Abstract: The gravimetric moisture content of peat is the main factor limiting the ignition and spread propagation of smouldering fires. Our aim is to use controlled laboratory experiments to better understand how the spread of smouldering fires is influenced in natural landscape conditions where the moisture content of the top peat layer is not homogeneous. In this paper, we study for the first time the spread of peat fires across a spatial matrix of two moisture contents (dry/wet) in the laboratory. The experiments were undertaken using an open-top insulated box (22×18×6 cm) filled with milled peat. The peat was ignited at one side of the box initiating smouldering and horizontal spread. Measurements of the peak temperature inside the peat, fire duration and longwave thermal radiation from the burning samples revealed important local changes of the smouldering behaviour in response to sharp gradients in moisture content. Both, peak temperatures and radiation in wetter peat (after the moisture gradient) were sensitive to the drier moisture condition (preceding the moisture gradient). Drier peat conditions before the moisture gradient led to higher temperatures and higher radiation flux from the fire during the first 6 cm of horizontal spread into a wet peat patch. The total spread distance into a wet peat patch was affected by the moisture content gradient. We predicted that in most peat moisture gradients of relevance to natural ecosystems the fire self-extinguishes within the first 10 cm of horizontal spread into a wet peat patch. Spread distances of more than 10 cm are limited to wet peat patches below 160% moisture content (mass of water per mass of dry peat). We found that spatial gradients of moisture content have important local effects on the horizontal spread and should be considered in field and modelling studies.

Response to Reviewers: Please see carefully the suggestions that I sent in the PDF attached in the last revision.
ANSWER: We have updated the manuscript according to the suggestions done by the reviewer in the PDF.
See comments 1 and 2.
We have also added a conclusions section to the manuscript according to the reviewer’s suggestion in the PDF.

1. Explain the ANOVA analysis carried out (e.g. if it is One Way, and the level of significance). Please do it where I suggested you to do. This is important for the reader.

ANSWER: We have updated the explanation of the ANOVA analyses carried out. The following text has been added to the methods section: “The effects of moisture content treatment and distance from the moisture gradient on peak temperature and combustion duration were estimated using one-way ANOVAs. The differences between treatment levels were estimated using Tukey’s Honesty Significant Difference (HSD) post-hoc test with a significance level of $p=0.05$.”. Now in lines 210-214.

We have also updated the results of the ANOVA analysis to be more clear, in lines 284-293: “In the experiments with PRE MC of 25% and POST of 150%, we found that the distance from the moisture content gradient was associated with differences in the peak temperature (one-way ANOVA $F_{2,16}=11.1, p<0.001$). Before the Em breakpoint (at −4 cm and +1 cm from the moisture gradient) no difference in the peak temperatures was found ($384 \pm 25^\circ C$ and $349 \pm 24^\circ C$, respectively; Fig. 3a). However, the peak temperature at +6 cm from the moisture gradient ($155 \pm 93^\circ C$) was less than peak temperatures before the breakpoint (Tukey’s HSD $p<0.05$). The combustion durations ($113 \pm 11$ min, $107 \pm 10$ min and $56$ min at −4 cm, +1 and +6 cm, respectively) were not associated with the distance from the moisture gradient (one-way ANOVA $F_{2,16}=1.6, p=0.2$)”.

And also in lines 295-304: “We found that PRE MC was associated with peak temperatures at +1 cm (one-way ANOVA $F_{4,25}=6.6, p<0.001$). Peak temperatures did not differ between PRE MC of 25% and 50%, ($349 \pm 24^\circ C$, $329 \pm 21^\circ C$, respectively), but a higher PRE moisture content significantly decreased the peak temperatures (e.g. $137 \pm 27^\circ C$ in PRE=150% MC) (Tukey’s HSD $p<0.05$). The combustion duration differed across PRE MC treatments (one-way ANOVA $F_{3,19}=4.3, p=0.02$). The combustion duration was similar for PRE MC of 25% and 50%, ($107 \pm 10$ min and $99 \pm 18$ min, respectively) but at higher PRE moisture contents (100%, 125% and 150% MC) the combustion duration decreased to $43 \pm 5$ min, $81 \pm 9$ min and $78 \pm 9$ min respectively (Tukey’s HSD $p<0.05$)”.

Finally we have deleted a sentence containing one ANOVA analysis that did not add any relevant information to the section. The updated paragraph is: “The finer resolution of the radiated energy flux data (Em) added information on the location where the changes in fire behaviour took place (Table 2, Fig 4, Fig. S2). The majority of breakpoints in Em were located after the increase of moisture content, indicating a continuation of PRE-moisture gradient behaviour for up to 6 cm into the POST peat. Two moisture content combinations (PRE=150%, POST=150% and PRE=125%, POST=250%) had breakpoints in Em before the moisture gradient (Table 2, Fig. S2)””. Now in lines 311-317.

ANSWER: The references in the manuscript and the bibliographic list have been updated following the reviewer’s examples and the most recent STOTEN open access papers, as suggested.
Dear Damia Barcelo

We would like to thank for the constructive reviews to the manuscript “Effects of spatial heterogeneity in moisture content on the horizontal spread of peat fires” (ID STOTEN-D-15-05176R1). All comments have been addressed and detailed in our online answer to the Decision Letter, with corresponding changes made directly to the manuscript.

Yours sincerely,

Nuria Prat-Guitart
Dear Ms. Nuria Prat

Please see carefully the suggestions that I sent in the PDF attached in the last revision.

ANSWER: We have updated the manuscript according to the suggestions done by the reviewer in the PDF:
- See comments 1 and 2.
- We have deleted the subsection titles in the introduction.

Abstract (limit: 400 words)

The gravimetric moisture content of peat is the main factor limiting the ignition and spread propagation of smouldering fires. Our aim is to use controlled laboratory experiments to better understand how the spread of smouldering fires is influenced in natural landscape conditions where the moisture content of the top peat layer is not homogeneous. In this paper, we study for the first time the spread of peat fires across a spatial matrix of two moisture contents (dry/wet) in the laboratory. The experiments were undertaken using an open-top insulated box (22×18×6 cm) filled with milled peat. The peat was ignited at one side of the box initiating smouldering and horizontal spread. Measurements of the peak temperature inside the peat, fire duration and longwave thermal radiation from the burning samples revealed important local changes of the smouldering behaviour in response to sharp transitions in moisture content. Both, peak temperatures and radiation in wetter peat (after a transition of peat moisture gradient), were sensitive to the drier previous moisture condition (preceding the moisture gradient).

Drier peat conditions before the moisture transition led to higher temperatures and higher radiation flux from the fire during the first 6 cm of horizontal spread into a wet peat patch. The total spread distance into a wet peat patch was
affected by the moisture content of the peat before and after a moisture transition gradient. We predicted that in most peat moisture transition gradients of relevance to natural ecosystems the fire self-extinguishes within the first 10 cm of horizontal spread into a wet peat patch. Spread distances of more than 10 cm are limited to wet peat patches below 160% moisture content (mass of water per mass of dry peat).

Our aim is to use controlled laboratory experiments to better understand how the spread of smouldering fires is influenced in natural landscape conditions where the moisture content of the top peat layer is not homogeneous. We found that spatial changes in moisture content have important local effects on the horizontal spread and should be considered in field and modelling studies.

Keywords: peatland, smouldering, propagation, breakpoint analysis, step-change, infrared image analysis.

1. Introduction

1.1. Smouldering fires in peatlands

Peatland soils are significant reservoirs of carbon, they cover less than 3% of the Earth’s land surface but they store 25% of the world’s terrestrial carbon, approximately ~560 Gt of carbon (Yu 2012; Turetsky et al., 2015; Yu, 2012). The drainage of peatlands for human activities combined with a lack of external water inputs (e.g. rain) perturbs peatland hydrological feedbacks (Waddington et al., 2015), leading to a suppression of the water table causing and drying of the surface peat leading to alterations in the system’s hydrology. Despite external water inputs (e.g. rain) being the primary control on peatland hydrology, enhanced drainage makes peatlands highly vulnerable to drying and subsequently fires (Turetsky et al., 2011).

During flaming wildfires of the surface vegetation, part of the heat can be transferred to the organic soil (e.g. duff, peat) and may ignite a smouldering fire (Rein, 2013). These flameless fires are more difficult to detect and suppress than flaming vegetation fires (Rein, 2013). Peat fires can spread both on the surface and in-depth through the sub-surface of a peatland and can initiate new flaming fires well away from the initial region of smouldering peat (Putzeys et al., 2007; Rein, 2016). Very large amounts of peat can be consumed during smouldering fires, releasing carbon gases (e.g. CO₂, CO
and CH₄) and other greenhouse gases to the atmosphere (Gorham, 1991; Turetsky et al., 2014, 2015). The 1997 Indonesian peat fires are estimated to have consumed approximately 32% of the soil carbon stock from Indonesia, ~0.95 Gt of carbon, which is equivalent to 15% of the global fossil fuels emissions for that year (Page et al., 2002). A 2007 peat fire event in the arctic tundra is estimated to have reduced 30% of the soil depth in the whole area studied and consumed 19% of the soil carbon stock of the region (Mack et al., 2011). The IPCC climate change projections forecast an increase in drought frequency and severity in many peatlands worldwide (Roulet et al., 1992), suggesting that peatlands will become more vulnerable to peat fires in the future (IPCC, 2013). This implies that larger amounts of carbon may be released to the atmosphere further contributing to the climate change and turning peatlands into carbon-sources rather than potential carbon sinks (Billett et al., 2010; Flannigan et al., 2009; Turetsky et al., 2002, 2014).

1.2. Variability of moisture content in topmost peat layers

In peatlands, the physiochemical properties of the surface-unsaturated peat layers are influenced by the position of the water table and its associated hydrological responses (Waddington et al., 2015). Changes in water table position alter surface transpiration, evaporation and peat decomposition, which contribute to the moisture variability of the surface layers of peat (Turetsky et al., 2014, Waddington et al., 2015). The vegetation also plays a very important role in determining the moisture content distribution of the topmost peat layer. Hummock-forming Sphagnum mosses retain high levels of moisture in the whole peat profile (Hayward and Clymo, 1982; McCarter and Price, 2014). Other mosses (e.g. hollow Sphagnum species and feather mosses) do not have the same capacity to uptake water from the water table, depending more on the regularity of external water inputs (Thompson and Waddington, 2013). As a consequence, during drought periods Sphagnum hummocks remain wet while the surrounding peat becomes drier. The presence of vascular plants causes shading and interception of precipitation also affecting the surface transpiration and evaporation (Waddington et al., 2015). The rooting systems from trees are also a source of moisture spatial heterogeneity in the topmost peat layers (Rein et al., 2008).—The combination of all these ecohydrological factors, specially
1.3. Factors controlling peat ignition and propagation

During drought events, causes large moisture heterogeneity on the topmost layers of peatlands (Nungesser, 2003; Petrone et al., 2004). The main factors governing the ignition and spread of smouldering are peat moisture content, organic content and bulk density (Frandsen, 1987, 1997; Reardon et al., 2007; Reardon et al., 2008; Watts, 2012). Once peat is ignited, the fire is sustained by the energy released during the oxidation of the char (Hadden et al., 2013). This energy is dissipated, some being lost to the surroundings and some being transferred to drive the drying and pyrolysis of peat particles ahead of the oxidation front (Rein, 2016). If the energy produced is enough to overcome heat losses to the environment and preheat the surrounding peat, the smouldering front becomes self-propagating (Ohlemiller, 1985; Huang and Rein, 2014; Ohlemiller, 1985). The spread can be horizontal and vertical and the extent of smouldering in each direction depends largely on the conditions of the peat and the environment (Benscoter et al., 2011; Reardon et al., 2007; Rein, 2013). A vertically spreading smouldering front can penetrate a few meters into the soil (Rein, 2013). However, more often tends to be extinguished after a few centimetres as downward spread is limited by either the water table or the mineral soil layer (Benscoter et al., 2011; Huang and Rein, 2015; Zaccone et al., 2014). A smouldering front that spreads horizontally can contribute to consume a large extension-area of dry peat soils above the water table. This kind of spread (Benscoter and Wieder, 2003; Shetler et al., 2008), and coupled with the spread of vegetation wildfires, often results in large surface areas being affected (Benscoter and Wieder, 2003; Shetler et al., 2008).

Previous studies have highlighted the importance of peat moisture content on the ignition and spread of peat fires (Frandsen, 1987; Huang and Rein, 2014, 2015; Lawson et al., 1997; Reardon et al., 2007; Huang and Rein, 2014; Huang and Rein, 2015). A 50% probability of ignition and early propagation has been estimated at 110-125% MC¹ (Frandsen, 1987; Huang and Rein, 2015; Reardon et al., 2008; Huang and

¹ Gravimetric moisture content is the mass of water per mass of dry peat expressed as a percentage.
Recent experimental smouldering fires reveal horizontal spread rates between 1 to 9 cm h\(^{-1}\) in peats below 150% MC (Prat-Guitart et al., PhD Thesis, 2015). In peats with higher moisture content, between 150-200% MC, the smouldering is weak and self-extinguishes within the first 10 cm of the sample (Frandsen, 1997; Reardon et al., 2007).

Moisture content distributions of the topmost layer in peatlands are highly relevant to determining the spread of smouldering fires. Post peat-fire landscapes are often characterised by irregular peat consumption, were patches of peat associated with *Sphagnum* hummocks remain unburnt (Hudspith et al., 2014; Shetler et al., 2008; Terrier et al., 2014; Hudspith et al., 2014). Enhanced peat consumption has also been observed under trees, suggesting that fires spread through the peat adjacent to the roots (Davies et al., 2013; Miyanishi and Johnson, 2002). However, there is little understanding of how varying the peat moisture content (e.g. transition from feather moss to *Sphagnum*) across a spatial landscape affects the horizontal propagation of peat fires. This study experimentally examines the behaviour of a smouldering front as it propagates through a sharp transition of gradient of peat moisture content in order to (1) identify local changes in the fire behaviour associated with a transition of moisture content and (2) test whether the previous contiguous drier moisture content ahead of a transition affects the fire behaviour into a wet peat.

### 2. Materials and Methods

#### 2.1. Experimental system

In order to study the effect of a moisture content gradient on the smouldering spread behaviour in conditions that mimic the varying moisture content of real peatlands, we designed a simplified milled peat system that allows the natural sources of peat heterogeneity, such as moisture content, bulk density, mineral content and particle size moisture content to be controlled (Prat-Guitart et al., 2015). The smouldering experiments were conducted in an 18×22×6 cm open-top box (insulated fibreglass container) of similar thermal conductivity as peat (0.07-0.11 W m\(^{-1}\) K\(^{-1}\)) to minimise boundary effects (Benscoter et al., 2011; Frandsen, 1987; Garlough and Keyes, 2011; Rein et al., 2008; Benscoter et al., 2011; Garlough and Keyes, 2014). The peat samples
were 5 cm in depth. The samples were kept shallow to facilitate the formation of a
plane smouldering front spreading horizontally from one side of the box to the other.
As a result, we focus solely on the horizontally spread and not on the vertical spread.
The experiments were limited to 12 h to avoid day-and-night temperature fluctuations.

The analysis of the spread inside the box was divided in three regions: (i) ignition
region, (ii) region ahead of the moisture transition gradient (PRE) and (iii) region
following the transition gradient (POST) (Fig. 1). The ignition region was at one side
of the box where an 18-cm long electric igniter coil was buried in a 2-cm strip of peat
at ~0% MC. The PRE region was adjacent to the ignition and consisted of a 10-cm
strip of conditioned peat. The POST region was a peat sample of the same size as PRE
but with higher moisture content. A clear straight boundary separated PRE and POST
regions creating a sharp increase in moisture content at approximately 10 cm
from the ignition location.

The milled peat samples were oven-dried at 80°C for 48 h and then rewetted in small
samples of less than 300 g of peat to achieve the desired moisture content. Since
oven-dried peats can become hydrophobic, the rewetted peat samples were sealed in
plastic bags for at least 24 h prior to the experiment to reach moisture equilibrium.

One day is more than an order of magnitude longer than the typical infiltration time
of severely hydrophobic soil (Kettridge et al., 2014). This protocol therefore
minimises heterogeneity within the moisture content of the peat samples. We used 14
PRE-POST moisture content combinations in our experiment (Table 1). The PRE
samples never exceeded 150% MC in order to be below the threshold of 125-150%
MC for self-sustained spread for more than 10 cm (Frandsen, 1997; Prat-Guitart et al.,
in press; Reardon et al., 2007; Prat-Guitart et al. PhD Thesis). The moisture content of
POST peats (between 125% and 250% MC) represents wet peats around the threshold
of self-sustained spread. All peats had a mineral content² of 2.6 ± 0.2%. Within the

² Mass of mineral particles per mass of dry organic peat.
box volume, $p$  

Peat bulk density (mass of dry peat per unit volume) $^2$ varied between 55 and 140 kg m$^{-3}$. The variation in density was being due in part due to the expansion of wet peat when water was added (Table 1). Bulk densities were representative of peat soils from temperate and boreal peatlands (Davies et al., 2013; Lukenbach et al., 2015; Thompson and Waddington, 2013; Wellock et al., 2011).

[Table 1]

The ignition protocol consisted in powering the ignition region with 100 W for 30 minutes using the electric igniter coil (Rein et al., 2008). This energy input is strong and similar to a burning tree stump and is enough to ignite dry peat (Rein et al., 2008). After 30 minutes the igniter coil was turned off and a linear smouldering combustion front spread through the samples of peat. A visual and infrared cameras imaged the surface of the smouldering every minute (Prat-Guitart et al., 2015). The infrared camera (SC640, FLIR Systems, US) captured the radiated energy flux from the peat at a resolution of 0.05×0.05 cm (i.e. one pixel equated to 0.25 mm$^2$). The images were corrected for the angle of the infrared and webcam cameras and processed to extract the values of radiated energy flux at a pixel scale. Details of the methods are given in Prat-Guitart et al. (2015). An array of seven K-type thermocouples (1.5 mm diameter) monitored the smouldering temperatures inside the peat samples at 1 cm from the bottom of the box. One thermocouple was situated in the ignition region and the other six were distributed to capture the temperature 4 cm before the moisture transition gradient and then at 1 and 6 cm after the transition moisture increase (Fig. 1).

2.2. Behaviour of the smouldering front

Smouldering temperatures have often been analysed to study the peat combustion and fire spread (Rein et al., 2008; Benscoter et al., 2011; Rein et al., 2008; Zaccone et al., 2014). We analysed the thermocouple data to identify changes in the combustion temperatures due to the sharp transition of peat moisture. For each thermocouple, we

$^2$ Mass of dry peat per unit volume.
estimated the **combustion** duration of combustion temperatures, as the time taken since the start of the combustion (increase above 100°C) and until the peat burnout (decreased below 200°C for the last time). We also estimated the peak temperature as the 90th percentile of the thermocouple temperature profile. To demonstrate the effect of **PRE** moisture content on the spread into **POST** peats, we statistically compared the temperatures of 22 experiments with the same **POST** moisture content (150% **MC**) but different **PRE** moisture contents (25% - 150% **MC**). The effects of moisture content treatment and distance from the moisture gradient on peak temperature and **combustion** burn duration were estimated using one-way ANOVAs. The differences between treatment levels were estimated using Tukey’s Honesty Significant Difference (HSD) post-hoc test with a significance level of \( p < 0.05 \). Temperature profiles from all the **PRE-POST** combinations are provided in the supplementary materials (Fig. S1).

We also analysed the radiation flux from the smouldering of peat in order to identify changes in the smouldering behaviour due to the transition of moisture content. Even though the information from infrared imagery was limited to spread on the peat’s surface, it allowed the smouldering spread to be monitored at a finer resolution than any array of thermocouples. We built a time-profile of each pixel’s radiation flux (kW m\(^{-2}\)) and the radiation flux rate (kW m\(^{-2}\) min\(^{-1}\)) (Fig. 2). The start of the smouldering fire is defined by a peak in the radiation flux rate (Prat-Guitart et al., 2015). The last occurrence of a similar radiation flux value is used to define the end of the smouldering fire. From our defined start and end times of combustion we calculated the median radiated energy flux during combustion \((E)\). Repeating this procedure for each pixel of the infrared box image gave a matrix of median radiation fluxes \(E\) during combustion.

We analysed the spatial autocorrelation of \(E\) by computing the data’s semivariance (half average squared difference between pairs of pixels) (Bivand et al., 2008). The semivariogram was produced using a subset of \(E\) from each experimental burn.
Subsets of $E$ were selected from a central area of PRE peat away from any boundary.

We then fitted a theoretical spherical model to the semivariogram. The spatial range of the semivariogram indicated the distance where the data exhibited no spatial autocorrelation. To avoid statistical issues of spatial autocorrelation we considered 48 sub-regions (2×1 cm) from each box and ensured that sub-regions were separated by at least 1 cm. This separation is greater than the scale of autocorrelation in the data for $E$. We estimated the median $E$ in each sub-region ($E_m$) and the median absolute deviation.

Piecewise linear regression was used to identify a step-change in $E_m$ as a function of distance from the moisture gradient (Crawley, 2013). The analysis was performed on data from each moisture combination ($i$) separately as

$$E_{mi} = \beta_{d1}(x_i < c_i) + \beta_{d2}(x_i > c_i) \quad \text{Eq. (1)}$$

where $x_i$ is the distance (cm) from the moisture transition, $c_i$ is the position of the breakpoint, $\beta_{d1}$ and $\beta_{d2}$ are the estimated intercepts before and after the $a-E_m$ breakpoint. To estimate the position of the breakpoint, Equation 1 was fitted for values of $c_i$ ranging from −4 cm to +8 cm in steps of 0.1 cm, and multiple times to find the values of $c_i$ that produced the minimum residual standard error was selected. We tested possible values of $c_i$ in a distance step of 0.1 cm between −4 and +8 cm from the transition of moisture content.

### 2.3. Spread distance after a moisture transition

The spread distance was estimated from the first last visual image taken after the fire had extinguished (assessed with the infrared images). We used the visual images to distinguish by eye between the burnt and unburnt peat based on the colour; white and grey for the char and ash and brown for the unburnt peat (Fig. 1). We estimated the final position of the smouldering front into POST peat using the boundary between burnt and unburnt peat regions, (often of irregular shape). The median spread distance after the moisture transition ($D_T$) was estimated by manually removing the
areas where fresh peat had collapsed. We associated \( D_T \) with the moisture content of PRE and POST peats using the following statistical model

\[
\sqrt{(D_T)_i} = \beta_0 + \beta_1 PRE_i + \beta_2 POST_i + \beta_3 PRE_i \cdot POST_i + \epsilon_i \quad \text{Eq. (2)}
\]

where \( \beta_0, \beta_1, \beta_2 \) and \( \beta_3 \) are regression coefficients and \( \epsilon_i \) are normally distributed residuals of the \( i^{th} \) experimental replicate of each PRE and POST combination. The dependent variable (\( D_T \)) was square root transformed to normalise the distribution of the residuals. Experiments where the smouldering front completely consumed the POST sample (i.e. extinguished due to the box wall) were discarded since it was not possible to quantify \( D_T \).

The image processing was done in Matlab with the Image Processing Toolbox (Mathworks, version R2012b 8.0.0.783). The data analysis was done with R project statistical software (Development Core Team, 2013). The spatial autocorrelation analysis was done with packages automap (Hieistra et al., 2009) and gstat (Pebesma, 2004).

4. Results

4.1. Smouldering behaviour

In experiments combining PRE MC of 25% and POST of 150% a \( \text{bstepchangbreakpoint} \) in \( E_m \) was identified at \( c_i = 1.5 \) cm after the moisture transition gradient (Table 2). The \( E_m \) before the \( \text{bstepchangbreakpoint} \) point was 3.92 ± 0.05 kW m\(^{-2}\) (mean ± standard error), whereas after the \( \text{breakpoint} \) it decreased to 2.89 ± 0.12 kW m\(^{-2}\). In the experiments with PRE MC of 25% and POST of 150%, we found that the distance from the moisture content gradient was associated with differences in the peak temperature peaks estimated across the experiments of PRE MC of 25% and POST of 150% (one-way ANOVA \( F_{2,16}=11.1, p<0.001 \)). Before the \( \text{breakpoint} \) in \( E_m \) (at \(-4 \) cm and +1 cm from the transition moisture gradient), no difference in the peak temperatures was found were similar (are similar 384 ± 25°C and 349 ± 24°C, respectively; Fig. 3a). However, while the peak
temperature After the breakpoint in $E_{2\text{p}}$ peak temperature at +6 cm from the transition moisture gradient was significantly decreased (155 ± 93°C) was less than peak temperatures before the breakpoint (ANOVA $F_{2,16}$ = 11.1, $p$ value < 0.001 with Tukey’s HSD post hoc test, $p$ < 0.05). There combustion durations (113 ± 11 min, 107 ± 10 min and 56 min at −4 cm, +1 and +6 cm, respectively) did not show no significant differences were not associated with the distance from the moisture gradient (one-way ANOVA $F_{2,16}$ = 1.6, $p$ = 0.2) in combustion duration that could be matched associated to the effect of changes in the a moisture gradient $E_{2\text{p}}$, breakpoint (113 ± 11 min, 107 ± 10 min and 56 min for −4 cm, +1 and +6 cm, respectively) (ANOVA $F_{2,16}$ = 1.6, $p$ value = 0.2).

At +1 cm from the transition moisture gradient both combustion duration and peak temperatures were affected by the PRE moisture contents (red lines in Fig. 3). We found that PRE MC was associated with peak temperatures at +1 cm to differ between PRE-MC (one-way ANOVA $F_{4,23}$ = 6.6 $p$ < 0.001). Peak temperatures were higher did not differ between similar when PRE MC were of 25% and 50% (439 ± 24°C, 329 ± 21°C, respectively), but a higher PRE moisture content significantly and decreased the peak temperatures for higher PRE moisture (e.g. 137 ± 27°C in PRE = 150% MC) (ANOVA $F_{4,23}$ = 6.63 $p$ value < 0.001 with Tukey’s HSD post hoc test $p$ < 0.05).

Similarly, the combustion duration was different differed across PRE MC treatments (one-way ANOVA $F_{3,7}$ = 4.3 $p$ = 0.02). The combustion duration was similar for were also found when PRE MC of 25% and 50% (107 ± 10 min and 99 ± 18 min, respectively), but at higher PRE moisture contents (100%, 125% and 150% MC), the combustion duration decreased to than 100% MC (43 ± 5 min, min 81 ± 9 min and 78 ± 9 min) or more respectively (ANOVA $F_{3,7}$ = 4.3 $p$ value = 0.02 with Tukey’s HSD post hoc test $p$ < 0.05). At +6 cm from the transition moisture gradient (blue lines in Fig. 3) the combustion duration and peak temperatures were different from the ones reported for PRE MC of 150% (one-way ANOVAs $F_{3,7}$ = 1.1 $pp$-value = 0.4, $F_{2,3}$ = 0.65 $pp$-value = 0.5, respectively).
The finer resolution of the radiated energy flux data \( (E_m) \) added information on the location where the changes in fire behaviour took place ([Table 2, Fig 4, Fig. S2]). The majority of breakpoints in \( E_m \) were located after the increase of moisture content, indicating a continuation of PRE-transition-moisture gradient behaviour for up to 6 cm into the POST peat. The radiation flux emitted after the breakpoint continued to be associated to PRE-MC (ANOVA \( F_{1,309}=15.5, \ p \text{-value}<0.001 \) with Tukey HSD post hoc test). Two moisture content combinations (PRE=150%, POST=150% and PRE=125%, POST=250%) had breakpoints in \( E_m \) before the moisture transition gradient ([Table 2, Fig. S2]).

4.2. Spread distance into wet peat

The spread distance \( (D_T) \) showed no difference between PRE of 25% and 50% MC (ANOVA \( F_{1,22}=0.067, \ p \text{-value}=0.8 \) (Fig. 5). For all other peat combinations, the smouldering front spread no further than 5 cm into the wetter peat \( (D_T < 5 \text{ cm}) \). Experiments that combined PRE MC of 125% or POST MC of 250% MC always had self-extinction less than 1 cm after the moisture transition.

The spread distance into wet peat was well described by PRE and POST moisture content conditions (Table 3, Fig. 6). Increasing either PRE or POST moisture contents decreased the spread distance. The coefficient \( \beta_1 \) was higher \((-0.06, -0.04, \) 95% confidence interval) than \( \beta_2 \) \((-0.03, -0.02) \), indicating a bigger effect of PRE moisture content on \( D_T \) than POST moisture content. The interaction term \( \text{PRE} \times \text{POST} \)
showed that the effect of $PRE$ on reducing the spread distance was larger when $POST$ peats had lower moisture content.

[Table 3]

[Figure 6]

$PRE\ MC$ above 125% lead to smouldering self-extinction immediately after the transition ($<1\ cm$) for any $POST\ MC$ (Fig. 7). Similarly, high $POST\ MC$ (greater than 260% $MC$) spreads for less than 1 cm for any $PRE\ MC$. Equation 2 predicts that spread for more than 10 cm can be achieved when most $PRE\ MC$ is below 50% combined with $POST\ MC$ below 160%.

[Figure 7]

5. Discussion

5.1. Effects of peat moisture content heterogeneity on the propagation dynamics

We have analysed the behaviour of smouldering fires through a transition gradient in peat moisture. We find that the peat moisture before the transition gradient influences the fire spread into the wet peat beyond. The smouldering ignition and spread in peats with homogeneous moisture conditions are primarily limited by the moisture content of the peat (Frandsen, 1987, 1997; Garlough and Keyes, 2011; Lawson et al., 1997; Reardon et al., 2007; Garlough and Keyes 2011). However, we show that fire spread in milled peats with heterogeneous moisture conditions is strongly influenced by the moisture conditions of adjacent peat as well as the immediate moisture content of the peat.

Whilst, this study reports limited spread distances of 10 cm into a more moist peat, the scale of the experiment was enough to examine local changes in fire behaviour during the spread through a moisture transition gradient. Our analysis of radiation flux
suggests two main effects of the **PRE** peat conditions on the fire behaviour after a moisture transition. First, the strongest effect of **PRE** peat conditions happens within the first centimetres (<7 cm) after the moisture transition (Fig. 4, Fig. S2). In this region the combustion duration and the peak smouldering temperatures have similar behaviour to the adjacent drier peat. The smouldering front spreading close to the moisture gradient transition evaporates part of the water from the wet peat (Ohlemiller, 1985). Consequently, a few centimetres ahead of the moisture gradient transition are already drier when the smouldering front reaches the wetter **POST** peat. Second, the location of the breakpoint could be interpreted as a new moisture gradient transition created by the dynamics of the smouldering fire. After the breakpoint the smouldering fire continues spreading but is less affected by the **PRE** MC conditions (Fig. 4). Experiments with **PRE**=50% and **POST**=150% did not have a substantial change in \( E_m \) after the breakpoint but an increase of the standard error of the \( E_m \) after (Table 2). We tested the sensitivity of the results obtained to changes in the methods used to analyse the infrared images. Variation of the thresholds used to determine \( E \) produced different \( E \) and \( E_m \) outputs, although the results did not change qualitatively.

The analysis of thermocouple temperature data also supports the effect of **PRE** peat conditions on the smouldering spread into **POST** peat. While the temperatures measured at 1 cm after the moisture gradient transition correspond to the region of **POST** peat more affected by the **PRE** MC conditions, the temperatures recorded at 6 cm after the transition—moisture gradient were less affected by the **PRE** peat conditions (Fig. 4). We found that **POST** MC of 150% reach temperatures between 100 and 500°C at 1 cm after the moisture gradient transition. Some of these temperatures are lower than typical oxidation temperatures 400-600°C reported for natural peats ≤100% MC (Benscoter et al., 2011; Rein et al., 2008). Only temperatures above 300°C indicate on-going peat oxidation (Chen et al., 2011). Between 100°C and 300°C evaporation and pyrolysis processes dominate the smouldering and little oxidation is expected (Huang and Rein, 2014). Compared to the infrared images, the resolution of thermocouple data are limited and only providing data from fire behaviour around the thermocouple. In some burns, the thermocouples registered oscillations in combustion temperatures between 50 and 300°C (i.e. Fig. 3a and Fig. 3b), which could be caused by the local dynamics of the particles surrounding the
thermocouple. The milled peat particle size was below 1 cm in diameter and had variable density due to differences in the degree of decomposition. Differences in the infiltration rates and hydrophobicity of the peat particles during the rewetting process (Kettridge et al., 2014) could cause short-term heterogeneity (~10 min) in the moisture content of a peat sample. This short-term heterogeneity was minimised by our protocol, which allowed samples to equilibrate for 24 h prior to an experiment. Any remaining variation in peat moisture will impact the fine-scale spread of the fire between particles (i.e. <1 cm), but have a minor effect on the average spread of the fire throughout a peat sample of 20 × 20 cm.

The moisture gradient between PRE and POST peat could cause movement of the water through the transition boundary. Higher peat moisture content in POST peat could move to PRE peat, due to differences in implied high-unsaturated hydraulic conductivity (capacity of water movement in unsaturated soil per unit volume) (Boelter, 1965; Hillel, 1980). Milled peats below 200% MC have a small unsaturated hydraulic conductivity and therefore very little water movement is expected for the duration of the experimental burns (Letts et al., 2000; Holden and Ward, 1997). Peat soils at 250% MC have a higher hydraulic conductivity, between $10^{-5}$ and $10^{-4}$ m s$^{-1}$ (Boelter, 1968). Since the smouldering fronts reached POST peat before less than 4 h after ignition implying minimal in all burns, we expected a water movement between 0.2 and 0.9 cm towards the PRE peat during that time. Only peat samples with PRE of 125% and POST 250% and homogeneous 150% MC had a breakpoint in $E_m$ right before the transition-moisture gradient (Fig. S2). This breakpoint before the initial location of the gradient that could be caused by a weak smouldering spread due to the high moisture content in those PRE peat the movement of moisture content (ig. S2). Even after several hours, little moisture evaporation is expected for peat moisture contents below 250% MC may also be considered to alter the moisture content of the peat after several hours (Kettridge et al., 2012) of burning. However, our data (Prat-Guitart et al., in press) confirm that there is little in this study we quantified unsubstantial changes in peat moisture content after 12 h at ambient temperature. Movement of water is therefore mainly due to evaporation and condensation ahead of the smouldering front, which is driven by the oxidative combustion reactions (Rein, 2016).
The spread distance into a wet peat is also affected by local changes in fire behaviour caused by the moisture gradient transition. The moisture content conditions of PRE peat conditions control the fire spread during the first 10 cm into a wet peat (Table 3). Only PRE MC of 25 or 50% combined with POST MC of 100 or 150% and few homogeneous peats with 150% MC led to peat fires that could propagate more than 10 cm. The fire behaviour found for this moisture content combinations agrees with results from previous studies indicating self-sustained spread for 10 cm or more in similar moisture conditions (Frandsen, 1997; Prat-Guitart et al., 2015; Reardon et al., 2007; Rein et al., 2008; Prat-Guitart et al. 2015).

Our simplified laboratory experiments enabled the effect of moisture content on the spread of smouldering fires to be studied whilst controlling for mineral content, bulk density and other artefacts in the peat (Belcher et al., 2010; Frandsen, 1987; Belcher et al., 2010; Hadden et al., 2013; Zaccone et al., 2014). We note that studying smouldering fire behaviour in field samples of peat soil would make the analysis more complex and the results more difficult to interpret because of the multiple uncontrolled factors (e.g. bulk density, organic composition, pore size) that vary between field samples (McMahon et al., 1980). However, our results (Prat-Guitart et al., in press) and those of others indicate that the effect of a moisture transition on the spread of smouldering fire in natural peats will also be further influenced by peat bulk density (Frandsen, 1991; Lukenbach et al., 2015; Prat-Guitart et al. PhD Thesis), mineral content (Frandsen, 1987; Garlough and Keyes, 2011), depth (Benscoter et al., 2011; Huang and Rein, 2015), as well as other factors such as the organic composition, structure, pore size distribution and the degree of peat decomposition.

Future research should aim to further develop our experimental work to understand how other peat properties contributing to the heterogeneity of moisture content of peatlands affect the spread of peat fires.

5.2. Application to peatland fires

The results obtained in our milled peat experiments in the laboratory where a moisture content gradient was implemented for the first time, give a first insight results contribute to the understanding of the peat fire behaviour and interpretation of
post peat-fire landscapes. Often, post fire studies report irregular consumption of peat, where wet *Sphagnum* hummocks are left unburnt (Benscoter and Wieder, 2003; Hudspith et al., 2014; Shetler et al., 2008; Hudspith et al., 2014). Our results suggest that differences in peat moisture content could cause the smouldering fire consumption in the dry peat in the surroundings of *Sphagnum* hummocks and likely reduced the size of the wet patches.

In peatlands, smouldering fires happen during extreme weather events, due to reductions of surface moisture content (Terrier et al., 2014; Turetsky et al., 2015). Peat fires in surface peat layers are part of the natural cycle of peatlands, often limited by the spatial heterogeneity of moisture content. These fires reduce peat accumulation, enhance biodiversity and facilitate the access of surface vegetation to the water table (Waddington et al., 2015). The spatial distribution of moisture content at a microtopographical scale has a strong influence on the smouldering fire spread (Benscoter and Wieder, 2003). We predicted fire spread of less than 10 cm into a wet patch for most of the moisture content combinations involving peat ≥160% MC (Fig. 7). *Sphagnum* hummocks have a variable size, between 20 and 200 cm diameter (Nungesser, 2003; Petrone et al., 2004), meaning than most of the hummock surface can remain unburnt. Natural peatlands have high water table levels and heterogeneous distributions of surface moisture (Waddington et al., 2015). Our controlled peat experiments have only looked at surface horizontal spread. This is one kind of spread that, together with vertical spread, happens during peat fires due to the three-dimensional shape of the smouldering front (Ohlemiller, 2002). In these peatlands, smouldering fires happen during extreme weather events, due to reductions of surface moisture content (Terrier et al., 2014; Turetsky et al., 2014). Peat fires in surface peat layers are part of the natural cycle of peatlands, often limited by the spatial heterogeneity of moisture content. These fires reduce peat accumulation, enhance biodiversity and facilitate the access of surface vegetation to the water table (Waddington et al., 2014). Drained or harvested peatlands are likely to have drier surface layers and smaller *Sphagnum* hummocks (Cagampan and Waddington, 2008). Under these circumstances smouldering fires can lead to extensive consumption of the topmost peat layers.

---

17
Future modelling of peatland fires needs to consider variations in the underlying moisture content because of its effect on the smouldering propagation at a fine-scale in more complex smouldering spread scenarios. Modelling of peat fires incorporating the effect of peat moisture changes will lead to more accurate estimates of carbon emissions, fire perimeter and area burned (Benscoter and Wieder, 2001, 2003). Another studied variable, combustion temperatures, are often used as indicators of fire intensity (Keeley 2009; Hudspith et al. 2014). The transition between two moisture contents was reported to affect oxidation temperatures (fig. 3), suggesting that peat combustion temperatures are affected by fine scale variations of moisture content.

Finally, ecosystem management and fire management should also take into account the spatial variation of peat moisture content to manage the fire risk, avoid large areas of peat being consumed by fires and moisture maps may allow better estimates of fire or burn severity to be made. It may be that peat fires can be managed by assuming that extinction could be achieved by rising the moisture content of strategically located peat areas above 200% MC. This technique may have a wider range of ecological benefits than of flooding entire areas by blocking ditches or using destructive techniques such as bull-dozing trenches or soil compression (Watts 2012; Davies et al., 2013; Watts, 2012). As such further work is required to assess the importance of moisture transitions in understanding the spread of smouldering peatland fires.

Conclusions
We studied the role of moisture content as a limiting factor of smouldering propagation in situations where peat moisture content is not homogeneous. Our approach presents a useful method toward building an understanding peatland smouldering fire behaviour that enable new information about the influence of moisture content transitions in peatland systems. We show that fire spread into wet peat patches is strongly affected by local transitions of moisture content. The moisture content of the peat before the transition governs the fire behaviour into a wet peat for the first centimetres of spread. After that distance it is likely that peat fires self-extinguish leaving unburnt patches of wet peat. Future research on peat fire behaviour
should consider local variation in moisture content to better understand the spread of
smouldering fronts through peat layers.

PRE and POST are the moisture contents of the two peat blocks before and after the sharp moisture transition, respectively. Dry-peat bulk density (ρ) is the mass of dry peat per unit volume, bulk density of the dry peat mass (median ± median absolute deviation); and wet peat density is the bulk density of mass of the moist peat per unit volume and volumetric moisture content is the volume of water per unit volume. Number of experimental burn replicates (n) for each combination of PRE and POST moisture contents.
Table 2. Location of the breakpoint and the median energy flux (\(E_m\)) estimated before and after the breakpoint.

All results are for a moisture content \(POST = 150\%\ MC\). Breakpoint is the location (\(c_d\)), relative to the moisture transition gradient of a breakpoint in \(E_m\) estimated using piecewise linear regression (equation 1). CI is the breakpoint location’s 95% confidence interval. \(E_m\) before is \(E_m\) before the breakpoint (mean ± standard error), \(E_m\) after is the \(E_m\) after the breakpoint.

Abstract (limit: 400 words)

The gravimetric moisture content of peat is the main factor limiting the ignition and spread propagation of smouldering fires. Our aim is to use controlled laboratory experiments to better understand how the spread of smouldering fires is influenced in natural landscape conditions where the moisture content of the top peat layer is not homogeneous. In this paper, we study for the first time the spread of peat fires across a spatial matrix of two moisture contents (dry/wet) in the laboratory. The experiments were undertaken using an open-top insulated box (22×18×6 cm) filled with milled peat. The peat was ignited at one side of the box initiating smouldering and horizontal spread. Measurements of the peak temperature inside the peat, fire duration and longwave thermal radiation from the burning samples revealed important local changes of the smouldering behaviour in response to sharp gradients in moisture content. Both, peak temperatures and radiation in wetter peat (after the moisture gradient) were sensitive to the drier moisture condition (preceding the moisture gradient).

Drier peat conditions before the moisture gradient led to higher temperatures and higher radiation flux from the fire during the first 6 cm of horizontal spread into a wet peat patch. The total spread distance into a wet peat patch was affected by the moisture content gradient. We predicted that in most peat moisture gradients of
relevance to natural ecosystems the fire self-extinguishes within the first 10 cm of horizontal spread into a wet peat patch. Spread distances of more than 10 cm are limited to wet peat patches below 160% moisture content (mass of water per mass of dry peat). We found that spatial gradients of moisture content have important local effects on the horizontal spread and should be considered in field and modelling studies.

1. Introduction

Peatland soils are significant reservoirs of carbon, they cover less than 3% of the Earth’s land surface but they store 25% of the world’s terrestrial carbon, approximately ~560 Gt of carbon (Turetsky et al., 2015; Yu, 2012). The drainage of peatlands for human activities combined with a lack of external water inputs (e.g. rain) perturbs peatland hydrological feedbacks (Waddington et al., 2015), leading to a suppression of the water table and drying of the surface peat. Enhanced drainage makes peatlands highly vulnerable to drying and subsequently fires (Turetsky et al., 2011). During flaming wildfires of the surface vegetation, part of the heat can be transferred to the organic soil (e.g. duff, peat) and may ignite a smouldering fire (Rein, 2013). These flameless fires are more difficult to detect and suppress than flaming vegetation fires (Rein, 2013). Peat fires can spread both on the surface and in-depth through the sub-surface of a peatland and can initiate new flaming fires well away from the initial region of smouldering peat (Putzeys et al., 2007; Rein, 2016).

Very large amounts of peat can be consumed during smouldering fires, releasing carbon gases (e.g. CO$_2$, CO and CH$_4$) and other greenhouse gases to the atmosphere (Gorham, 1991; Turetsky et al., 2015). The 1997 Indonesian peat fires are estimated to have consumed approximately 3% of the soil carbon stock from Indonesia, ~0.95 Gt of carbon, which is equivalent to 15% of the global fossil fuels emissions for that year (Page et al., 2002). A 2007 peat fire event in the arctic tundra is estimated to have reduced 30% of the soil depth in the whole area studied and consumed 19% of the soil carbon stock of the region (Mack et al., 2011). The climate change projections forecast an increase in drought frequency and severity in many peatlands worldwide.
(Roulet et al., 1992), suggesting that peatlands will become more vulnerable to peat fires in the future (IPCC, 2013). This implies that larger amounts of carbon may be released to the atmosphere further contributing to the climate change and turning peatlands into carbon-sources rather than potential carbon sinks (Billett et al., 2010; Flannigan et al., 2009; Turetsky et al., 2002, 2015).

In peatlands, the physiochemical properties of the surface-unsaturated peat layers are influenced by the position of the water table and its associated hydrological responses (Waddington et al., 2015). Changes in water table position alter surface transpiration, evaporation and peat decomposition, which contribute to the moisture variability of the surface layers of peat (Waddington et al., 2015). The vegetation also plays a very important role in determining the moisture content distribution of the topmost peat layer. Hummock-forming *Sphagnum* mosses retain high levels of moisture in the whole peat profile (Hayward and Clymo, 1982; McCarter and Price, 2014). Other mosses (e.g. hollow *Sphagnum* species and feather mosses) do not have the same capacity to uptake water from the water table, depending more on the regularity of external water inputs (Thompson and Waddington, 2013). As a consequence, during drought periods *Sphagnum* hummocks remain wet while the surrounding peat becomes drier. The presence of vascular plants causes shading and interception of precipitation also affecting the surface transpiration and evaporation (Waddington et al., 2015). The rooting systems from trees are also a source of moisture spatial heterogeneity in the topmost peat layers (Rein et al., 2008). The combination of all these ecohydrological factors, specially during drought events, causes large moisture heterogeneity on the topmost layers of peatlands (Nungesser, 2003; Petrone et al., 2004).

The main factors governing the ignition and spread of smouldering are peat moisture content, organic content and bulk density (Frandsen, 1987, 1997; Reardon et al., 2007; Rein et al., 2008; Watts, 2012). Once peat is ignited, the fire is sustained by the energy released during the oxidation of the char (Hadden et al., 2013). This energy is dissipated, some being lost to the surroundings and some being transferred to drive the drying and pyrolysis of peat particles ahead of the oxidation front (Rein, 2016). If the energy produced is enough to overcome heat losses to the environment and preheat the surrounding peat, the smouldering front becomes self-propagating (Huang
and Rein, 2014; Ohlemiller, 1985). The spread can be horizontal and vertical and the extent of smouldering in each direction depends largely on the conditions of the peat and the environment (Benscoter et al., 2011; Reardon et al., 2007; Rein, 2013). A vertically spreading smouldering front can penetrate a few meters into the soil (Rein, 2013). However, more often tends to be extinguished after a few centimetres as downward spread is limited by either the water table or the mineral soil layer (Benscoter et al., 2011; Huang and Rein, 2015; Zaccoone et al., 2014). A smouldering front that spreads horizontally can contribute to consume a large area of dry peat soils above the water table. This kind of spread coupled with the spread of vegetation wildfires, often results in large surface areas being affected (Benscoter and Wieder, 2003; Shetler et al., 2008).

Previous studies have highlighted the importance of peat moisture content on the ignition and spread of peat fires (Frandsen, 1987; Huang and Rein, 2014, 2015; Lawson et al., 1997; Reardon et al., 2007). A 50% probability of ignition and early propagation has been estimated at 110-125% $MC^1$ (Frandsen, 1987; Huang and Rein, 2015; Rein et al., 2008). Recent experimental smouldering fires reveal horizontal spread rates between 1 to 9 cm h$^{-1}$ in peats below 150% $MC$ (Prat-Guitart et al., in press). In peats with higher moisture content, between 150-200% $MC$, the smouldering is weak and self-extinguishes within the first 10 cm of the sample (Frandsen, 1997; Reardon et al., 2007).

Moisture content distributions of the topmost layer in peatlands are highly relevant to determining the spread of smouldering fires. Post peat-fire landscapes are often characterised by irregular peat consumption, were patches of peat associated with Sphagnum hummocks remain unburnt (Hudspith et al., 2014; Shetler et al., 2008; Terrier et al., 2014). Enhanced peat consumption has also been observed under trees, suggesting that fires spread through the peat adjacent to the roots (Davies et al., 2013; Miyanishi and Johnson, 2002). However, there is little understanding of how varying the peat moisture content (e.g. transition from feather moss to Sphagnum) across a spatial landscape affects the horizontal propagation of peat fires. This study experimentally examines the behaviour of a smouldering front as it propagates

---

1 Gravimetric moisture content is the mass of water per mass of dry peat expressed as a percentage.
through a gradient of peat moisture content in order to (1) identify local changes in
the fire behaviour associated with a transition of moisture content and (2) test whether
the contiguous drier moisture content ahead of a transition affects the fire behaviour
into a wet peat.

2. Materials and Methods

2.1. Experimental system

In order to study the effect of a moisture content gradient on the smouldering spread
behaviour we designed a simplified milled peat system that allows the natural sources
of peat heterogeneity, such as moisture content, bulk density, mineral content and
particle size to be controlled (Prat-Guitart et al., 2015). The smouldering experiments
were conducted in an 18×22×6 cm open-top box (insulated fibreboard container) of
similar thermal conductivity as peat (0.07-0.11 W m⁻¹ K⁻¹) to minimise boundary
effects (Benscoter et al., 2011; Frandsen, 1987; Garlough and Keyes, 2011; Rein et
al., 2008). The peat samples were 5 cm in depth. The samples were kept shallow to
facilitate the formation of a plane smouldering front spreading horizontally from one
side of the box to the other. As a result, we focus solely on the horizontally spread and
not on the vertical spread. The experiments were limited to 12 h to avoid day-and-
night temperature fluctuations.

The analysis of the spread inside the box was divided in three regions: (i) ignition
region, (ii) region ahead of the moisture gradient (PRE) and (iii) region following the
gradient (POST) (Fig. 1). The ignition region was at one side of the box where an 18-
cm long electric igniter coil was buried in a 2-cm strip of peat at ~0% MC. The PRE
region was adjacent to the ignition and consisted of a 10-cm strip of conditioned peat.
The POST region was a peat sample of the same size as PRE but with higher moisture
content. A clear straight boundary separated PRE and POST regions creating a sharp
gradient in moisture content at approximately 10 cm from the ignition location.
The milled peat samples were oven-dried at 80°C for 48 h and then rewetted in small samples of less than 300 g of peat to achieve the desired moisture content. Since oven-dried peats can become hydrophobic, rewetted peat samples were sealed in plastic bags for at least 24 h prior to the experiment to reach moisture equilibrium. One day is more than an order of magnitude longer than the typical infiltration time of severely hydrophobic soil (Kettridge et al., 2014). This protocol therefore minimises heterogeneity within the moisture content of the peat samples. We used 14 PRE-POST moisture content combinations in our experiment (Table 1). The PRE samples never exceeded 150% MC in order to be below the threshold of 125-150% MC for self-sustained spread for more than 10 cm (Frandsen, 1997; Prat-Guitart et al., in press; Reardon et al., 2007). The moisture content of POST peats (between 125% and 250% MC) represents wet peats around the threshold of self-sustained spread. All peats had a mineral content\(^2\) of 2.6 ± 0.2%. Within the box volume, peat bulk density (mass of dry peat per unit volume) varied between 55 and 140 kg m\(^{-3}\). The variation in density was in part due to the expansion of peat when water was added (Table 1). Bulk densities were representative of peat soils from temperate and boreal peatlands (Davies et al., 2013; Lukenbach et al., 2015; Thompson and Waddington, 2013; Wellock et al., 2011).

The ignition protocol consisted in powering the ignition region with 100 W for 30 minutes using the electric igniter coil (Rein et al., 2008). This energy input is strong and similar to a burning tree stump and is enough to ignite dry peat (Rein et al., 2008). After 30 minutes the igniter coil was turned off and a linear smouldering combustion front spread through the samples of peat. A visual and infrared cameras imaged the surface of the smouldering every minute (Prat-Guitart et al., 2015). The infrared camera (SC640, FLIR Systems, US) captured the radiated energy flux from the peat at a resolution of 0.05×0.05 cm (i.e. one pixel equated to 0.25 mm\(^2\)). The images were corrected for the angle of the infrared and webcam cameras and processed to extract

\(^2\) Mass of mineral particles per mass of dry organic peat.
the values of radiated energy flux at a pixel scale. Details of the methods are given in Prat-Guitart et al. (2015). An array of seven K-type thermocouples (1.5 mm diameter) monitored the smouldering temperatures inside the peat samples at 1 cm from the bottom of the box. One thermocouple was situated in the ignition region and the other six were distributed to capture the temperature 4 cm before the moisture gradient and then at 1 and 6 cm after the moisture increase (Fig. 1).

2.2. Behaviour of the smouldering front

Smouldering temperatures have often been analysed to study the peat combustion and fire spread (Benscoter et al., 2011; Rein et al., 2008; Zaccone et al., 2014). We analysed the thermocouple data to identify changes in the combustion temperatures due to the sharp transition of peat moisture. For each thermocouple, we estimated the combustion duration, as the time taken since the start of the combustion (increase above 100°C) and until the peat burnout (decreased below 200°C for the last time). We also estimated the peak temperature as the 90th percentile of the thermocouple temperature profile. To demonstrate the effect of PRE moisture content on the spread into POST peats, we statistically compared the temperatures of 22 experiments with the same POST moisture content (150% MC) but different PRE moisture contents (25% - 150% MC). The effects of moisture content treatment and distance from the moisture gradient on peak temperature and combustion duration were estimated using one-way ANOVAs. The differences between treatment levels were estimated using Tukey’s Honesty Significant Difference (HSD) post-hoc test with a significance level of $p=0.05$. Temperature profiles from all the PRE-POST combinations are provided in the supplementary materials (Fig. S1).

We also analysed the radiation flux from the smouldering of peat in order to identify changes in the smouldering behaviour due to the transition of moisture content. Even though the information from infrared imagery was limited to spread on the peat’s surface, it allowed the smouldering spread to be monitored at a finer resolution than any array of thermocouples. We built a time-profile of each pixel’s radiation flux (kW m$^{-2}$) and the radiation flux rate (kW m$^{-2}$ min$^{-1}$) (Fig. 2). The start of the smouldering fire is defined by a peak in the radiation flux rate (Prat-Guitart et al., 2015). The last
occurrence of a similar radiation flux value is used to define the end of the
smouldering fire. From our defined start and end times of combustion we calculated
the median radiated energy flux during combustion ($E$). Repeating this procedure for
each pixel of the infrared box image gave a matrix of median radiation fluxes $E$
during combustion.

We analysed the spatial autocorrelation of $E$ by computing the data’s semivariance
(half average squared difference between pairs of pixels) (Bivand et al., 2008). The
semivariogram was produced using a subset of $E$ from each experimental burn.
Subsets of $E$ were selected from a central area of PRE peat away from any boundary.
We then fitted a theoretical spherical model to the semivariogram. The spatial range
of the semivariogram indicated the distance where the data exhibited no spatial
autocorrelation. To avoid statistical issues of spatial autocorrelation we considered 48
sub-regions (2×1 cm) from each box and ensured that sub-regions were separated by
at least 1 cm. This separation is greater than the scale of autocorrelation in the data for
$E$. We estimated the median $E$ in each sub-region ($E_m$) and the median absolute
devation.

Piecewise linear regression was used to identify a step-change in $E_m$ as a function of
distance from the moisture gradient (Crawley, 2013). The analysis was performed on
data from each moisture combination ($i$) separately as

$$E_{mi} = \beta_{d1}(x_i < c_i) + \beta_{d2}(x_i > c_i)$$  \hspace{1cm} \text{Eq. (1)}

where $x_i$ is the distance (cm) from the moisture gradient, $c_i$ is the position of the
breakpoint, $\beta_{d1}$ and $\beta_{d2}$ are the estimated intercepts before and after the breakpoint. To
estimate the position of the breakpoint, equation 1 was fitted for values of $c_i$ ranging
from −4 cm to +8 cm in steps of 0.1 cm, and the values of $c_i$ that produced the
minimum residual standard error was selected.
2.3. Spread distance after a moisture gradient

The spread distance was estimated from the first visual image taken after the fire had extinguished (assessed with the infrared images). We used the visual images to distinguish by eye between the burnt and unburnt peat based on the colour; white and grey for the char and ash and brown for the unburnt peat (Fig. 1). We estimated the final position of the smouldering front into POST peat using the boundary between burnt and unburnt peat regions (often of irregular shape). The median spread distance after the moisture gradient ($D_T$) was estimated by manually removing the areas where fresh peat had collapsed. We associated $D_T$ with the moisture content of PRE and POST peats using the following statistical model

$$\sqrt{(D_T)} = \beta_0 + \beta_1 PRE_i + \beta_2 POST_i + \beta_3 PRE_i \cdot POST_i + \epsilon_i \quad \text{Eq. (2)}$$

where $\beta_0$, $\beta_1$, $\beta_2$, and $\beta_3$ are regression coefficients and $\epsilon_i$ are normally distributed residuals of the $i^{th}$ experimental replicate of each PRE and POST combination. The dependent variable ($D_T$) was square root transformed to normalise the distribution of the residuals. Experiments where the smouldering front completely consumed the POST sample (i.e. extinguished due to the box wall) were discarded since it was not possible to quantify $D_T$.

The image processing was done in Matlab with the Image Processing Toolbox (Mathworks, version R2012b 8.0.0.783). The data analysis was done with R project statistical software (Development Core Team, 2013). The spatial autocorrelation analysis was done with packages automap (Hiemstra et al., 2009) and gstat (Pebesma, 2004).

4. Results

4.1. Smouldering behaviour
In experiments combining PRE MC of 25% and POST of 150% a breakpoint in $E_m$ was identified at $c_l = 1.5$ cm after the moisture gradient (Table 2). The $E_m$ before the breakpoint was $3.92 \pm 0.05$ kW m$^{-2}$ (mean ± standard error), whereas after the breakpoint it decreased to $2.89 \pm 0.12$ kW m$^{-2}$. In the experiments with PRE MC of 25% and POST of 150%, we found that the distance from the moisture content gradient was associated with differences in the peak temperature (one-way ANOVA $F_{2,16}=11.1$, $p<0.001$). Before the $E_m$ breakpoint (at −4 cm and +1 cm from the moisture gradient) no difference in the peak temperatures was found ($384 \pm 25^\circ$C and $349 \pm 24^\circ$C, respectively; Fig. 3a). However, the peak temperature at +6 cm from the moisture gradient ($155 \pm 93^\circ$C) was less than peak temperatures before the breakpoint (Tukey’s HSD $p<0.05$). The combustion durations (113 ± 11 min, 107 ± 10 min and 56 min at −4 cm, +1 and +6 cm, respectively) were not associated with the distance from the moisture gradient (one-way ANOVA $F_{2,16}=1.6$, $p=0.2$).

At +1 cm from the moisture gradient both combustion duration and peak temperatures were affected by the PRE moisture contents (red lines in Fig. 3). We found that PRE MC was associated with peak temperatures at +1 cm (one-way ANOVA $F_{4,25}=6.6$, $p<0.001$). Peak temperatures did not differ between PRE MC of 25% and 50%, (349 ± 24°C, 329 ± 21°C, respectively), but a higher PRE moisture content significantly decreased the peak temperatures (e.g. 137 ± 27°C in PRE=150% MC) (Tukey’s HSD $p<0.05$). The combustion duration differed across PRE MC treatments (one-way ANOVA $F_{3,19}=4.3$, $p=0.02$). The combustion duration was similar for PRE MC of 25% and 50% (107 ± 10 min and 99 ± 18 min, respectively) but at higher PRE moisture contents (100%, 125% and 150% MC) the combustion duration decreased to 43 ± 5 min, 81 ± 9 min and 78 ± 9 min respectively (Tukey’s HSD $p<0.05$). At +6 cm from the moisture gradient (blue lines in Fig. 3) the combustion duration and peak temperatures were not different from to the ones reported for PRE MC of 150% (one-way ANOVAs $F_{3,7}=1.1$, $p=0.4$, $F_{2,3}=0.65$, $p=0.5$, respectively).

[Figure 3]
The finer resolution of the radiated energy flux data \((E_m)\) added information on the location where the changes in fire behaviour took place (Table 2, Fig 4, Fig. S2). The majority of breakpoints in \(E_m\) were located after the increase of moisture content, indicating a continuation of \(PRE\)-moisture gradient behaviour for up to 6 cm into the \(POST\) peat. Two moisture content combinations (\(PRE=150\%, POST=150\%\) and \(PRE=125\%, POST=250\%\)) had breakpoints in \(E_m\) before the moisture gradient (Table 2, Fig. S2).

[Figure 4]

[Table 2]

4.2. Spread distance into wet peat

The spread distance \((D_T)\) showed no difference between \(PRE\) of 25% and 50% MC (ANOVA \(F_{1,22}=0.067\ p=0.8\)) (Fig. 5). For all other peat combinations, the smouldering front spread no further than 5 cm into the wetter peat \((D_T < 5\ cm)\). Experiments that combined \(PRE\) MC of 125% or \(POST\) MC of 250% MC always had self-extinction less than 1 cm after the moisture transition.

[Figure 5]

The spread distance into wet peat was well described by \(PRE\) and \(POST\) moisture content conditions (Table 3, Fig. 6). Increasing either \(PRE\) or \(POST\) moisture contents decreased the spread distance. The coefficient \(\beta_1\) was higher \((-0.06, -0.04, 95\%\) confidence interval) than \(\beta_2\) \((-0.03, -0.02)\), indicating a bigger effect of \(PRE\) moisture content on \(D_T\) than \(POST\) moisture content. The interaction term \(PRE \times POST\) showed that the effect of \(PRE\) on reducing the spread distance was larger when \(POST\) peats had lower moisture content.
PRE MC above 125% lead to smouldering self-extinction immediately after the transition (<1 cm) for any POST MC (Fig. 7). Similarly, high POST MC (greater than 260% MC) spreads for less than 1 cm for any PRE MC. Equation 2 predicts that spread for more than 10 cm can be achieved when most PRE MC is below 50% combined with POST MC below 160%.

5. Discussion

5.1. Effects of peat moisture content heterogeneity on the propagation dynamics

We have analysed the behaviour of smouldering fires through a gradient in peat moisture. We find that the peat moisture before the gradient influences the fire spread into the wet peat beyond. The smouldering ignition and spread in peats with homogeneous moisture conditions are primarily limited by the moisture content of the peat (Frandsen, 1987, 1997; Garlough and Keyes, 2011; Lawson et al., 1997; Reardon et al., 2007). However, we show that fire spread in milled peats with heterogeneous moisture conditions is strongly influenced by the moisture conditions of adjacent peat as well as the immediate moisture content of the peat.

Whilst, this study reports limited spread distances of 10 cm into a more moist peat, the scale of the experiment was enough to examine local changes in fire behaviour during the spread through a moisture gradient. Our analysis of radiation flux suggests two main effects of the PRE peat conditions on the fire behaviour after a moisture gradient. First, the strongest effect of PRE peat conditions happens within the first centimetres (<7 cm) after the moisture gradient (Fig. 4, Fig. S2). In this region the combustion duration and the peak smouldering temperatures have similar behaviour
to the adjacent drier peat. The smouldering front spreading close to the moisture
gradient evaporates part of the water from the wet peat (Ohlemiller, 1985).
Consequently, a few centimetres ahead of the moisture gradient are already drier
when the smouldering front reaches the wetter POST peat. Second, the location of the
breakpoint could be interpreted as a new moisture gradient created by the dynamics of
the smouldering fire. After the breakpoint the smouldering fire continues spreading
but is less affected by the PRE MC conditions (Fig. 4). Experiments with PRE=50%
and POST=150% did not have a substantial change in $E_m$ after the breakpoint but an
increase of the standard error of the $E_m$ after (Table 2). We tested the sensitivity of the
results obtained to changes in the methods used to analyse the infrared images.
Variation of the thresholds used to determine $E$ produced different $E$ and $E_m$ outputs,
although the results did not change qualitatively.

The analysis of thermocouple temperature data also supports the effect of PRE peat
conditions on the smouldering spread into POST peat. While the temperatures
measured at 1 cm after the moisture gradient correspond to the region of POST peat
more affected by the PRE MC conditions, the temperatures recorded at 6 cm after the
moisture gradient were less affected by the PRE peat conditions (Fig. 4). We found
that POST MC of 150% reach temperatures between 100 and 500°C at 1 cm after the
moisture gradient. Some of these temperatures are lower than typical oxidation
temperatures 400-600°C reported for natural peats ≤100% MC (Benscoter et al., 2011;
Rein et al., 2008). Only temperatures above 300°C indicate on-going peat oxidation
(Chen et al., 2011). Between 100°C and 300°C evaporation and pyrolysis processes
dominate the smouldering and little oxidation is expected (Huang and Rein, 2014).
Compared to the infrared images, the resolution of thermocouple data are limited and
only providing data from fire behaviour around the thermocouple. In some burns, the
thermocouples registered oscillations in combustion temperatures between 50 and
300°C (i.e. Fig. 3a and Fig. 3b), which could be caused by the local dynamics of the
particles surrounding the thermocouple. The milled peat particle size was below 1 cm
in diameter and had variable density due to differences in the degree of
decomposition. Differences in the infiltration rates and hydrophobicity of the peat
particles during the rewetting process (Kettridge et al., 2014) could cause short-term
heterogeneity (~10 min) in the moisture content of a peat sample. This short-term
heterogeneity was minimised by our protocol, which allowed samples to equilibrate for 24 h prior to an experiment. Any remaining variation in peat moisture will impact the fine-scale spread of the fire between particles (i.e. <1 cm), but have a minor effect on the average spread of the fire throughout a peat sample of 20 × 20 cm.

The moisture gradient between PRE and POST peat could cause movement of the water through the transition boundary. Higher moisture content in POST peat could move to PRE peat, due to differences in unsaturated hydraulic conductivity (capacity of water movement in unsaturated soil per unit volume) (Boelter, 1965; Hillel, 1980).

Milled peats below 250% MC have a small unsaturated hydraulic conductivity and therefore very little water movement is expected for the duration of the experimental burns (Holden and Ward, 1997). The smouldering fronts reached POST peat less than 4 h after ignition implying minimal water movement during that time. Only peat samples with PRE of 125% and POST 250% and homogeneous 150% MC had a breakpoint in $E_m$ before the moisture gradient (Fig. S2). This breakpoint before the initial location of the gradient could be caused by a weak smouldering spread due to the high moisture content in those PRE peat. Even after several hours, little moisture evaporation is expected for peat moisture contents below 250% MC (Kettridge et al., 2012). Our data (Prat-Guitart et al., in press) confirm that there is little change in peat moisture content after 12 h at ambient temperature. Movement of water is therefore mainly due to evaporation and condensation ahead of the smouldering front, which is driven by the oxidative combustion reactions (Rein, 2016).

The spread distance into a wet peat is also affected by local changes in fire behaviour caused by the moisture gradient. The moisture content conditions of PRE peat conditions control the fire spread during the first 10 cm into a wet peat (Table 3). Only PRE MC of 25 or 50% combined with POST MC of 100 or 150% and few homogeneous peats with 150% MC led to peat fires that could propagate more than 10 cm. The fire behaviour found for this moisture content combinations agrees with results from previous studies indicating self-sustained spread for 10 cm or more in similar moisture conditions (Frandsen, 1997; Prat-Guitart et al., 2015; Reardon et al., 2007; Rein et al., 2008).

Our simplified laboratory experiments enabled the effect of moisture content on the spread of smouldering fires to be studied whilst controlling for mineral content, bulk
density and other artefacts in the peat (Belcher et al., 2010; Frandsen, 1987; Hadden et al., 2013; Zaccone et al., 2014). We note that studying smouldering fire behaviour in field samples of peat soil would make the analysis more complex and the results more difficult to interpret because of the multiple uncontrolled factors (e.g. bulk density, organic composition, pore size) that vary between field samples (McMahon et al., 1980). Our results (Prat-Guitart et al., in press) and those of others indicate that the spread of smouldering fire in natural peats will also be influenced by peat bulk density (Frandsen, 1991; Lukenbach et al., 2015), mineral content (Frandsen, 1987; Garlough and Keyes, 2011), depth (Benscoter et al., 2011; Huang and Rein, 2015), as well as the organic composition, structure, pore size distribution and the degree of decomposition. Future research should aim to further develop our experimental work to understand how other peat properties contributing to the heterogeneity of moisture content of peatlands affect the spread of peat fires.

5.2. Application to peatland fires

The results obtained in our milled peat experiments in the laboratory where a moisture content gradient was implemented for the first time, give a first insight to the understanding of the peat fire behaviour and interpretation of post peat-fire landscapes. Often, post fire studies report irregular consumption of peat, where wet Sphagnum hummocks are left unburnt (Benscoter and Wieder, 2003; Hudspith et al., 2014; Shetler et al., 2008). Our results suggest that differences in peat moisture content could cause smouldering consumption in the dry peat surrounding Sphagnum hummocks and likely reduced the size of the wet patches.

In peatlands, smouldering fires happen during extreme weather events, due to reductions of surface moisture content (Terrier et al., 2014; Turetsky et al., 2015). Peat fires in surface peat layers are part of the natural cycle of peatlands, often limited by the spatial heterogeneity of moisture content. These fires reduce peat accumulation, enhance biodiversity and facilitate the access of surface vegetation to the water table (Waddington et al., 2015). The spatial distribution of moisture content at a microtopographical scale has a strong influence on the smouldering fire spread (Benscoter and Wieder, 2003). We predicted fire spread of less than 10 cm into a wet
patch for most of the moisture content combinations involving peat ≥160% MC (Fig. 7). *Sphagnum* hummocks have a variable size, between 20 and 200 cm diameter (Nungesser, 2003; Petrone et al., 2004), meaning than most of the hummock surface can remain unburnt. Natural peatlands have high water table levels and heterogeneous distributions of surface moisture (Waddington et al., 2015). Our controlled peat experiments have only looked at surface horizontal spread. This is one kind of spread that, together with vertical spread, happens during peat fires due to the three-dimensional shape of the smouldering front (Ohlemiller, 2002). Future modelling of peatland fires needs to consider variations in the underlying moisture content because of its effect on the smouldering propagation at a fine-scale in more complex smouldering spread scenarios. Modelling of peat fires incorporating the effect of peat moisture changes will lead to more accurate estimates of carbon emissions, fire perimeter and area burned (Benscoter and Wieder, 2003). Finally, ecosystem management and fire management should also take into account the spatial variation of peat moisture content to manage the fire risk, avoid large areas of peat being consumed by fires and moisture maps may allow better estimates of fire or burn severity to be made. It may be that peat fires can be managed by assuming that extinction could be achieved by rising the moisture content of strategically located peat areas above 200% MC. This technique may have a wider range of ecological benefits than flooding entire areas by blocking ditches or using destructive techniques such as bull-dozing trenches (Davies et al., 2013; Watts, 2012).

**Conclusions**

We studied the role of moisture content as a limiting factor of smouldering propagation in situations where peat moisture content is not homogeneous. Our approach presents a useful method toward building an understanding peatland smouldering fire behaviour that enable new information about the influence of moisture content transitions in peatland systems. We show that fire spread into wet peat patches is strongly affected by local transitions of moisture content. The moisture content of the peat before the transition governs the fire behaviour into a wet peat for the first centimetres of spread. After that distance it is likely that peat fires self-extinguish leaving unburnt patches of wet peat. Future research on peat fire behaviour
should consider local variation in moisture content to better understand the spread of
smouldering fronts through peat layers.

Table 1. Peat moisture content and bulk density combinations of the experimental burns.

*PRE* and *POST* are the moisture contents of the two peat blocks before and after the sharp moisture gradient, respectively; peat bulk density (*ρ*) is the mass of dry peat per unit volume (median ± median absolute deviation); wet density is the mass of moist peat per unit volume and volumetric moisture content is the volume of water per unit volume. Number of experimental burn replicates (*n*) for each combination of *PRE* and *POST* moisture contents.

**Table 2. Location of the breakpoint and the median energy flux ($E_m$) estimated before and after the breakpoint.**

All results are for a moisture content $POST = 150\%\ MC$. Breakpoint is the location ($c_i$, relative to the moisture gradient) of a breakpoint in $E_m$ estimated using piecewise linear regression (equation 1). CI is the breakpoint location’s 95% confidence interval. ‘$E_m$ before’ is $E_m$ before the breakpoint (mean ± standard error), ‘$E_m$ after’ is the $E_m$ after the breakpoint.

**Figure Captions**

**Fig. 1.** Image of an on-going experimental burn. A glowing coil ignites the peat at the ignition region. The fire spreads through a region of PRE peat (dry peat) and then through a region of POST peat (wet peat). Dashed line indicates the location of the sharp gradient of moisture content between PRE and POST peat. Thermocouples monitor the temperatures inside the peat sample.

**Fig. 2.** Smouldering fire detection in radiation flux from infrared images. a) Time-profile of a pixel’s radiation flux. b) Time-profile of the pixel’s rate of radiation flux. Red dots indicate start and end of the smouldering fire.

**Fig. 3.** Examples of temperature versus time profiles from five experiments (a-e). All experimental burns had POST peat moisture content of 150% and PRE peat moisture content of (a) 25%, (b) 50%, (c) 100%, (d) 125% and (e) 150%. Dot dash-black, solid red and double dash-blue lines correspond to thermocouples −4cm, +1cm and +6cm from the moisture gradient, respectively. Profiles end when the fire self-extinguished.

**Fig 4.** Median radiation flux during smouldering combustion ($E_m$) as a function of distance from the moisture gradient. Data are for moisture contents of POST=150% MC and PREs of (a) 25%, (b) 50%, (c) 100%, (d) 125% and (e) 150% MC. Solid vertical red line indicates location of a breakpoint in $E_m$ (Table 2) and dashed red lines the 95% confidence interval. Solid horizontal red lines are the $E_m$ means over the four experiment replicates estimated using equation 1.

**Fig. 5.** Observations of spread distance ($D_T$) into POST peat. Subplots are for PRE peats of (a) 25%, (b) 50%, (c) 100% and (d) 125% MC.

**Fig. 6.** Spread distance ($D_T$) as function of POST moisture gradient. Symbols represent experimental observations for PRE conditions, circle = 25%, star = 50%, square = 100%, triangle = 125% MC. Lines are model predictions from the coefficients in Table 3.

**Fig. 7.** Predicted spread distance (cm) into a wet peat for a range of PRE and POST moisture content combinations using the model in Table 3.
