING to state UP. If the module needs no initialization, the state goes directly from DOWN to UP.

If \( p \) is in state LOADING, then sending it a message will make the sender wait until \( p \) is in state UP. Note that this can lead to a deadlock situation. In case the Babel-17 runtime can detect this deadlock, a **DeadLock**-exception is thrown.

If \( p \) is already in state UP, then \( A \) does not change the state of the module.

Note that the state of a module is not directly accessible and only sometimes indirectly observable via the **DeadLock**-exception.

Here is an example that leads to a deadlock:

```plaintext
module deadlock
  def x = 10
  val a = deadlock.x + 1
  def y = a * a
end
deadlock.y
```

Note that the following example does **not** lead to a deadlock:

```plaintext
module noDeadlock
  def x = 10
  val a = x + 1
  def y = a * a
end
noDeadlock.y
```

The most straightforward way to avoid deadlock problems is to write modules which need no initialization.

27.2. Type Definitions. A module may contain type definition statements. A new type \( t \) is introduced via

```plaintext
typedef t pat = expr
```

where \( t \) is an identifier, \( pat \) a pattern and \( expr \) an expression. Like a **def** statement, the above introduces a new function \( t \). Unlike a **def** statement, it also introduces a new type \( t \). The new function \( t \) has the property that all non-exceptional values \( v \) it returns will have type \( t \) and will consist of two components: an inner value, and an outer value. The inner value \( i \) is just the argument that was passed to \( t \). The outer value \( o \) is the result of evaluating and forcing \( expr \) in case this does not lead to an exception. If \( pat \) does not match, then a **DomainError**-exception is thrown.

The point of all this is that the value \( v \) behaves just like its outer value \( o \), i.e. \( v \) responds to the same messages as \( o \), and does so in the same way. Nevertheless, the type of \( v \) is \( t \), whatever the type of \( o \) might be. This means that you can implement the behavior of \( v \) by choosing an appropriate \( o \) which accesses the hidden encapsulated state \( i \). This hidden state can also be accessed in the module in which the type has been defined via the inner-value pattern \((t \ p)\) which matches \( v \) if it has type \( t \) and its inner value \( i \) matches \( p \).

Let’s look at a first type definition example:
module cards
typedef rank i =
    match i
        case 14 => Ace
        case 13 => King
        case 12 => Queen
        case 11 => Jack
        case x if 2 <= x <= 10 => Number x
    end
end

In the above we define the type *cards.rank*. We can create a value of this type like this:

```ml
val k = cards.rank 13
```

The expression (:cards.rank) evaluates to the type *cards.rank*, therefore

```ml
(typeof k) == (:cards.rank)
```

evaluates to `true`.

Note that there is no other way to create a value of type *cards.rank* than via the *rank* function in the module *cards*. If you want to access the inner value of a value of type *cards.rank*, you can do so within the module *cards* via the inner-value pattern:

```ml
module cards
typedef rank ... 
... 
def rank2num(rank n) = n
... 
end
```

Now you can access the inner value of a rank even outside of the *cards* module by calling the *rank2num* function we just defined. The following evaluates to `true`:

```ml
cards.rank2num (cards.rank 14) == 14
```

You can use the fact that a rank value behaves like its outer value to do pattern matching on rank values:

```ml
def rank2str(r : rank) =
    match r
        case (Ace !) => "ace"
        case (King !) => "king"
        case (Queen !) => "queen"
        case (Number ! n) => "number"+n
    end
```

It is possible to distribute the definition of a type *t* over several statements:

```ml
typedef t pat1 = expr1
... 
typedef t patn = exprn
```

So an alternative way of defining the rank type would have been:
module cards
typedef rank 14 = Ace
typedef rank 13 = King
typedef rank 12 = Queen
typedef rank 11 = Jack
typedef rank (n if 2 <= n <= 10) = Number n
end

As a shortcut notation, several typedef clauses belonging to the same type \( t \) can be combined into a single one by separating the different cases by commas:

module cards
typedef rank 14 = Ace, 13 = King, 12 = Queen, 11 = Jack, (n if 2 <= n <= 10) = Number n
end

Another shortcut notation allows you to write instead of

typedef \( t (x \text{ as } p) = x \)

just

typedef \( t \ p \)

Finally, it is possible to identify a type with the module it is defined in by using the same name for the type and the module. For example:

module util.orderedSet
typedef orderedSet ...
...
end

This defines the module \( \text{util.orderedSet} \) and the type \( \text{util.orderedSet.orderedSet} \). Because of our convention of identifying modules and types that have the same name, you can refer to the type \( \text{util.orderedSet.orderedSet} \) also just by \( \text{util.orderedSet} \). In particular, the following evaluates to \( \text{true} \):

\[
(: \text{util.orderedSet.orderedSet}) == (:\text{util.orderedSet})
\]

This is all there is to defining your own types in Babel-17. In the following we list a few common type definition patterns: \textit{simple enumerations}, \textit{algebraic datatypes}, and \textit{abstract datatypes}.

27.3. Simple Enumerations. It is easy to define a type that is just an enumeration:

module cards
typedef suit Spades, Clubs, Diamonds, Hearts
end

We may choose to represent our rank type rather as an enumeration, too:

module cards
typedef rank Ace, King, Queen, Jack, Number (n if 2 <= n <= 10)
end
27.4. **Algebraic Datatypes.** For enumeration types, the inner value is always equal to the outer value. This property is also shared by the more complex algebraic datatypes which are typically recursively defined:

```babel-17
module cards
  typedef bintree Leaf _, Branch (_, bintree, _) : bintree
end
```

27.5. **Abstract Datatypes.** The type definition facility of Babel-17 is powerful enough to allow you to define your own abstract datatypes. Currently there is no type in Babel-17 for representing sets that are ordered by a given (i.e., not necessarily the built-in) order. So let’s define our own. To keep it simple, we use lists to internally represent sets:

```babel-17
module util.orderedSet
  private orderedSet, ins
  typedef orderedSet (leq, list) = nil
  def empty (leq : fun) = orderedSet (leq, [])
  def insert (orderedSet (leq, list), y) = orderedSet (leq, ins (leq, list, y))
  def toList (orderedSet (leq, list)) = list
  def ins (leq, [], y) = [y]
  def ins (leq, x::xs, y) =
    if leq (y, x) then
      if leq (x, y) then x::xs else y::x::xs end
    else
      x::(ins (leq, xs, y))
    end
end
```

From outside the module, the only way to create values of type `orderedSet` is by calling `empty` and `insert`. The only way to inspect the elements of an `orderedSet` is via `toList`.

27.6. **Type Conversions.** It often makes sense to convert a value of one type into a value of another type. Probably the most prominent example of this is converting an `Integer` to a `Real` and rounding a `Real` to an `Integer`.

Because type conversions are so ubiquitous, there is special notation for it in Babel-17. To convert a value `v` canonically to a value of type `t`, the notation

```babel-17
v :-< t
```

is used. If `t` is a value of type `type`, you can write

```babel-17
v :-< (t)
```

to express the conversion operation.

Your own object can implement conversion to a type `t` via
object
...
def this :> t = ...
....
end

In case your object cannot convert to t, it should throw a DomainError-exception.
You can annotate your def-statements with a return type t, for example:
def myfun pat : t = expr

This is just another notation for
def myfun pat = (expr :> t)

27.7. **Automatic Type Conversions.** Type conversions are actually differentiated into two separate classes: those which are automatically applied, and those which are only applied in conjunction with the :> operator.

Your own object can implement automatic type conversion to a type t via

object
...
def this : t = ...
....
end

Note that an automatic type conversion takes precedence over a non-automatic one when used in conjunction with the :> operator. In particular,

class

def this : int = 1
def this :> int = 2
end :> int

class

will evaluate to 1.

27.8. **Import.** A module can be accessed from anywhere via its module path. For example will

module hello.world
def x = 2
end

hello.world.x

result in the value 2.

To avoid typing long module paths you can import them:

import hello.world.x

(x, x, x)

will evaluate to (2, 2, 2).

You can also import types this way:

import util.orderedSet.orderedSet
def e : orderedSet = util.orderedSet.empty
Alternatively, to make the above statement even shorter, import both the type and its enclosing module:

```python
import util.orderedSet
def e : orderedSet = orderedSet.empty
```

It is not possible to just import all members of a module; Babel-17 is dynamically typed, and the danger of accidental mayhem just would be too big.

You can rename imports, for example:

```python
import util.orderedSet => set
def e : set = set.empty
```

You can combine several imports into a single one:

```python
import util.orderedSet.{empty, insert => orderedInsert}
def e : set = set.empty
```

All imports must be grouped together at the beginning of a block, and later `import`-statements in this group take earlier `import`-statements in this group (and outside this group, of course) into account.

There is the `root`-keyword that denotes the module root. Instead of `import util.orderedSet` you could just as well say

```python
import root.util.orderedSet
```

You can also use it in expressions, like in

```python
val e = root.util.orderedSet.empty
```

The `root`-keyword comes in handy in situations when you want to explicitly make sure that there is no name aliasing going on:

```python
import com.util
import util.orderedSet
```

here the second import actually imports `com.util.orderedSet`. If you want to import `util.orderedSet` instead, write

```python
import com.util
import root.util.orderedSet
```

### 27.9. Abstract Datatypes, Continued.

We have seen previously how to define our own abstract datatype `orderedSet`. This is already fine, but we would like `orderedSet` to integrate more tightly with how things work in Babel-17. In particular,

1. ordered sets should be comparable in a way that makes sense; right now, the expression

   ```python
   insert (empty leq, 1) == insert (empty leq, 2)
   ```

   evaluates to `true` because both values have outer value `nil`,
2. instead of `insert (r, x)` we just want to write `r + x`,
3. instead of `toList r` we want to write `r :> list`,
4. we want to be able to traverse the set via

   ```python
   for x in r do ... end
   ```

   (5) and we want to be able to write
with empty leq do
  yield a
  yield b
  yield c
end

for the set consisting of the elements a, b and c.

We can achieve all that by replacing the line

typedef orderedSet (leq, list) = nil

with the following code:

typedef orderedSet (leq, list) =
  object

  ## (1)
  def compare (orderedSet (leq2, list2)) = list ~ list2

  ## (2)
  def plus x = insert (this, x)

  ## (3)
  def this : list = list

  ## (4)
  def iterate =
    match list
      case [] => ()
      case (x::xs) => (x, orderedSet (leq, xs))
    end

  ## (5)
  def collector_close = this
  def collector_add x = this + x
  def empty = orderedSet (leq, [])
end

28. Unit Tests

Unit testing has become a corner stone of most popular software development methodologies. Therefore Babel-17 provides language support for unit testing in form of the unittest keyword. This keyword can be used in two forms.

First, it can be used as part of the name of a module, for example like in

module util.orderedSet.unittest
import util.orderedSet._
def leq (a, b) = a <= b
def geq (a, b) = a >= b

#assert insert (insert (empty leq, 3), 1) => list == [1, 3]
#assert insert (insert (empty geq, 3), 1) => list == [3, 1]

def unittest =
  begin
    def leq (a, b) = a <= b
def geq (a, b) = a >= b

    #assert insert (insert (empty leq, 3), 1) => list == [1, 3]
    #assert insert (insert (empty geq, 3), 1) => list == [3, 1]
  end
end

Second, it can be used to separate a module definition into two parts:

module util.orderedSet
typedef orderedSet ...
...
unittest
def leq (a, b) = a <= b
def geq (a, b) = a >= b

#assert insert (insert (empty leq, 3), 1) => list == [1, 3]
#assert insert (insert (empty geq, 3), 1) => list == [3, 1]

def unittest =
  begin
    def leq (a, b) = a <= b
def geq (a, b) = a >= b

    #assert insert (insert (empty leq, 3), 1) => list == [1, 3]
    #assert insert (insert (empty geq, 3), 1) => list == [3, 1]
  end
end

except for the fact that this is not legal Babel-17.
The idea is that Babel-17 can run in two modes. In production mode, all unit tests are ignored. In unit testing mode, you can run your unit tests. Usually in production mode, you would switch off assertions, and in unit testing mode you would turn them on, but that is up to you.

An important detail is that production code is separated from unit testing code, i.e. while unit testing code can import other unit testing code and production code, production code can only import other production code. For example,

```pseudo
module mystuff

import util.orderSet.unittest => test

test ()
end
```

is not legal Babel-17, because the production code module `mystuff` cannot import the unit testing function `util.orderSet.unittest`. On the other hand, the following is valid Babel-17:

```pseudo
module mystuff.unittest

import util.orderSet.unittest => test

test ()
end
```

29. Native Interface

Babel-17 exposes the platform it is running on through its native interface. To query which platform you are running on, use the expression

```pseudo
native Platform
```

If there is no underlying platform you can access, the value `nil` is returned.

29.1. The Java Platform. In case of

```pseudo
native Platform == Java
```

there is a limited form of Java interoperability available. With

```pseudo
val v = native New (classname, x_1, \ldots, x_n)
```

you can create a value `v` of type `native_` that is a wrapper for a Java object of class `classname`; the `x_i` are the arguments that are passed to the constructor. Table 10 describes how values are converted between Babel-17 and Java.

You can access the fields of `v` and call its methods by sending messages to `v`. This holds also true for static fields and messages. So for example, you can do the following:

```pseudo
val ar = native New ("java.util.ArrayList", 5)
val _ =
begin
Table 10. Conversions between Babel-17 and Java Values

</tbody>
</table>

ar.add 1
ar.add 10
ar.add 5
ar.add ((18, 13, 15),)

end

ar.toArray ()

This evaluates to (1, 10, 5, (18, 13, 15)).

Ambiguities are resolved in some way. The only rule you can rely on is that access to methods shadows access to fields. Note that ambiguities not only arise because of typing ambiguities, but also because messages in Babel-17 are case-insensitive, but in Java method and field names are case-sensitive.

You can instantiate a native value that corresponds to a Java class classname via

val c = native Class classname

The value c will in addition to the normal class fields and methods also understand messages that correspond to the static fields and methods of the class. For example:

val c = native Class "java.lang.Integer"
c.parsInt "120"

will evaluate to 120.

30. Standard Library

The standard library is an important part of the language definition of Babel-17 and consists of the built-in types of Babel-17. In future versions of Babel-17, also the module lang and all its submodules are part of the standard library.

The messages implemented by the built-in types of the standard library can be grouped as follows:

- collector related messages (Section 24),
- collection related messages (Section 25),
- putback messages that implement lens functionality,
- those messages that are listed as syntactic sugar in Table 8
- messages specific to the type.

As a convention, all messages that are normally only used via some sort of syntactic sugar end with an underscore in their name.
Table 11. Additional messages for collection/collector $c$

<table>
<thead>
<tr>
<th>Message</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>$c$.isEmpty</td>
<td>checks if $c$ is an empty collection</td>
</tr>
<tr>
<td>$c$.empty</td>
<td>an empty collection that has the same type as $c$</td>
</tr>
<tr>
<td>$c$.size</td>
<td>the size of collection $c$</td>
</tr>
<tr>
<td>$c + x$</td>
<td>adds $x$ as member to collection $c$</td>
</tr>
<tr>
<td>$c ++ d$</td>
<td>adds all members of $d$ as members to $c$</td>
</tr>
<tr>
<td>$c - x$</td>
<td>removes from $c$ all members that are equal to $x$</td>
</tr>
<tr>
<td>$c -= d$</td>
<td>removes from $c$ all members that are equal to an element in $d$</td>
</tr>
<tr>
<td>$c ** d$</td>
<td>removes from $c$ all members that are not equal to an element in $d$</td>
</tr>
<tr>
<td>$c$.head</td>
<td>the first element of $c$</td>
</tr>
<tr>
<td>$c$.tail</td>
<td>all elements of $c$ except the first one</td>
</tr>
<tr>
<td>$c$.atIndex $i$</td>
<td>the $i$-th element of $c$</td>
</tr>
<tr>
<td>$c$.indexOf  $x$</td>
<td>the lowest $i$ such that $c$.atIndex $i$ $==$ $x$</td>
</tr>
<tr>
<td>$c$.contains $x$</td>
<td>checks if $c$ contains $x$</td>
</tr>
<tr>
<td>$c$.take $n$</td>
<td>forms a collection out of the first $n$ elements of $c$</td>
</tr>
<tr>
<td>$c$.drop $n$</td>
<td>forms a collection by dropping the first $n$ elements of $c$</td>
</tr>
<tr>
<td>$c/f$</td>
<td>maps the function $f$ over all elements of $c$</td>
</tr>
<tr>
<td>$(c * f) a_0$</td>
<td>folds $f$ over $c$ via $a_{i+1} = f(c_i, a_i)$</td>
</tr>
<tr>
<td>$c \not\in f$</td>
<td>filters $c$ by boolean-valued function $f$</td>
</tr>
<tr>
<td>$c // f$</td>
<td>map created by all key/value pairs $(x, f(x))$ where $x$ runs through the elements of $c$; later pairs overwrite earlier pairs</td>
</tr>
</tbody>
</table>

30.1. Collections and Collectors. The built-in types that can be used as collectors and collections are: List, Vector, Set, Map and String. In the case of maps, the elements of the collection are pairs (vectors of length 2) where the first element of the pair represents the key, and the second element the value the key is mapped to. For strings, the elements of the collection are strings of length 1, consisting of a single Unicode code point.

All built-in collection/collector types implement the messages described in Table 11.

30.2. Type Conversions. Many built-in types have conversions defined between them. Some of these type conversions are automatic, and some are not. Table 12 lists all of them. Note that a ”yes” and ”auto” do not necessarily mean that all values of the source type can be converted to the destination type. For example, $5^{1000}$ cannot be converted to real, and $5.1$ cannot be automatically converted to int, but nevertheless $5.1 :> \text{int} == 5$ holds.

In the rest of this section we enumerate for each built-in type all messages that are supported by this type. Collector and collection messages are excluded from this enumeration.
Table 12. Type Conversions $\text{src} :> \text{dest}$

<table>
<thead>
<tr>
<th>src</th>
<th>int</th>
<th>bool</th>
<th>real</th>
<th>string</th>
<th>list</th>

</tbody>
</table>

Table 13. List/Vector-specific messages

<table>
<thead>
<tr>
<th>$l$</th>
<th>$i$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$l$</td>
<td>same as $l$ atIndex $i$</td>
</tr>
<tr>
<td>$-l$</td>
<td>reverses $l$</td>
</tr>
</tbody>
</table>

30.3. **Integer.** Integers can be arbitrarily large and support the usual operations (*, binary and unary -, *, ^, div, mod). Division and modulo are Euclidean.

The expression $a \text{ to } b$ denotes the list of values $a, a + 1, \ldots, b$. The expression $a \text{ downto } b$ denotes the list of values $a, a - 1, \ldots, b$.

30.4. **Reals.** Reals are intervals bounded by floating point numbers. For more information on them see Section 15.

30.5. **String.** Implements no messages specific for strings. The semantics of the indexOf and contains messages is extended with respect to the usual collection semantics to not only search for strings of length 1, but arbitrarily long strings.

30.6. **List and Vector.** Those messages specific to lists and vectors are listed in Table 13.

30.7. **Set.** There are no messages specific to sets except that for a set $s$ the expression $s \times x$ is equivalent to $s$.contains $x$ and therefore tests if $x$ is an element of $s$.

30.8. **Map.** The messages specific to maps are listed in Table 14. Note that the operators -, --, ** and // deviate in their semantics from the usual collection semantics, but that the operators + and ++ do behave according to the usual collection semantics.

30.9. **Object.** Custom objects respond exactly to the set of messages defined in their body, with one exception: if the custom object implements all four of these messages:

- collector.add_
- collector.close_
- empty
- collectoriterate_
Table 14. Map-specific Messages

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>c.contains x</code></td>
<td>checks if <code>c</code> contains <code>x</code></td>
</tr>
<tr>
<td><code>c.containsKey k</code></td>
<td>checks if <code>c</code> contains <code>(k, v)</code> for some <code>v</code></td>
</tr>
<tr>
<td><code>m + (k,v)</code></td>
<td>map created from the map <code>m</code> by associating <code>k</code> with <code>v</code></td>
</tr>
<tr>
<td><code>m - k</code></td>
<td>map created from the map <code>m</code> by removing the key <code>k</code></td>
</tr>
<tr>
<td><code>m ++ n</code></td>
<td>map created from the map <code>m</code> by adding the key/value pairs that are elements of <code>n</code></td>
</tr>
<tr>
<td><code>m -- n</code></td>
<td>map created from <code>m</code> by removing all keys that are elements of <code>n</code></td>
</tr>
<tr>
<td><code>m ** n</code></td>
<td>map created from <code>m</code> by removing all keys that are not elements of <code>n</code></td>
</tr>
<tr>
<td><code>m k</code></td>
<td>returns the value <code>v</code> associated with <code>k</code> in <code>m</code>, or returns a dynamic exception with parameter <code>DomainError</code> if no such value exists</td>
</tr>
<tr>
<td><code>m // f</code></td>
<td>map created by applying the function <code>f</code> to the key/value pairs <code>(k, v)</code> of <code>m</code>, yielding key/value pairs <code>(k, f(k, v))</code></td>
</tr>
</tbody>
</table>

then the custom object automatically inherits standard implementations for all messages listed in Table [1] and for the three type conversions to `list`, `vector` and `set`. These standard implementations are shadowed by actual implementations the custom object might provide.

31. What’s Next?

Where will Babel-17 go from here? There are two dimensions along which Babel-17 has to grow in order to find adoption.

**Maturity and breadth of implementations** While there will probably always be a reference implementation of Babel-17 that strives for simplicity and clarity and sacrifices performance to achieve this, Babel-17 will need quality implementations on major computing platforms like JavaVM, Android, iOS and HTML 5. A lot of the infrastructure of these implementations can be shared, so once there is a speedy implementation of Babel-17 running for example on the Java Virtual Machine, the other implementations should follow more quickly. For example, there are many many opportunities for both static and particularly dynamic optimizations of the standard library implementation.

**Development of the language** Babel-17 is a dynamically typed purely functional programming language with a module system that has powerful encapsulation mechanisms. Some way of dealing with state, user interfaces, and communication with the outside world will be added to future versions of Babel-17.
