Abstract

Mobile malware has been increasingly identified based on unwanted behaviours like sending premium SMS messages. However, unwanted behaviours for a group of apps can be normal for another, i.e., they are context-sensitive. We develop an approach to automatically explain unwanted behaviours in context and evaluate the automatic explanations via a user-study with favourable results. These explanations not only state whether an app is malware but also elaborate how and in what kind of context a decision was made.

1 Introduction

Researchers and malware analysts have identified hundreds and thousands of mobile apps as malware [EOMC11, ZJ12] and organised them into families based on some unwanted behaviours, e.g., stealing personal information, accessing locations, collecting contacts information, sending premium messages constantly, etc. However, except some malware analysis reports for several famous malware families [ZJ12, S+13], e.g., Geinimi, Basebridge, Spitmo, Zitmo, Gimmaster, Ggtracker, Droidkungfu, etc., people don’t know what kind of behaviour makes a mobile app bad. This suggests a research problem: automatically producing a short paragraph to explain unwanted behaviours.

A naive method is to: train a linear classifier from a collection of identified malware instances and benign apps, choose features with top weights which are assigned by this classifier, then process selected features through templates to output text. This method has been adopted in research, e.g., the Drebin system [A+14a].

However, by greedily choosing features to output text, the generated explanations are inaccurate. This is mainly because unwanted behaviours of mobile apps are context-sensitive, i.e., an unwanted behaviour in one group of apps can be normal in another. For example, collecting locations is normal for jogging tracker apps, but unwanted for card game apps.

Instead, our new approach is to organise sample apps into fine-grained groups by their behavioural similarity. We set the context of an app in question to the group whose members’ behaviours are the most similar to this app’s behaviours. By exploiting behavioural difference between malware and benign apps in this context, we decide whether the target app is malware, and if so, we produce an explanation. Here are two example automatic explanations.

a. This app is a chatting app, but, after a USB massive storage is connected, it will: retrieve a class in a runnable package; read information about networks; connect to Internet.

b. This app is an anti-virus app, but, it will: read your phone state after a phone call is made; read your phone state then connect to Internet; send SMS messages after a phone call is made.

- **Formalisation.** We approximate the behaviour of an Android app by a finite-state automaton, i.e., a collection of finite control-sequences of events, actions, and annotated API calls. From this automaton we extract happen-before features to denote that something happens before another.

- **Learning.** We organise sample apps into groups using clustering methods, and characterise unwanted behaviours for each group by exploring the difference between malware instances and benign apps within the same group.

- **Explanation.** We decide whether a target app is malware by choosing a group then checking against this group whether the app has any unwanted behaviour, i.e., a behaviour exhibited by a malware instance in the group. The corresponding features are fed through hand-built templates to produce text as explanations.

The main contributions of this paper are to:

- demonstrate that the happen-before feature is an appropriate abstract of app behaviours with respect to learning and explaining;
- introduce the context into behaviour explanations and develop a clustering-based method to organise sample apps into groups;
- remove redundancy in features by carefully choosing phrases to present;
- compare our approach with several alternative methods and report favourable evaluation results based on surveying end users.

### 1.1 Related Work

To automatically detect Android malware, machine learning methods have been applied to train classifiers [ADY13, GYAR13, GTGZ14, YSMM13]. All of them were to obtain good fits to the training data by trying different methods and features. Explanations of chosen features have received much less consideration.

The tool Drebin [A⁺14a] is the first attempt to automatically generate explanations of Android malware. It generates explanations by choosing features with top weights from a linear classifier then processes them through hand-built templates to output text. A broad range of syntax-based features, e.g., permissions, API calls, intents, URLs, etc., were collected for training. However, the syntax-based features cannot capture sophisticated behaviours; greedily choosing features with top weights might produce inaccurate explanations; the selected features include redundancy which will clutter the final explanation.

Our approach overcomes these limitations by: using semantics-based features, e.g., happen-befores; introducing the context and collecting context-sensitive unwanted behaviours; aggregating and selecting phrases to present.

A recent prototype DescribeMe [ZDFY15] generates text from data-flows by feeding features through hand-built templates. The main drawback is its scalability: to produce data-flows is too expensive for most apps.

The idea of context is similar with the cluster used in the tool CHABADA [GTGZ14]. This tool detects the outliers (abnormal API usage) within the clusters of apps by using OC-SVM (one-class SVM). These clusters were grouped by the descriptions of apps using LDA (Latent Dirichlet Allocation). However, for most sample apps which were collected from alternative Android markets, e.g., Wandoujia, Baidu, and Tencent in China, it is hard to get their descriptions, not mentioning that these descriptions are in different languages.

Automata are much more accurate than the manifest information, e.g., permissions and actions, which were often used as input features for malware detection or mitigation [BKvOS10, EOM09, F⁺11]. Compared with a simple list of API calls appearing in the code, an automaton can capture more sophisticated behaviours. This is needed in practice, because API calls appearing in the code contain “noise” caused by the dead code and libraries [ADY13]; and, some unwanted behaviours only arise when some API methods are called in certain orders [C⁺13, KB15, Y⁺14]. On the other hand, automata are less accurate than models which capture data-flows. But, it is much easier to generate automata using our tool for apps en masse than generating data-flows using tools like FlowDroid [A⁺14b] or Amandroid [WROR14]. In particular, people can annotate appealing API methods to generate compact behaviour automata more efficiently, rather than considering all data-dependence between statements.

### 2 Characterising App Behaviours

We use a simplified synthetic example to illustrate the characterisation of app behaviours. It is an Android app which constantly sends out the device ID and the phone number by SMS messages in the background when an incoming SMS message is received.

We approximate its behaviour by using the automaton in Figure 1. It tells us: this app has two entries which are respectively specified by actions MAIN and SMS_RECEIVED; it will collect the device ID and the phone number in a Broadcast Receiver, then send SMS messages out in an AsyncTask; the behaviour of sending SMS messages can also be triggered by an interaction from the user, e.g., clicking a button, touching the screen, long-pressing a picture, etc., which is denoted
by the word “click”. All states in this automaton are accepting states since any prefix of an app’s behaviours is one of its behaviours as well.

This automaton is a collection of finite control-sequences of actions, events, and annotated API calls, which is constructed from the bytecode of an Android app. Actions reflect what happens in the environment and what kind of service an app requests for, e.g., an incoming message is received, the device finishes booting, the application wants to send an email by using the service supplied by an email-client, etc. Events denote the interaction from the user, e.g., clicking a picture, pressing a button, scrolling down the screen, etc. Annotated API calls tell us whether the app does anything we are interested in. For instance, getDeviceID, getLine1Number, and sendTextMessage are annotated API calls in the above example.

A behaviour that is unwanted for one kind of app can be innocuous for another. For example, sending SMS messages is normal for messaging apps, but unwanted for an E-reader app; a user might expect that a weather forecast app accesses his or her locations, but might feel uncomfortable if a messaging app does so. Therefore, to understand and explain unwanted behaviour, we need a notion of context.

### 3 Learning Unwanted Behaviours

A behaviour that is unwanted for one kind of app can be innocuous for another. For example, sending SMS messages is normal for messaging apps, but unwanted for an E-reader app; a user might expect that a weather forecast app accesses his or her locations, but might feel uncomfortable if a messaging app does so. Therefore, to understand and explain unwanted behaviour, we need a notion of context.

#### 3.1 Constructing Context

Unwanted behaviours in general only account for a small part of a malicious app’s activities. This is by design: malicious apps seek to hide their bad behaviours, and are often constructed by repackaging benign applications [Z+14, Z+13]. This observation gives us a notion of context: we group together apps, benign or malicious, whose behaviours are mostly the same. Then, within the context, we distinguish unwanted from normal behaviours by exploring features which are mostly associated with malware. This produces a fine-grained, behavioural notion of context, that is more discriminating than categories, e.g., GAME, TOOLS, and WEATHER, etc., or clusters produced from developer-written textual descriptions [GTGZ14].

We formalise this idea in Figure 2. Sample apps are organised into groups. Apps in the same group share common behaviours, in the sense that their feature vectors are similar. Ideally, repackaged apps will be in the same group with the original benign apps. A group can consist of only benign apps or only malware. Two sets of features are constructed: normal and unwanted. The normal set is the union of all behaviours of benign apps. The unwanted set consists of abnormal behaviours of malware, that is, the relative complement of the normal set in the collection of behaviours of malware instances.

The rule behind this construction is: a benign app can not have any unwanted behaviour and a malware instance must have some unwanted behaviour whatever its other behaviours are. Every sample app in the same group is required to follow this rule. Otherwise, there is a conflict in the group. To solve this conflict, we split
3.2 Classification

We want to decide whether an app in question is malware, by using the constructed context and unwanted behaviours. The size and the portion of malware vary largely across groups. This results in: it is hard to train a classifier for each group using classical learning methods, e.g., SVM, naive Bayes, and logistic linear regression. Therefore, we calculate the distances between the target app and each group. The closest group is chosen as the context. Then, we decide whether the target app is malware by applying the following logic rules:

- **Conservatively normal.** The target app is classified as benign if it has no unwanted behaviour and all its behaviours are normal, i.e., $\text{feature}(\text{app}) \subseteq \text{normal}$.

- **Aggressively malicious.** The target app is classified as malicious if one of its behaviours is unwanted, i.e., $\text{feature}(\text{app}) \cap \text{unwanted} \neq \emptyset$.

- **Neutrally suspicious.** If the target app has no malicious behaviour and some of its behaviours are abnormal. We consider its abnormal behaviours as suspicious and label it as unknown. That is, according to current knowledge we can not decide whether it is malware. The decision have to be postponed until more sample apps of this group are acquired.

We randomly chose 1,000 apps with benign and malicious half-and-half as the training set; and an equal number of apps as the testing set. They contain some famous benign apps, i.e., Google Talk, Amazon Kindle, Youtube, Facebook, etc., and some instances in famous malware families, e.g., DroidKungfu, Plankton, Zitmo, etc. These apps spread in around 30 categories from ARCADE GAME to WEATHER. Many advertisement libraries were also found in these apps, e.g., Admob, Millenial Media, Airpush, etc.

To compare our classification method with general classifiers, we train a classifier using an implementation of L1-regularized Logistic Regression [Tib94] (abbreviated as L1LR). We apply our method to construct context and collect unwanted behaviours from happen-befores which are extracted from the automata of apps in the training set. Further, we apply the logic rules discussed earlier, to decide whether a target app is malware against unwanted behaviours for a chosen group.

<table>
<thead>
<tr>
<th>classifier</th>
<th>edge labels in automata</th>
<th>happen-befores</th>
<th>precision</th>
<th>recall</th>
<th>precision</th>
<th>recall</th>
</tr>
</thead>
<tbody>
<tr>
<td>context</td>
<td>83%</td>
<td>88%</td>
<td>80%</td>
<td>92%</td>
<td></td>
<td></td>
</tr>
<tr>
<td>L1LR</td>
<td>83%</td>
<td>89%</td>
<td>85%</td>
<td>88%</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

We report the classification performance as above. It shows that for different features the classification performance of our method is only slightly worse than L1LR, with no more than a 5% drop in precision. This is because some apps are labelled as unknown in our method. We can achieve better classification performance by adding syntax-based features,
e.g., permissions and API calls, as input features. Rather, our goal is to develop a classification method whose output yields better explanations. Considering happen-befores can capture more sophisticated app behaviours, we prefer to using unwanted behaviours selected from happen-befores for the explanation generation.

### 4 Generating Explanations

In the classification against the context, the features in the intersection between unwanted behaviours of a context and behaviours of a target app are responsible for a decision, so-called salient features. For a training app in a decision context, if one of its behaviours is salient, then this app is a supporting app for this decision. In this section, we want to scale salient features and their supporting apps to generate an explanation for a target app. It explains how and in what kind of context a decision was made. We want to use these automatic explanations to convince people of the system’s automatic decision. Here is an example automatic explanation.

**com.keji.danti590 (v3.0.8)**

This application is malware. Its malicious behaviours are:

- After a USB mass storage is connected, it gets the superclass of a class in a runnable package.
- It retrieves classes in a runnable package.
- It reads information about networks.
- It connects to Internet.
- It reads your phone state then connects to Internet.

The supporting apps of this explanation are:

- **com.keji.danti607 (v3.0.8)** (TROJAN)
- **com.jjdd (v1.3.1)** (MALWARE)
- **com.keji.danti652 (v3.0.8)** (TROJAN)
- **com.keji.danti599 (v3.0.8)** (TROJAN)

It not only shows the decision (malware or benign) but also elaborates the most unwanted behaviours. A collection of supporting apps is displayed as well. Before presenting technical details, let us have a look at some salient features:

a. (Object:ConnectivityManager.getActiveNetworkInfo, Runnable:URL.openConnection)
   - It connects to Internet, if the behaviour “access networks state then connects to Internet”, supported by the feature (Object:ConnectivityManager.getActiveNetworkInfo, Runnable:URL.openConnection), appears in almost every app. Some of them are similar, e.g., if we want to capture the behaviour “connect to Internet”, then features URLConnection.openConnection and DefaultHttpClient.execute are considered as repeated features. This redundancy will further clutter the final explanation.

Based on these observations, we generate explanations as follows: map these salient features into simple phrases, process simple phrases through templates to output compound phrases, then select the most representative compound phrases to present.

First, for each permission, action, event, and each API call which is not governed by any permission, a phrase is assigned to describe its function. These phrases were extracted from brief documents on Android Developers. Second, for those permission-governed API calls, we look up their corresponding permissions and use phrases for these permissions. Third, for pair features we combine phrases for their coordinates to form compound phrases. The templates used in explanation are listed in Table 1. This step actually aggregates features to reduce redundancy.

By using the above method, for each supporting app, we get a collection of phrases with their appearance frequencies in this app. We rank phrases for each supporting app using the TF-IDF (term frequency - inverse document frequency) and choose the top-

\[
\text{tfidf} = \frac{\text{tf}(t,d) \times \log \frac{\text{df}(t)}{\text{IDF}(d)}}
\]

where \( \text{df}(t) \) is the collection of all phrases for each supporting app and \( \text{IDF}(d) \) denotes the appearance frequency of \( t \) in \( d \). This step helps remove trivial phrases (features).

We formalise the above approach in Figure 3. The function \textit{feature_to_phrase} constructs a phrase for a given feature by using templates given in Table 1. Functions \textit{sel_tfidf} and \textit{sel_df} will respectively select phrases for each supporting app and representatives for the whole collection of supporting app. The function \textit{frequency} produces the frequency of a feature appearing in an app.

### 5 Evaluation

In this section, we report a user-evaluation of the automatic explanations. We want to show: (a) explanations produced from semantics-based features are bet-
<table>

   end if
end for
exp ← select(df, select(df, corpus, m), n)
return judge, exp, supp

Twelve apps are randomly chosen from the test set. We apply the above methods to generate explanations for these apps. The generated explanations are organised into samples. Each sample consists of two explanations for the same app, which are respectively produced by applying two different methods. Two example samples are given in Figure 4.

For each sample, a participant of this survey was invited to choose the explanation which he/she prefers, and to give a convince-score between 1 and 5 to each explanation. This score indicates to what extent an explanation convinces the participant. We collected participants’ preferences as well as convince-scores.

We use the Google Form to create this survey. People from universities, software companies, and finance firms in UK and China were invited by mailing lists to participate in this survey. All participants have no idea of the mechanism behind the automatic explanation discussed in this paper. We collected data from the first 20 responses. These respondents include: seven junior and one senior software engineers, seven postgraduate students, one lecturer, three data analysts, and one malware analyst. Three of them declared to be familiar with Android programming and malware analysis. Two of them haven’t used any Android app.
We report the user-evaluation results as above. It shows that the context construction achieves the highest average convince-score 3.61. Most respondents prefer explanations produced by the context construction. We do paired T-test respectively on the three comparisons: M-Context versus M-Syntax, M-Context versus M-Semantics, and M-Context versus M-L1LR. We set the significance level at 0.05, then calculate the difference between their convince-scores and test the null hypothesis: the average is less than or equal to 0. Their p-values are 0.02, 0.0002, and 0.05 respectively. That is, all null hypotheses are rejected at significance level 0.05. The automatic explanation by applying the context construction is better than alternative methods.

Respondents commented that explanations revealed some behaviours they had not realised before, e.g., an app called “com.antivirus.kav” sends SMS after a phone call is made, and supporting apps improve their understanding of the given explanation, e.g., they prefer to believing the given explanation is benign when they see familiar benign app names like Google Talk in the supporting apps. But, some of them, especially the malware analyst and those postgraduate students, wanted to see detailed features we use to produce explanations. This explains why M-Syntax is slightly better than M-Semantics in this surveying: API names are included in explanations produced by M-Syntax but not in M-Semantics. In practice, we can hide detailed features from users and only present them on-demand as evidence.

## 6 Conclusion

We have presented a new approach to automatically generate explanations of unwanted behaviours for mobile apps. A user-study by surveying end users shows that this approach is effective. There are still certain types of high-level behaviours that are exhibited in Android malware but cannot be fully captured by our approach, e.g., gain root access and perform DDoS attacks [ZJ12]. This is because these complex behaviours do not correspond to simple semantics-based features like happen-befores. In further work, a promising approach to remove this limitation might be to exploit more semantics-based features to capture these high-level behaviours.
