Abstract
Region-based JIT compilation operates on translation units comprising multiple basic blocks and, possibly cyclic or conditional, control flow between these. It promises to reconcile aggressive code optimisation and low compilation latency in performance-critical dynamic binary translators. Whilst various region selection schemes and isolated code optimisation techniques have been investigated it remains unclear how to best exploit such regions for efficient code generation. Complex interactions with indirect branch tables and translation caches can have adverse effects on performance if not considered carefully. In this paper we present a complete code generation strategy for a region-based dynamic binary translator, which exploits branch type and control flow profiling information to improve code quality for the common case. We demonstrate that using our code generation strategy a competitive region-based dynamic compiler can be built on top of the LLVM JIT compilation framework. For the ARM V5T target ISA and SPEC CPU 2006 benchmarks we achieve execution rates of, on average, 867 MIPS and up to 1323 MIPS on a standard x86 host machine, outperforming state-of-the-art QEMU-ARM by delivering a speedup of 264%.

Keywords  Dynamic binary translation; region-based just-in-time compilation; alias analysis

1. Introduction
Dynamic binary translation (DBT) is a widely used technology that makes it possible to run code compiled for a target platform on a host platform with a different instruction set architecture (ISA). With DBT, machine instructions of a program for the target platform are translated to machine instructions for the host platform during the execution of the program. Among the main uses of DBT are cross-platform virtualisation for the migration of legacy applications to different hardware platforms (e.g., Apple Rosetta and IBM PowerVM LX86 (Stahl and Anand 2010)) and the provision of virtual platforms for convenient software development for embedded systems (e.g., Virtual Prototype by Synopsys).

Efficient DBT heavily relies on Just-in-Time (JIT) compilation for the translation of target machine instructions to host machine instructions. Although JIT compiled code generally runs much faster than interpreted code, JIT compilation incurs an additional overhead. For this reason, only the most frequently executed code fragments are translated to native code whereas less frequently executed code is still interpreted. Of central concern are the size and shape of these translation units presented to the JIT compiler: While smaller code fragments such as individual instructions or basic blocks take less time for JIT compilation, larger fragments such as linear traces or regions comprising control flow offer more scope for aggressive code optimisation (Aycock 2003). For this reason, many modern DBT systems rely on regions as translation units for JIT compilation and several different region selection schemes have been proposed in the literature (Bruening and Duesterwald 2000; Hiniker et al. 2005; Hiser et al. 2006b; Hsu et al. 2013). However, it remains an open question as how to efficiently exploit such regions for JIT code generation resulting in improved performance.

Our main contribution is a complete, region-based JIT code generation strategy considering optimal handling of branch type information and region exits, registration of JIT compiled code in translation caches, continuous profiling and recompilation, region chaining, and host code generation including custom alias analysis. The key ideas can be summarised as follows: We collect branch type information during code discovery and profiling and only expose region entries and indirect branch targets, whereas direct branch targets are neither accessible from outside the region nor through the indirect branch target table. This directly improves code quality as unnecessarily exposed branch targets defeat control and data flow analysis. Only identified region entries are registered in the translation cache, we do not allow arbitrary entry to a region. Again, this optimisation aids control and data flow analysis and, thus, ultimately improves performance. In addition, we provide shortcuts for region exits and implement region chaining, improving the transition from one region to another. We continuously profile execution, grow and recompile regions using up-to-date profiling information to include newly discovered blocks and transitions. Finally, we apply a custom alias analysis for host code generation, exploiting knowledge about the structure of the code, which is difficult to uncover using standard alias analysis. Whilst some of these techniques have been investigated before in isolation, we combine them, for the first time, to a complete region-based JIT compilation strategy inside a DBT system.

We have implemented our novel code generation strategy in our multi-threaded DBT system targeting the ARM V5T ISA on a standard 12-core x86-64 host machine. We demonstrate its effectiveness across the SPEC CPU2006 integer benchmarks, where our system achieves an average execution rate of 867 MIPS, and up to 1323 MIPS. This is about 2.64 times faster than state-of-the-art QEMU-ARM.

1.1 Motivating Example
Most DBT systems will use some form of CPU state structure that contains the active state of the register file and any CPU flags – along with other control information. A DBT that works on an instruction-by-instruction basis will usually access this structure for...

[Figure 2] Host machine code generated using a naïve scheme and using our integrated, region-based code generation methodology.

region entries, and with careful profiling and capturing of CFG edge information, it can be determined which blocks are internal to the region.

In the example CFG, block A is a region entry, and blocks B, C and D are only branched to by control-flow from other blocks. Two branch fall-through edges exist as A→B and C→D, and two direct branches exist as B→C and C→D. It is important to note that there are two basic blocks (A and C) discovered with overlapping code. This is because (given the input $r_0 \geq 1$) the profiler will discover the fall-through edge A→B first, and then discover the direct edge B→C that branches inside A, and hence creates a new basic block C containing the latter half of A.

If entry was allowed via any block, target register values would need to be loaded from the CPU state structure in each block – ensuring that the correct register values are used. This would be detrimental in performance, especially in the case of the loop between B and C, as the value of the induction variable in $r_0$ would need to be read from memory in C and written to memory in B, rather than keeping $r_0$ in a host register.

However, if we change the constraints to only allow entry via block A, and keep B, C and D as region local blocks, then we can produce an optimised form that loads initial register values into a host CPU register, which is reused throughout the loop, until we exit the code sequence. Furthermore, at the end of the loop, we can store the updated register values back into the CPU state structure.

This difference is clearly demonstrated in Listing 2 and Listing 3 where Listing 2 shows an example of x86 assembly generated for the code sequence described in Listing 1. When every block has its address taken, the block must access memory to request the value of the target machine register from the state structure. In Listing 3 we can see that an optimised form can be generated where host registers are used to track the state of the target machine register, until the very end where the values are written back to memory. This removes all memory accesses from the loop between block B and C, and can exploit host ISA features to generate an extremely efficient loop.

In general, our guiding principle is speculation and optimisation for the common case, i.e. we use profiling information on branch types, region entries, and indirect branch targets immediately for code optimisation even if there is the possibility of later updates of this information, possibly initiating re-compilation.

1.2 Contributions

This paper is not concerned with developing new ways of region selection, but its focus is on a strategy for efficient code generation and optimisation for regions once these have been formed using any of the techniques presented in the literature (Breuning and

Duesterwald [2000] Himiker et al. [2005] Hiser et al. [2006b] Hsu et al. [2013]. Neither do we propose another technique for resolving indirect branches, but we show how branch type and control flow information can be exploited on top of any of the existing mechanisms for resolving indirect branches (Hiser et al. [2007] Dhanasekaran and Hazelwood [2011] Koju et al. [2012] Yin et al. [2012] Jia et al. [2013]). Overall, we make the following contributions in this paper:

1. We introduce a complete, region-based JIT code generation strategy suitable for integration in high-speed DBT systems,
2. we demonstrate how to exploit branch type profiling information to enable improved back-end code generation including loop optimisation.
3. we introduce light-weight region chaining, borrowing concepts from trace chaining, and
4. we develop a new custom alias analysis that allows us to more accurately separate independent memory accesses, again enabling improved back-end code generation.

1.3 Overview

The remainder of this paper is structured as follows. In Section 2 we provide the background to our DBT system and, in particular, the region selection scheme used throughout this paper. This is followed by the presentation of our novel code generation strategy in Section 3. We present our empirical evaluation in Section 4 before we discuss related work in Section 5. Finally, we summarise and conclude in Section 6.

2. Background

2.1 DBT System Overview

Figure 3 shows the main execution loop of our DBT, which employs an interpretable component and farm of concurrent JIT compiler threads to achieve maximum speed. We initially begin by running the target program through the interpreter and collect profiling information about the basic blocks by building a region-oriented control flow graph (CFG). Once a region has been determined to exceed a certain threshold it will be dispatched to a JIT compiler worker, which will translate the region to native code. This process is asynchronous, and the target program will continue executing in the interpreter. Once the native code has been compiled, it will be made available by registering region entry points in block metadata and when the interpreter encounters a registered block, it will update the translation cache and begin executing the native code.

Once inside native code, execution will remain there as long as blocks are available to execute. If a block is encountered that has not yet been compiled, control will return to the interpreter and profiling information updated accordingly. Gathering further profiling information about a region may lead to a region becoming eligible for recompilation, which gives rise to progressively optimal code, much like tiered or staged compilation (Joshi et al. [2004]).

2.2 Region Selection

In a DBT system, region selection is concerned with forming the shape of translation units, where a region is typically a collection of basic blocks connected by control flow edges. This stage follows code discovery and profiling and it determines the boundaries of a fragment of recently discovered target code, and prepares it for translation into native host code. A number of region selection schemes for use in JIT compilers and DBT systems have been developed, e.g. (Bruening and Duesterwald [2000] Himiker et al. [2005] Hiser et al. [2006b] Hsu et al. [2013]). The focus of these papers has been on policies for region selection, i.e. decisions on how far and for how long to grow a region, but they do not explore code generation strategies for regions. Often regions are distinguished from traces, whilst technically traces are degenerate regions they are often treated separately due to their linear shape, i.e. the absence of multiple control flow successors and, in particular, loops.

JIT compilers present in e.g. JAVA VMs would have meta-information about the structure of the program being executed, and could use this information for method-based region selection techniques. But, the presence of meta-information is not guaranteed and cannot be relied upon, and indeed is not present in a raw instruction stream, so the DBT must rely on dynamic profiling information to effectively perform region selection (Whaley [2001]). In this paper we use a page based region selection scheme similar to the one presented in (Bohm et al. [2011]). Such a scheme enables efficient MMU emulation and detection of self-modifying code through page protection mechanisms provided by the OS. As shown in Figure 4(B) we start building a dynamic CFG and insert basic blocks and control flow edges between wherever we encounter dynamic control flow. After a certain interval (in terms of blocks executed in the...
interpreter) we scan the CFG and form regions, depending on the
temperature and whether this is above a certain, adaptive threshold.
In our scheme page boundaries are also compulsory region bound-
aries. Regions are then passed to the JIT compiler for code gen-
eration, and profiling execution continues, possibly extending the
dynamically discovered CFG further (see Figure 4(C)).

3. Methodology

3.1 Overview

Our DBT begins executing a target program by means of an inter-
preter, which collects profiling information about execution flow as
it executes. The interpreter executes basic blocks of instructions
at a time, and edge information is collected about these blocks.
Metadata structures, which describe regions, are used to track the
"temperature" of a region, and when a "hot" region is detected, a
translation work unit is dispatched to a compiler work queue. An
idle JIT compiler worker thread picks up this work unit, and be-
gins compilation. A work unit consists of a list of basic blocks to
compile (which represents blocks within one region), the associ-
ated control-flow graph connecting those basic blocks together and
a list of the blocks which are region entries. The compiler then
translates each block in turn (on an instruction-by-instruction ba-
sis) into LLVM IR. Finally, when each block has been compiled, a
local jump table (sometimes also referred to as indirect branch target
buffer) is generated, which contains the addresses of each block
that is a region entry block and each block that is the target of an
indirect jump.

The region prologue is a small piece of set-up code common to
each region function, which loads values that are reused through-
out the native code (such as pointers to the various CPU state struc-
tures). Following this setup, an indirect branch via the previously
generated local jump table is performed to begin execution at the
desired basic block. A region function therefore, contains the trans-
lated native code for every block discovered (and marked as hot) in
the region, and invoking this function will branch to the block that
is to be executed, by accessing the program counter from the CPU
state structure.

It is important to note that not all basic blocks that have been
compiled have their addresses taken and corresponding entries reg-
istered in the local jump table. This constraint means that non-
region-entry basic blocks cannot be entered from outside the re-

gion. The consequence, and indeed benefit, of not taking addresses
certain regions allows LLVM to be more aggressive during the
optimisation, phase – potentially merging basic blocks together
and performing inter-block optimisations.

In Figure 4 the control-flow graph labelled A describes the
actual control-flow of the target program, where B and C show the
discovered control-flow, along with region boundaries. The shaded
portion of B is magnified in Figure 5 which shows how blocks
within a region are compiled to a region function, and how the
function chains to other region functions by means of the global
jump table.

3.2 Translation Lookup Cache

The translation lookup cache is a structure that lives in the execu-
tion engine component of the DBT and is used to resolve addresses
of basic blocks to native code. In fact, it is a mapping of block ad-
resses to the region function that contains the native translation of
a particular block. Only region entry blocks are entered in to the
translation cache, as it is only possible to branch to region entry
blocks from the local jump table.

3.3 Region Chaining

Chaining is becoming a common feature in trace based JIT compi-
lation systems, such as in the DALVIK VM and TRACEMONKEY.
This technique typically involves profiling execution flow between
compiled traces, and updating the translated code for hot edge
sources. In regions of inter-trace jumps, to jump directly to the destina-
tion translation unit. We extend trace chaining to region chaining,
which deals with hot control flow between regions. This can be the
result of hot inter-region edges emerging only after some warmup
time, where region selection has already partitioned code into re-
gions, or due to unavoidable region limits such as page boundaries
introduced by the region selection scheme (see also Section 2.3).

To simplify code generation we implement a weak form of re-
gion chaining, where we keep a global jump table of translated re-
gions. It is important to distinguish this from the translation cache –
the global jump table is only a jump table at region/page granu-
larity and is not used when transitioning from the interpreter into
native code. Conversely, the translation cache contains translation
information at basic block granularity and is only used when tran-
sitioning from interpreter to native code.

The global jump table contains one entry (initially empty) for
each possible region. Each entry consists of a single function
pointer. In our case, we have at most one region per page, so the
jump table contains $4GB/8KB = 524,288$ entries. These entries
are updated when a miss occurs in the translation cache described
above. Since, when we retranslate a region, we invalidate the trans-
lation cache entry for that region, this ensures that the global jump table
always points to the most up to date translation for each re-
gion.

The global jump table is used when it is determined that a
translated branch might have another region as its destination. This
determination is made differently depending on the circumstances:

1. For a direct branch: if the target is outside the current region,
then the global jump table is used if the branch is taken.

2. For an indirect branch if no targets within the current region
have been encountered so far: the global jump table is used
immediately.

3. For an indirect branch, if one or more targets within the current
region have been encountered: if the branch resolves to an
address within the current region, then the local jump table is
used, otherwise the global jump table is used.

Since the global jump table is initialised with ‘empty’ entries, the
requested entry must be checked before it is used (essentially a
null-pointer check). If the requested entry is empty, execution flow
leaves translated code.

3.4 Branching

A basic block is defined as a single-entry, single-exit linear code se-
quence, and as such the terminating instruction is always a branch
to one or more basic blocks. There are two types of branches that
can be made out of a basic block:

- Direct: A branch whose destination is known at JIT compila-
tion time, i.e. the destination is a PC-relative or absolute
address.

- Indirect: A branch whose destination is not known at JIT com-
ilation time, i.e. a branch that uses a register value to calculate
the destination.

These two cases can further be classified in to predicated and non-
predicated, which impose additional constraints on the control-flow
out of a basic block. When a branch is predicated, the fall-through
block for the branch not taken case can be treated as a direct branch.

In Figure 5 each node in the CFG (except for E) has been dis-
covered by the profiler, and as such the CFG has been compiled to
LLVM IR on a block-by-block basis. Node E and the corresponding
edge $E \rightarrow F$ have not yet been discovered by the profiler, i.e. they
have not yet executed, or have not exceeded the compilation threshold.
Nodes A and F are region entries, and H and I are the targets of
indirect branches. As such, these nodes have their block addresses
taken, and a corresponding entry added to the local jump table. The
other nodes are never accessed by an indirect jump (as far as the
current profiling information is concerned) so their block addresses
are not taken, and no entry is registered in the local jump table.

This leads to the case where native code may be available for a
basic block, i.e. it has been compiled, but it is not reachable from
outside the region.
3.4.1 Direct Branches
Where we have a direct branch from basic block A to B, (and B has no indirect branch predecessors), we do not have to add the address of B to the local jump table and instead we can emit LLVM IR to perform a direct branch to B.

There are two approaches that we take when generating the proper control-transfer sequence, and they depend on whether or not the terminating block is predicated or non-predicated.

For a non-predicate branch, given we know at compile time that the jump target, if the target lies outside the region boundary, we generate code to transfer control via the global jump table – as shown by node H. This means we chain directly to the region containing the destination block (if available). If the target lies within the region, as shown by node A, then we can check to see if we are compiling that particular block in this work unit, and if so, we can emit LLVM IR that directly branches to it. If the destination block is not in the work unit, then we must return immediately to the interpreter, as a native translation is not available in this round of compilation.

For a predicated branch, the same sequence applies as before, except we first determine whether or not the branch is to be taken. If the branch is not taken, then the fall-through block is directly branched to (if present in the work unit).

3.4.2 Indirect Branches
As we cannot know at JIT compile time what the destination of an indirect branch might be, we have to rely on profiling information to assist in making decisions about how to transfer control from a basic block to a successor. An important point to note is that we can treat a predicated indirect branch instruction as having a single direct edge to the fall-through block, and treat this as in the direct branch case (Section 3.4.1).

If the edge information we receive at compile time contains no edges, then we must transfer control via the global jump table. This is demonstrated in Figure 5 as node I, and is because we know that the local jump table cannot satisfy our jump (since an entry would only be available if we have encountered that particular edge). Exiting via the global jump table is required because the indirect branch may be to a different region. If it turns out that this speculation is incorrect (or if the destination region does not contain a translation for the target block) we return to the interpreter.

If the edge information contains exactly one edge, then we can emit a simple comparison instruction to determine whether or not that edge should be taken. If the edge is correct, we branch directly to that basic block and otherwise fall back to the global jump table. Node C (before discovery of E) is an example of this, where we have a single indirect edge CD, but have not yet discovered CE.

Finally, for a block with multiple indirect successors (such as node G), we emit code to check that the target block lies within the same region, and if so we perform an indirect branch via the local jump table. If the target block lies outside the current region, we branch via the global jump table.

Other implementations of local jump tables are possible, e.g. some of the techniques presented in (Hiser et al. 2007), (Koj et al. 2012), (Jia et al. 2013), (Yin et al. 2012), (Dhamnekar and Hazelwood 2011) could act as drop-in replacements, however, we have found our implementation to provide sufficiently low lookup times and high hit rates.

3.5 Region Registration in Translation Caches
Every basic block that is encountered by our DBT has metadata held about it, which describes certain properties about the block, and contains a pointer to the region function containing its implementation, if it has been identified as a region entry. When the execution engine begins executing a block, it looks up the block metadata and checks to see if a native translation exists – if so, the translation cache is updated and native code is entered. Additionally, the global jump table is updated with a pointer to the function for the region containing the block. If a region is recompiled, the block metadata will be updated to reflect the new function pointer and the change would propagate through to the translation cache.

3.6 Continuous Profiling and Recompilation
The mixing of instructions and data, and the presence of indirect branching make it impossible to fully and accurately determine the precise control flow of a program from machine code only. Although techniques exist which attempt to extract control flow information from programs statically (Kinder et al. 2009), these often must be extremely conservative and thus DBT systems using them suffer from poor performance.

On the other hand, techniques for extracting control flow information at run time are becoming increasingly effective (Joshi et al. 2004). These techniques often do not capture all possible control flow paths through a program in their first pass – thus, it is necessary to profile the program continuously.

We may therefore discover new control flow within regions which we have already translated and compiled. If we do not retranslate the relevant regions when we encounter such control
flow at run time we can only evaluate it sub-optimally. For example, we may discover that a block which we previously excluded from the translated code table is in fact a region entry. In this case, we must return to the interpreter to execute this block, since we do not have a translation entry for it.

Our technique does not require any special treatment for the retranslation of regions. Instead, the profiling system does not distinguish between already translated and non-translated regions. If pre-compiled untranslated code or control flow is encountered in a translated region, it is executed using the interpreter and profiled. If it is frequently executed and becomes hot, the full region will be retranslated in order to include the new code and control flow.

3.7 Host Machine Code Generation

A translation work unit is the unit provided to a JIT compiler worker thread and consists of a list of basic block descriptors, along with basic block edge information, representing a particular region. Each instruction in a block is translated to LLVM IR one-by-one, using a technique similar to (Wagstaff et al. 2013) and once the instructions have been translated, a block epilogue is emitted. This epilogue is generated based on the type of control-flow associated with the block, and essentially contains the IR that transfers control to the next block.

Finally, after all the blocks in the translation work unit have been compiled, and the region prologue has been generated, a single LLVM function remains that represents the region just compiled. This function is then passed through the LLVM optimiser, as described in Section 3.7.1.

After the optimisation passes have completed, the LLVM IR is compiled to native machine code using the LLVM JIT compiler interface and when the native code is available, each basic block that is marked as a region entry has a pointer to the newly compiled function stored in its metadata.

3.7.1 LLVM Optimisation Passes

During the translation phase, an LLVM module is built containing the function that represents the region being translated. The module also contains helper functions, which are highly amenable to inlining. All the helper functions are marked as internalisable, and an inlining pass is applied. Typically, the helper functions will provide a very small function (such as reading the PC register, or writing to target machine memory), and are easily inlined.

After inlining, the resulting module is subjected to a number of LLVM passes, based on the standard CLANG -O3 optimisation level. The main difference is that instead of using an LLVM provided alias analysis implementation, we use ours as described in Section 3.7.2.

Since we allowed some basic blocks not to be region entry points, this has opened up more scope for aggressive loop optimisation, which yields the full benefit of a region-based JIT. With a trace-based JIT, loop optimisations rarely happen, as traces are inherently linear. However, with our region-based approach, we can perform a significant amount of loop optimisations across the control-flow within a region, which would also not be possible if we allowed entry to the region from any basic block.

3.7.2 Alias Analysis

Alias analysis of pointers is an important phase that enables further program optimisations to reason better about data flow. For example, a dead store elimination pass uses pointer aliasing information to determine whether or not a redundant store to a memory location can be eliminated, based on any memory accesses that happen between those stores.

Listing 4 shows how incomplete pointer aliasing information can lead to the optimiser being unable to remove dead stores. The stores on lines 1 and 5 are killed by the store on line 7, but because the optimiser cannot detect that the operations on pointers in lines 2-4 do not alias, it cannot remove the stores. This directly translates to machine code as shown in Listing 5, which is safe (and correct), but in our case not at all optimal.

Listing 4. LLVM IR after dead store elimination

```
store i32 36076, 132+ %4
%42 = load i64, inttoptr (i64 61931224 to i64+)
%43 = add i64 %42, 6
store i64 %43, 164+ inttoptr (i64 61931224 to i64+)
store i32 36076, 132+ %4

... store i32 36092, 132+ %4
```

Listing 5. X86 machine code due to target lowering

```
movl $37076, 60(%r12)
addq $6, 61931224
movl $37076, 60(%r12)
movl $36092, 60(%r12)
```

In the example shown in Figure 6, the problem stems from the alias analysis implementation (quite correctly) being unable to determine whether or not the pointer held in %4 aliases with the constant pointer value 61931224. Assuming that %4 and 61931224 alias is a safe assumption and as such generates safe code. But, armed with the knowledge about the working of our DBT, we know that %4 contains a pointer to a CPU state register, and that the constant pointer is an address that does not intersect with the CPU state structure, hence we can say that they do not alias. Providing this guarantee to LLVM’s dead store elimination optimisation pass enables the pass to remove the redundant stores, and generate better code. The particular example described above is important for region-based compilation, as redundant updates to the CPU state are eliminated, hence reducing the number of memory operations occurring in a particular sequence.

When a loop is involved, keeping target machine register values in host registers instead of constantly reading and writing to the CPU state structure improves performance significantly – but this kind of loop optimisation can only work to its full potential when combined with the jump table optimisation technique described in Section 3.4.

4. Experimental Evaluation

4.1 Experimental Methodology

We have evaluated our DBT code generation approach using the SPEC CPU2006 integer benchmark. It is widely used and considered to be representative of a broad spectrum of application domains. We used it together with its reference data sets. The benchmarks have been compiled using the GCC 4.6.0 C/C++ cross-compilers, targeting the ARM V5T architecture (without hardware floating-point support) and with -O2 optimisation settings.

We have measured the elapsed real time between invocation and termination of each benchmark in our DBT system using the UNIX time command on the host machine described in Table 1 with our DBT system configured as in Table 2. We used the average elapsed time over 10 runs for each benchmark and configuration in order to calculate execution rates (using MIPs in terms of target instructions) and speedups. For summary figures we report harmonic means weighted by dynamic target instruction.
Figure 7. Absolute performance figures (in MIPS) for the long-running SPEC CPU2006 integer benchmarks for both QEMU-ARM and our DBT, indicating that the quality of the generated code by our system is superior to the code generated by QEMU-ARM.

count. For the comparison to the state-of-the-art we use the ARM port of QEMU 1.4.2 as a baseline.

Additionally, we have also evaluated our DBT using the EEMBC-1.1 benchmark suite. These benchmarks are typically shorter running and serve to evaluate the performance of the JIT compiler portion of our DBT. In order to normalise performance to particular duration, we adjusted the iteration count of each benchmark so that it ran for about ten seconds in QEMU, then we invoked the benchmark with the same iteration count in our DBT and measured performance in the same manner as for SPEC.

4.2 Experimental Results for SPEC CPU2006

Figure 7 gives an overview of the absolute performance of QEMU vs. our DBT. In every case, we improve on QEMU, and on average achieve a 2.64x improvement in absolute performance.

The biggest improvement is achieved for 473.astar, which can be attributed to the benchmark responding well to our ability to apply loop optimisations within a region. The relative performance improvement of 473.astar when region chaining is enabled is negligible, and so indicates that the majority of time is spent in region local code. Aggressive loop optimisations are performed within this region (where the bulk of the algorithm lies). This explains the excellent performance improvement over QEMU, which performs no such optimisations. This explanation can also be applied to 464.h264ref, which benefits greatly from our ability to optimise loops better than QEMU.

The smallest improvement is for 462.libquantum, which may be due to the benchmark itself being heavy in arithmetic instructions, but not so much in looping constructs. This particular characteristic explains the excellent performance of QEMU, and hence why we only see a 1.2x improvement in this case. QEMU’s block-based optimisations work well here, due to the linear nature of the arithmetic instructions and larger basic block sizes.

Interestingly, the relative performance improvements as optimisations are enabled (shown in Figure 8) of 462.libquantum are similar to that of 473.astar, and the absolute performance of both the benchmarks are within the same area - but 462.libquantum is already fast in QEMU.

4.3 Impact of Optimisations

Figure 8 shows how combinations of the optimisations described in Section 3 affect the relative performance of the DBT. The baseline is using standard LLVM -O3 optimisation and partial evaluation, but without any of our optimisations described in the paper applied.

Overall, the addition of our custom alias analysis improves every benchmark, except for 429.mc. On average this gives a 1.32x performance improvement, but it is the combination of all our strategies that yield the best result. Jump table optimisation on its own does not give rise to a significant performance improvement, but responds well when combined with alias analysis. This may be due to the fact that the most interesting optimisation to apply across basic blocks is to remove dead stores and to keep host registers live with frequently used values (potentially from the CPU state structure). Without the precise aliasing information this kind of optimisation is not possible to do effectively, and so the combination of both jump table optimisation and custom alias analysis give rise to the best performance improvements.
473.astar remains at baseline performance when the region chaining optimisation is applied, and this may be due to the majority of execution being spent in region-local code. It has an absolute performance figure of > 1000 MIPS, which indicates fast running code, but the benefits of region chaining are minimal, due to the lack of inter-region control-flow.

403.gcc is a particularly control-flow heavy benchmark, and responds well to the combination of all the optimisations together. Also of interest is the 429.mcf benchmark, which does not consistently improve in performance like the majority of the other benchmarks. Despite this, 429.mcf is more than 1.5 times faster in our DBT system than in QEMU.

4.4 JIT Compilation Performance

The execution time of the SPEC Cpt:2006 benchmarks with their reference data sets is dominated by the time spent executing native code, whereas the fraction accounted for JIT compilation time is small. For such long-running benchmarks code quality is paramount and this where our region based code optimisations outperform simpler basic block or trace based schemes. However, JIT compilation time is still important for shorter-running applications, or programs that exhibit phased behaviour and, hence, exercise the JIT compiler more heavily. To evaluate JIT compilation performance of our DBT system we have run additional, smaller benchmarks, where time for JIT compilation constitutes a larger portion of the overall time (see Figure 9).

In every case, we beat QEMU in absolute execution performance, but as in the SPEC results, our relative performance improvements vary greatly. As can be seen, the most significant result here is that we execute fft00 at a rate of 6138 MIPS compared to QEMU’s 3897.95. However, this only shows a modest relative performance gain of 1.5x, where as idctn01 outperforms QEMU by 2.85x. We can attribute these variances again to the characteristics of individual benchmarks in the suite, where we can say that in the benchmarks which are amenable to loop optimisations, i.e. contain more intra-region loops, we show a greater relative performance improvement. Overall, these results demonstrate that even for shorter-running applications where JIT compilation latency plays a greater role than absolute code quality our system is highly competitive despite its use of larger translation units and aggressive code optimisations.

5. Related Work

5.1 Region based DBT Systems

Region based JIT compilation has been used for some time in JAVA virtual machines, e.g. (Suganuma et al. 2003, 2006), but has only been considered more recently for DBT systems (Jones and Topham 2009, Böhm et al. 2011, Kaufmann and Spallek 2013). The reason for this late adoption of region based policies has been presumably the increased latency for compilation and optimisation of larger regions, which has only been addressed recently with the introduction of decoupled, latency-hiding JIT task farms (Böhm et al. 2011). The bulk of the work in this field has focused on region selection, though, and less on code generation and optimisation for dynamically discovered regions. In (Jones and Topham 2009) large translations units, i.e. regions, are introduced for dynamic binary translation and region selection policies based on strongly connected components, control flow graph fragments and OS pages are compared. A refined page based region selection scheme is developed in (Böhm et al. 2011) and combined with a parallel JIT compilation task farm. Specific optimisations for a DBT system, which compiles target- to host code via JVM bytecode, are considered in (Kaufmann and Spallek 2013).

5.2 Code Generation and Optimisation in DBT Systems

Most DBT systems appear to have adopted a code generation strategy operating on individual basic blocks or linear traces of basic blocks. For example, QEMU uses such an approach using its own tiny code generator (TCG) and additional block chaining, translation caching and lazy condition evaluation (Bellard 2005). DYNAMO (Bala et al. 2000) is a dynamic optimisation system, i.e. the input is an executing native instruction stream. DYNAMO uses an interpreter for initial execution until a “hot” instruction sequence is identified. At that point, DYNAMO generates an optimised version of the trace into a software code cache. DYNAMO treats backward branches as trace delimiters, i.e. traces are by definition linear. After translation it emits an optimised single-entry, multi-exit,
In this paper we have developed a novel, integrated approach to JIT code generation within region-based DBT systems. We exploit branch type information, introduce region chaining, develop selective region registration in translation caches, add on continuous profiling and recompilation, and finally include custom alias analysis to enable aggressive code optimisations, which would not be possible in a JIT scheme based on linear traces. We demonstrate the efficiency of our region-based JIT code generation approach using the SPEC CPU2006 benchmarks compiled for the ARM V5T ISA, which our DBT system translates on-the-fly to the host machine’s x86 ISA. In comparison to state-of-the-art QEMU-ARM we achieve an average speedup of 2.64, and up to 4.25 for individual benchmarks. We show that each of the techniques developed in this paper on their own contribute to increased code quality, but it is the particular combination of code generation steps that results in performance improvements greater than the sum of its parts.
