Background: The present interdisciplinary consensus review proposes clinical considerations and recommendations for anaesthetic practice in patients undergoing gastrointestinal surgery with an Enhanced Recovery after Surgery (ERAS) programme.

Methods: Studies were selected with particular attention being paid to meta-analyses, randomized controlled trials and large prospective cohort studies. For each item of the perioperative treatment pathway, available English-language literature was examined and reviewed. The group reached a consensus recommendation after critical appraisal of the literature.

Results: This consensus statement demonstrates that anaesthesiologists control several preoperative, intraoperative and postoperative ERAS elements. Further research is needed to verify the strength of these recommendations.

Conclusions: Based on the evidence available for each element of perioperative care pathways, the Enhanced Recovery After Surgery (ERAS) Society presents a comprehensive consensus review, clinical considerations and recommendations for anaesthesia care in patients undergoing gastrointestinal surgery within an ERAS programme. This unified protocol facilitates involvement of anaesthesiologists in the implementation of the ERAS programmes and allows for comparison between centres and it eventually might facilitate the design of multi-institutional prospective and adequately powered randomized trials.
Editorial comment: what this article tells us

This consensus paper includes a number of recommendations to enhance recovery in patients undergoing gastrointestinal surgery. Preoperatively, optimization of medical disease and cessation of smoking and alcohol intake are emphasized. Prevention of nausea and vomiting is important. Careful titration of anaesthetics and ensuring full recovery of neuromuscular blockade are recommended. During surgery, there should be normal values of arterial oxygen level, intraoperative temperature and glucose concentration. The article also includes recommendations regarding fluid therapy, opioid-sparing analgesia and mobilization.

Over 234 million major surgical procedures are performed globally each year and despite advances in surgical and anaesthetic care, morbidity after abdominal surgery is still high. Fast-track or enhanced recovery after surgery (ERAS) clinical pathways have been proposed to improve the quality of perioperative care with the aim of attenuating the loss of functional capacity and accelerating the recovery process.

The ERAS pathways reduce the delay until full recovery after major abdominal surgery by attenuating surgical stress and maintaining postoperative physiological functions. The implementation of the ERAS pathways has been shown to impact positively in reducing postoperative morbidity, and as a consequence, length of stay in hospital (LOS) and its related costs.

In recent years, several studies have highlighted the impact of the anaesthetic management on postoperative morbidity and mortality. In view of the evidence that many elements of the ERAS programme published by the ERAS Society in 2009 are of related to anaesthetic care, it is imperative that guidelines on perioperative care include recommendations approved by an interdisciplinary team comprising anaesthesiologists and surgeons.

As a follow-up of the previous manuscript where the pathophysiological basis of the ERAS were analysed, this article represents an effort of the ERAS Society (www.erassociety.org) to present a consensus review of clinical considerations, including recommendations, for optimal anaesthesia care for patients undergoing gastrointestinal surgery within the ERAS programme. It is not the purpose of this manuscript to provide detailed information about each single ERAS element and for each type of gastrointestinal surgical procedure. Most of the ERAS elements have been already discussed extensively, specifically for different types of surgical procedures, as well the quality of evidence supporting each ERAS element. It must be acknowledged that evidence supporting some of the ERAS elements still remains controversial.

Methods

An interdisciplinary group of physicians, anaesthesiologists and surgeons who are experts in the field of ERAS programmes were invited to participate in the preparation of this consensus statement.

Literature search

The authors met in October 2012 and the topics for inclusion were agreed upon and allocated. The principal literature search utilized MEDLINE, Embase and Cochrane databases to identify contributions related to the topic published between January 1966 and May 2014. Medical Subject Headings (MeSH) terms were used, as were accompanying entry terms for the patient group, interventions and outcomes. Key words included “anaesthesia”, “anaesthesia”, “analgesia”, “surgery”, “enhanced recovery” and “fast track”. Reference lists of all eligible articles were checked for other relevant studies. Conference proceedings were not searched. Expert contributions came from within the ERAS Society Working Party.

Study selection, assessment and data analyses of the identified trials

Based on the literature search, titles and abstracts were screened by individual reviewers to identify reviews, case series, non-randomized studies, randomized control studies, meta-analyses and systematic reviews that were considered for each individual topic. Discrepancies in
judgment were resolved by the senior author and during committee meetings of the ERAS Society Working Party.

**Recommendations**

Recommendations were made by the panel based on the evidence supporting each ERAS element. Specifically, “Strong recommendations” indicate that the panel was confident that the desirable effects of adherence to a recommendation outweighed the undesirable effects. “Weak recommendations” indicate that the desirable effects of adherence to a recommendation probably outweighed the undesirable effects, but the panel was less confident. Recommendations were based on the balance between desirable and undesirable effects, and on values and preferences.

**Part A. Preoperative ERAS elements**

**An ERAS approach to preoperative evaluation**

**Pre-admission risk stratification**

Risk scoring systems have been used to try and identify which patients are at higher risk of death and complications from major surgery. Up to 80% of postoperative deaths come from this high-risk group\(^20\). It is imperative not only to provide patients with an overview of the risk of surgery but also to select those patients for further investigation and optimization and decide which perioperative care pathway the patients should be on for resource allocation. In a major retrospective study in the USA, Khuri et al. analysed data on 105,951 patients undergoing a variety of different specialty major surgical procedures. The striking result was that if patients had a major complication within 30 days of surgery then it reduced median survival by 69% at 8 years\(^21\). Therefore, identification for risk factors for any major complication of surgery is also important.

**Scoring systems for surgery.** Many different scoring systems, some of them procedure-specific, have been developed for patients undergoing surgery. The purpose of this section is to give an overview of the most common scoring system use in clinical practice beside the well known American Society of Anesthesiologists (ASA) physical status score.

**POSSUM scores:** in 1991, Copeland et al. described the POSSUM (Physiological and Operative Severity Scoring for the enUmeration of Mortality and morbidity) scoring system for general surgical patients\(^22\). This is a two part scoring system based on physiological assessment (12 variables) and operative severity (six variables). Each variable has a 1–4 point range depending on severity. The system predicts 30-day risk for mortality (matrix for the 50% prediction of risk of mortality: specificity = 99.3% and sensitivity = 54.1%) and morbidity (matrix for the 50% prediction of risk of morbidity: specificity = 92.4% and sensitivity = 52.1%).

The Portsmouth POSSUM (P-POSSUM) better predicts postoperative mortality\(^23\), as the original POSSUM logistic regression equation overpredicts mortality especially in low-risk patients. POSSUM has been also modified slightly for different specialties such as colorectal\(^24\), oesophageal\(^25\) and vascular surgery\(^26\) to try and improve sensitivity and specificity for these specialties.

**Assessing cardiac risk in non-cardiac surgery**—Cardiovascular risk can be predicted by multivariate risk incidences that include clinical and surgical criteria, and biological markers\(^27–29\). These tools have been incorporated in the recent ACC/AHA 2014 guidelines on perioperative cardiovascular evaluation and care for non-cardiac surgery\(^30\).

**The Lee index**—The Lee Index is a modification of the original Goldman cardiac risk index\(^31\). It comprises six independent clinical determinants of major perioperative cardiac events:

1. History of ischaemic heart disease (IHD)
2. History of cerebrovascular disease
3. Heart failure
4. Preoperative insulin treatment for diabetes mellitus
5. Serum creatinine > 177 µmol/l
6. High-risk type of surgery
All factors contribute 1 point equally to the index, and for patients with an index of 0, 1, 2 and 3 points the incidence of major cardiac complications is estimated at 0.4%, 0.9%, 7% and 11% respectively.\(^3\)

Cardiovascular Risk Calculator—A similar tool to determine the postoperative probability of myocardial infarct or cardiac arrest has been validated by Gupta and colleagues in 211,410 patients undergoing surgery. It contains five independent predictors:\(^2\)

1. Type of surgery
2. Dependent functional status (inability to perform activities of daily living in the 30 days before surgery, partially independent or totally independent)
3. Abnormal serum creatinine
4. American Society of Anesthesiologists class (ASA)
5. Increasing age

More recently there has been increasing awareness that perioperative myocardial injury does not always present with any of the typical ischaemic features of chest pain, electrocardiogram changes, rhythm disturbance or heart failure. The VISION study measured troponins and showed a spectrum of results with 44% of troponin rises fulfilling the criteria for myocardial injury without fulfilling a traditional definition of perioperative myocardial infarction.\(^3\)

**Assessment of functional capacity.** Estimating functional capacity is an important start of assessing a patient. Functional capacity is measured in metabolic equivalents (METs). One MET equals the basal metabolic rate at rest. Climbing one flight of stairs demands 4 METs and strenuous activity such as playing tennis or swimming is > 10 METS. The inability to perform 4 METS indicates poor functional capacity and is associated with an increased incidence of postoperative cardiac events.\(^3\) The presence of good functional capacity, even in the presence of stable IHD or other risk factors is associated with a good outcome.\(^3\)

As patients poorly estimate their functional capacity, it is important to obtain an independent assessment using dynamic testing.

**Dynamic Tests**

Walk Tests—(2 min, 6 min, shuttle) All these tests measure the distance covered over a set period of time by the patient. They have been validated in clinical practice and are easy to administer.\(^3\) Norms according to age and gender have been created. Although they correlated with cardiopulmonary testing, they have not been used to determine whether to operate or not on patients undergoing high-risk surgery.

Cardiopulmonary Exercise Testing (CPET)—This is a dynamic non-invasive objective test that evaluates the ability of a patient’s cardiopulmonary system to adapt to a sudden increase in oxygen demand. The ramped exercise test is performed on a cycle ergometer with ECG monitoring and analysis of expired carbon dioxide and oxygen consumption, the later being directly related to oxygen delivery and a linear function of cardiac output when exercising. With increasing exercise, oxygen consumption will eventually exceed oxygen delivery. Aerobic metabolism becomes inadequate to meet the metabolic demands and blood lactate rises reflecting supplementary anaerobic metabolism. The value for oxygen consumption at this point is known as the anaerobic threshold (AT), expressed as ml/kg/min VO\(_2\) peak(max) can also be measured. Both values have been used to try and predict the risk of complications. Older’s original work in colorectal patients showed that if a patient’s AT was less than 11 ml/kg/min, the patients was at higher risk of complications which was increased if there was the presence of ischaemic heart disease.\(^3\) Snowden et al. showed that an AT cut-off value of 10.1 ml/kg/min predicts complications better than an algorithm-based activity assessment (Veterans Activity Questionnaire Index [VASI]).\(^3\) Similarly, in patients undergoing pancreatic, hepatic and vascular surgery and AT < 10 ml/kg/min predicts complications and early postoperative death.\(^4\) VO\(_2\) max has also been studied to predict outcome and has been shown to be a sensitive marker for cardiopulmonary complications in patients undergoing oesophageal resection.\(^4\) Despite its high sensitivity, the specificity of the CPET is not high enough to identify patients with a significant...
preoperative risk correctly, as patients with low ATs can still undergo major surgery without complications.

**Risk of acute kidney injury (AKI).** Approximately 1% of patients undergoing non-cardiac surgery develop AKI, and it is associated with higher morbidity and mortality. Eleven preoperative risk factors (age 56 years or older, male sex, emergency surgery, intraperitoneal surgery, diabetes mellitus necessitating oral therapy, diabetes mellitus necessitating insulin therapy, active congestive heart failure, ascites, hypertension, mild preoperative renal insufficiency and moderate preoperative renal insufficiency) have been identified as independent predictors of AKI in patients undergoing non-cardiac surgery. The risk of developing postoperative AKI can be stratified in five classes based on the presence of these risk factors (General Surgery Acute Kidney Injury Risk Index).45

**Summary and recommendations:** preoperative scoring tools and functional capacity tests can be used to identify patients at risk of complications and to stratify perioperative risk (Table 1).

**Recommendation grade:**
- POSSUM: strong
- Lee Index: strong
- Cardiovascular Risk Calculator: strong

Smoking. Smokers often have comorbidities due to smoking such as chronic obstructive airways disease, emphysema, peripheral vascular and ischaemic heart disease and cerebrovascular

AT, anaerobic threshold; VO\(_2\) max, maximum oxygen consumption.
disease that can increase the risk of perioperative complications independently. Smokers without these comorbidities still have an increased perioperative risk, mainly due to poor wound and tissue healing which can lead to wound infection\(^48\) as well as cardiopulmonary complications such as chest infection. Studies have been undertaken to assess whether short-term abstinence from smoking can improve outcome. The cessation of smoking for 4 weeks prior to surgery has been shown to improve wound healing.\(^48\)–\(^50\) The use of nicotine replacement therapy (NRT) and counselling facilitate preoperative smoking cessation.\(^49\) Other pharmacological interventions are also available. Varenicline, in combination with two preoperative 15-minute standardized counselling sessions, started 1 week before surgery and followed up for 12 weeks, was shown to improve long-term smoking abstinence (RR 1.45, 95% CI 1.01–2.07, \(P = 0.04\)) but not reduce postoperative complications in comparison with placebo. However, nausea occurred more frequently in patients treated with varenicline (13.3% vs. 3.7%, \(P = 0.004\)).\(^51\) Antidepressants such as bupropion also seem beneficial to improve smoking cessation, but limited data are available in the perioperative setting.\(^52,53\)

**Preoperative anaemia.** Haemoglobin is one of the main determinants of oxygen delivery. Preoperative anaemia is common and is an independent predictor of mortality and postoperative complications.\(^54,55\) Haemoglobin levels should be corrected preoperatively, as it is common to expect a drop of haemoglobin concentrations due to blood loss and to the dilution effect of intravenous fluids. Correction of preoperative anaemia should take in consideration its aetiology.\(^56,57\) Iron, folate, vitamin B\(_{12}\) supplements and/or erythropoietin should be used when appropriate. Medical management of preoperative anaemia takes time and should be planned at least 3–4 weeks before elective surgery. Although preoperative blood transfusion corrects anaemia rapidly and could be used in severely anaemic patients and/or in patients undergoing surgery with expected profound blood loss, caution should be used as it has been associated with increased mortality and morbidity.\(^58\)–\(^60\) These effects seem to be dose-dependent.\(^58\) The risk of transfusion-related complications and the effect of blood transfusion on the immune system must be also considered.\(^36,57,61\) Evidence suggesting that normalizing preoperative haemoglobin levels prior to surgery reduces postoperative morbidity and mortality is lacking and studies evaluating the role of preoperative anaemia optimization are warranted.\(^57,62\) Implementation of perioperative blood management protocols can reduce the risk of allogenic blood transfusions.\(^56,57\)

**Cardiovascular risk reduction.** It is not the intent of this manuscript to discuss in detail perioperative cardiovascular strategies to reduce cardiovascular risk. These interventions are extensively discussed in the recent ACC/AHA 2014 guidelines.\(^30\)

**Asthma, COPD and diabetes.** Chronic conditions such as asthma, chronic obstructive airways disease, diabetes mellitus, malnutrition and frailty should be optimized prior to surgery.

**Summary and recommendation:** cessation of smoking and alcohol intake at least 4 weeks before surgery is recommended. Encouraging patients is not enough; pharmacological support and individual counselling should be offered to every patient who smokes and to alcohol abusers undergoing elective surgery. Optimization of medical conditions, such as cardiovascular diseases, anaemia, chronic obstructive airways disease, diabetes, nutritional status and frailty and should follow international recommendations.

**Recommendation grade:**
Smoking cessation: high
Nicotine replacement therapy and counselling: high
Alcohol cessation: low
Medical optimization: strong

**Pre-anaesthetic medications**
Patients undergoing major surgery are, as expected, anxious. Anxiety has also been shown in many studies to be the most common predic-
tor for postoperative pain and positively correlates with postoperative pain intensity. Furthermore, preoperative pain is also a significant predictor for postoperative pain. Therefore, education and counselling, and preoperative analgesic and anxiolytic medication must be specifically addressed during the preoperative assessment of the patient. Short-acting anxiolytics and analgesics can be administered to facilitate regional anaesthetic procedures and insertion of intravascular lines, provided they are used in adequate doses based on age and patients’ comorbidities. Short-acting benzodiazepines should be avoided in older patients (age > 60). Long-acting sedatives and opioids should be avoided as they may hinder recovery, thus impairing postoperative mobilization and direct participation, resulting in prolonged length of stay.

Summary and recommendation: long-acting anxiolytic and opioid should be avoided as they may delay discharge. Short-acting benzodiazepine should be avoided in the elderly.

Recommendation grade: strong

Preoperative fasting and carbohydrate loading
Although fasting guidelines of various anaesthesia societies support the safety of allowing clear fluids up to 2 h and solid food up to 6 h before the induction of anaesthesia, patients scheduled for elective surgery are commonly asked to fast from midnight. The evidence supporting this practice, with the belief to ensure an empty stomach before the induction of anaesthesia and decrease the risk of aspiration is lacking. On the contrary, it has been shown that fasting from midnight increases insulin resistance, patient’s discomfort and potentially decreases intravascular volume, especially in patients receiving mechanical bowel preparation. In fact, functional intravascular deficit after fasting time, as indicated by guidelines or after 8 h fasting is minimally affected in patients undergoing elective surgeries without mechanical bowel preparation. Results from two Cochrane meta-analyses have shown that gastric content of patients following anaesthesia fasting guidelines is the same or lower of the gastric content of patients fasting after midnight. Imaging studies have further supported the safety of allowing clear fluids up to 2 h before the induction of anaesthesia, showing complete gastric emptying with 90 min. Recently, the European and American Anesthesia Society have revised their fasting guidelines and have not changed their previous recommendations. Preoperative treatment with oral complex carbohydrates (CHO) (maltodextrin) with a relatively high concentration (12.5%), with 100 g (800 ml) administered the night before of surgery and 50 g (400 ml) 2–3 h before induction of anaesthesia, reduces the catabolic state induced by overnight fasting and surgery. Indeed, overnight fasting before surgery inhibits insulin secretion and promotes the release of catabolic hormones such as glucagon and cortisol. By increasing insulin levels preoperative treatment with oral CHO reduces postoperative insulin resistance, maintains glycogen reserves, decreases protein breakdown and improves muscle strength. Faster surgical recovery and better postoperative well-being still remains controversial. Delayed gastric emptying should be suspected in patients with documented gastroparesis, patients on prokinetic agents such as metoclopramide and/or domperidone, patients scheduled for gastrointestinal operations such oesophageal, gastric, fundoplication, paraesophageal hernia repair, gastro-jejunostomy, in patients who underwent previous Whipple’s procedure, in patients with achalasia and in patients with neurological diseases with dysphagia. Patients with diabetes with neuropathy and, less clearly, obese patients are considered to have delayed gastric emptying. However, gastric emptying after 300 ml of clear fluids 2–3 h before the induction of anaesthesia in obese patients has been shown to be similar to those of lean patients and gastric emptying after CHO administration in patients with uncomplicated diabetes is normal. The clinical relevance of preoperative CHO drinks in these specific populations remains to be established.

Summary and recommendation: Intake of clear fluids should be allowed until 2 h before induction of anaesthesia. Solids should be allowed...
until 6 h. Preoperative treatment with oral CHOs can be administered safely except in patients with documented delayed gastric emptying or gastrointestinal motility disorders and as well in patients undergoing emergency surgery.

**Recommendation grade:**
Adherence to fasting guidelines (avoid overnight fasting): strong
Administration of preoperative CHOs: strong
Administration of preoperative CHOs in diabetic and obese patients: weak

**Part B. Intraoperative and postoperative ERAS elements**

**Preventing and treating postoperative nausea and vomiting**

Despite significant advances in our knowledge of PONV and the introduction of new agents, the overall incidence of PONV is currently estimated to be 20–30%. In high-risk patients, the incidence in still as high as 70%, and it is one of the most unpleasant experiences in the perioperative period.

There are many risk factors that predispose patients to PONV. The most widely used scoring system was developed by Apfel et al., who created a simplified scoring system using only four risk factors – female gender, a history of motion sickness or PONV, non-smoking status and the use of postoperative opioids.

The multimodal approach to PONV within an ERAS programme contains the use of antiemetics and a total intravenous anaesthesia with propofol instead of inhalational agents. Avoidance of nitrous oxide is also important. Other factors like the reduction of preoperative fasting, carbohydrate loading and adequate hydration and high inspired oxygen concentrations may influence the prevalence of PONV. The use of regional anaesthetic techniques and the use of non-steroidal anti-inflammatory drugs (NSAIDs) as opioid-sparing strategies may have an additional indirect influence on the prevalence of PONV.

Classes of antiemetics (serotonergic, dopaminergic, cholinergic and histaminergic) are based on the antagonism of different kinds of central receptors that are all involved in the pathophysiology of PONV and all have shown to be superior to placebo in the prevention of PONV. Newer drugs as the neurokinin-1 receptor antagonists show encouraging results in initial trials. Unfortunately, none of the available pharmacological agents when used alone are effective in reducing the incidence of PONV by more than 25%. Antiemetic combinations are recommended for patients at higher risk of PONV. Combination therapy is more effective than monotherapy, and for high-risk patients, combination with 2–3 antiemetics in addition to propofol based total intravenous anaesthetic (TIVA) has the greatest likelihood of reducing PONV.

Examples of antiemetic drugs are serotonin antagonists like ondansetron 4 mg i.v. or dopamine antagonists like droperidol 0.625–1.25 mg i.v. given at the end of surgery or a transdermal patch of scopolamine placed the evening prior to or 2 h before surgery. Dexamethasone 4–5 mg i.v. after induction of anaesthesia has also been shown to be effective, but its immunosuppressive effects on long-term oncological outcome are unknown. Higher doses of dexamethasone have no additional effect and are associated to sleep disturbances. It should not be used in diabetic patients requiring insulin and not given prior to induction of anaesthesia due to perineal pain.

If PONV is present postoperatively, rescue therapy should be with an antiemetic from a different class unless the elapsed time from the previous antiemetic administration is greater than 6 h. After prophylactic administration of 4 mg ondansetron re-dosing for established PONV was shown to be no more effective than placebo.

**Summary and recommendation:** Aggressive PONV prevention strategy should be included in an ERAS protocol. All patients with 1–2 risk factors should receive as PONV prophylaxis a combination of two antiemetics. Patients with 3–4 risk factors should receive 2–3 antiemetics and total intravenous anaesthesia (TIVA) with propofol and opioid-sparing strategies should be encouraged.

**Recommendation grade:** strong.
Standard anaesthetic protocol and depth of anaesthesia monitoring

Although there are no studies comparing general anaesthetic techniques for gastrointestinal surgery, it is sensible to assume that within the ERAS protocol efforts have to be made to minimize the impact of anaesthetic agents and techniques on organ function, and to facilitate rapid awakening from anaesthesia thus accelerating recovery of the patient’s gastrointestinal and motor functions. As such particular attention can be drawn to the type of agents used and the monitoring of vital functions.

Traditionally the anaesthesiologist has relied on clinical signs to try and ensure appropriate depth of anaesthesia and avoidance of awareness but also avoiding overdose and the resultant depression of a patient’s physiological status. Depth of anaesthesia can now be measured by many devices but in terms of clinical evaluation the data on Bispectral Index (BIS) far exceeds other devices.103 Recent focus has been on using depth of anaesthesia monitoring not just to avoid awareness during surgery but also to titrate the minimum amount of anaesthetic necessary to avoid complications.103–116 This appears to have particular significance in the elderly population with cognitive dysfunction.117 Unfortunately BIS is not infallible. Many things can affect the BIS value, in particular neuromuscular relaxation, which is commonly used in anaesthesia. The specificity seems to be lower when using total intravenous anaesthesia (TIVA).106 There is also a lag time between EEG interpretation and the displayed BIS value.

When compared with clinical signs alone, BIS obtains lower rates of awareness during surgery.112–114,116 Anaesthetic depth guided by BIS may also help reduce the amount of drug given,107,116 with more rapid immediate recovery although the time to discharge home appears to be unaffected116. In Myles’ study, 138 patients needed to have BIS monitoring to avoid one case of awareness.112 Avidan’s studies104,105 have demonstrated that maintaining anaesthetic depth with an end tidal concentration (EATC) between 0.7 and 1.3 MAC equivalents can prevent intraoperative awareness as effectively as anaesthesia guided by a BIS value between 40 and 60. The use of nitrous oxide, a N-methyl-D-aspartate (NMDA) receptor antagonist, has been shown to reduce the risk of awareness118 with one study showing an NNT of 46.119 however, there were two cases of awareness in the ENIGMA study in patients having nitrous oxide.120 Recent studies have highlighted that patients with BIS levels < 45 under anaesthesia (reflecting increased suppression of brain activity) have an increased risk of death by up to 1.24-fold (95% CI 1.06–1.44).121 Subsequent analysis suggests this may be a reflection of elderly patients who have multiple problems and cognitive dysfunction and may have a reduced life expectancy prior to surgery more likely to have low BIS values. More studies are needed to clarify this point. There is increasing interest in anaesthetic drugs and analgesic techniques. (e.g. morphine and thoracic epidural analgesia) and their effect on cancer outcome but there is currently not enough consistent data to support making specific recommendations.122,123

Summary and recommendation: anaesthetic depth should be guided either maintaining an end tidal concentration of 0.7–1.3 MAC or BIS index between 40 and 60 with the aim not only to prevent awareness but also to minimize anaesthetic side effects and facilitate rapid awakening and recovery. Avoid too deep anaesthesia (BIS < 45), especially in elderly patients

Recommendation grade: strong

Neuromuscular blockade (NMB) and neuromuscular monitoring

This section discusses the importance of neuromuscular blockade and neuromuscular monitoring, and their potential implications specifically in the context of an ERAS programme. Neuromuscular blockade agents (NMBA) paralyse skeletal muscles, allowing optimal conditions for surgery. The level of NMB needed to obtain optimal surgical conditions can differ depending on the surgical approach. A deep NMB might be particularly useful when a laparoscopic approach is used.124,125 A recent systematic review showed that during certain laparoscopic procedures deep NMB (e.g. Post-Tetanic Count 1 or more; but Train of Four (TOF) Count of 0126) provide better surgical conditions than
moderate NMB, but limited evidence is available to support this practice. Moreover, the use of deep NMB during laparoscopic procedures, especially in countries where sugammadex is not available, may increase the risk of residual paralysis. Although moderate NMB certainly facilitates surgical work, the use of NMB might not be always necessary for patients undergoing open abdominal surgery. Indeed, an adequate level of anaesthesia without muscle relaxants can produce a good to excellent surgical field in approximately two-thirds of patients undergoing radical retropubic prostatectomy.

In the light of these considerations, the hypotheses that optimal NMB can potentially attenuate surgical stress by shortening the duration of surgery, and that it can facilitate the use of low pneumoperitoneum pressures, thereby reducing postoperative pain remain appealing, especially in the context of an ERAS programme. However, this needs to be tested in larger high-quality trials.

At the end of surgery, it is important to restore neuromuscular function to preoperative levels and avoid residual muscle paralysis which can be responsible for respiratory insufficiency, hypoxia, aspiration into the lungs as well as distress for the patient. Similarly, it might impair early mobilization. To avoid residual muscle paralysis long-acting NMBA should not be used. Hypothermia also influences neuromuscular function directly and prolongs duration of action and recovery time of NMBA significantly. Maintenance of normothermia is therefore essential to prevent residual paralysis.

The use of NMBA must be guided by adequate assessment of neuromuscular block and appropriate monitoring. In healthy volunteers, it has been demonstrated that there is risk of pharyngeal dysfunction or aspiration if TOF < 0.9. Furthermore, three clinical trials have demonstrated that there is a greater proportion of hypoxaemic events and prolonged stay in the recovery room if TOF < 0.9. Even more experienced anaesthesiologists cannot clinically identify the degree of residual curarization. Several studies have shown that clinical tests and qualitative (visual or tactile) assessment of neuromuscular function (TOF, double burst suppression or tetanic stimulation) are not reliable and sufficient to detect residual curarization, even when sugammadex is used. Quantitative methods such as mechanomyography and acceleromyography provide more accurate information. Although mechanomyography remains the goal-standard to measure neuromuscular function, its use in clinical practice remains limited. On the contrary, acceleromyography can be used easily to measure neuromuscular function and avoid residual paralysis.

There are three ways to avoid residual paralysis:

1. Waiting for a spontaneous recovery of neuromuscular function identified by a TOF > 0.9. This approach might not be convenient for brief surgical procedures, as the effect of some NMBA can last longer than 4 h, even after a single dose administered at the beginning of surgery. Side effects of reversal agents are avoided.

2. Administering cholinesterase inhibitors. Side effects of cholinesterase inhibitors and antimuscarinic agents have to be considered.

3. Administering sugammadex. Sugammadex selectively reverses the neuromuscular block induced by steroidal NMBA. Abrishami et al. demonstrated that sugammadex reverses neuromuscular block (rocuronium-induced) faster than neostigmine and independent of the depth of the neuromuscular block. Sugammadex can be used at different dosages, 2, 4 or 16 mg/kg to reverse moderate, deep or recently induced block, respectively. Sugammadex reverses neuromuscular block 3–4 times faster than neostigmine, and the neuromuscular block is completely reversed after 5 min.

Summary and recommendations: It remains controversial if deep neuromuscular blockade during laparoscopic surgery improves operating conditions. Neuromuscular function should be always monitored when using NMBA to avoid residual paralysis. Long-acting NMBA should be avoided. When NMBA are administered neuromuscular function should be monitored by using a peripheral nerve stimulator to ensure adequate muscle relaxation during surgery and optimal restoration of neuromuscular function at
the end of surgery. A TOF ratio of 0.9 must be achieved to ensure adequate return of muscle function and thus preventing complications.

**Recommendation grade:** Monitoring neuromuscular function: strong.

Reversing neuromuscular blockade: strong.

**Use of inspired oxygen**

Oxygen is a highly reactive gas which is ubiquitous in anaesthetic practice. In cellular physiology the controlled oxidation of glucose to carbon dioxide with the concurrent reduction of oxygen to water is the basis for aerobic metabolism and production of energy. Therefore, one of the highest priorities of the anaesthesiologist is to try to ensure a patient does not become hypoxic to avoid interruption of cellular metabolism.

Oxygen is widely available in anaesthesia and has traditionally been added to increase the inspired fraction of oxygen above 21% to overcome hypoxia under anaesthesia caused by physiological changes such as pulmonary shunt. Although increasing the FiO₂ is necessary to overcome hypoxia there has been increasing recognition that hyperoxia can cause damage due to the production of oxygen free radicals.

However, it has been suggested that high inspired oxygen concentration protects against the risk of surgical site infections. The PROXI trial, a multicentre RCT, found no differences between patients treated with a FiO₂ 30% vs. 80% in terms of SSI or pulmonary complications.¹³³ A meta-analysis including the PROXI trial showed that two subgroups of patients benefitted from high inspired oxygen therapy – those undergoing general anaesthesia and colorectal surgery.¹³⁰ However a high-heterogeneity was found among the studies included.¹³⁰ The latest meta-analysis including new nine RCTs (5001 patients) found a marginal reduction of SSI in patients undergoing colorectal surgery treated with high concentrations of oxygen vs. normal oxygen concentrations (RR 0.77, 95% CI 0.59–1.00, P = 0.03). The study also found that high oxygen concentrations reduce the incidence of late (24 h postoperatively) nausea and vomiting, but only in patients receiving volatile anaesthesia without antiemetic prophylaxis.⁹⁷ Based on these data, it still remains unclear if high concentrations of oxygen protects against the risk of SSI.

On the contrary was the long-term follow-up of patients included in the PROXI trial. This study showed a reduction in survival in patients with cancer who had received the higher inspired oxygen concentration.¹⁴¹ Unfortunately, the authors failed to report why patients died earlier than patients receiving normal inspired oxygen concentrations. Both this study and the analysis of outcomes of patients following cardiac arrest, which show a poorer neurological outcome in patients receiving a higher FiO₂,¹⁴²,¹⁴³ suggest that there can be harmful effects from receiving high inspired concentrations of oxygen.

Therefore, higher inspired oxygen concentrations of 80% may reduce surgical wound site infection especially in patients with colorectal cancer, but there may be deleterious effects on long-term cancer outcomes. To reduce wound infection to a minimum the importance of other contributing factors such as maintaining patient’s body temperature, cardiac output, glycaemic control, prophylactic antibiotics and minimizing surgical contamination should also be considered.

The short-term use of high inspired oxygen concentrations is widely practised in anaesthesia to overcome hypoxic episodes and to pre-oxygenate (de-nitrogenate) the lungs prior to the induction of anaesthesia. Edmark and colleagues looked at differing inspired concentrations (60%; 80%; 100%) of oxygen for 5 min prior to the induction of anaesthesia.¹⁴⁴ Computed tomography showed an increase in atelectasis in the 100% inspired oxygen group although patients took longer to desaturate. The use of 80% oxygen in a subgroup of the PROXI study and in a recent meta-analysis also did not demonstrate any increased risk of pulmonary complications.⁹⁷,¹⁴⁵

**Summary and recommendations**

1. The inspired fractional concentration of oxygen should be titrated to produce normal arterial oxygen levels and saturations. Prolonged periods of high inspired oxygen con-
centrations which result in hyperoxia should be avoided.

*Recommendation grade:* strong

2). 100% inspired oxygen concentrations can be used for pre-oxygenation prior to anaesthesia or for short periods to overcome hypoxia.

*Recommendation grade:* strong

### Preventing intraoperative hypothermia

Perioperative hypothermia, defined as a core temperature below 36°C is a common adverse consequence of anaesthesia and surgery. The prevalence of inadvertent hypothermia ranges from 50% to 90%, independently whether patients undergo laparoscopic or open surgery. Older adults are more prone to heat loss, whereas obesity has a protective effect.

Hypothermia in most patients undergoing general anaesthesia is the result of an internal core-to-peripheral redistribution of body heat that usually reduces core temperature by 0.5–1.5°C in the first 30 min after induction of anaesthesia.

Several meta-analyses and RCTs have demonstrated that preventing inadvertent hypothermia during major abdominal surgery significantly reduces wound infections, cardiac complications, bleeding and transfusion requirements, and improves immune function, the duration of post-anaesthetic recovery and overall survival. Therefore, it makes sense to prevent the loss of body heat as also recommended by the ERAS society.

Use of active warming devices is highly recommended in all cases lasting more than 30 min and this can be achieved by using different warming devices (forced air warming systems, circulating water garments or warmed i.v. solutions). Combined strategies, and among the others preoperative warming, should be considered in vulnerable groups such as older patients with cardiorespiratory diseases, and surgery of long duration. Rewarming should be performed to a core temperature of 35.5–36.0°C before emergence from anaesthesia, and every effort should be made to avoid shivering by using meperidine 0.25–0.5 mg/kg. Alternatively clonidine 1–2 µg/kg i.v. can be used.

### Summary and recommendation

Intraoperative hypothermia should be avoided by using active warming devices.

*Recommendation grade:* strong.

### Surgical techniques

The short-term benefits of laparoscopic vs. open surgery for abdominal surgery have been well established in the literature to date and include shorter length of stay, reduced postoperative morbidity, earlier passage of flatus and less narcotic analgesic requirements. However, long-term outcomes have shown equivalence between laparoscopic and open surgery. The fact that laparoscopic practice has improved since these trials were initiated, further consolidates the role played by this technique as the preferable one for abdominal surgery. In the context of an enhanced recovery programme, the multicentre randomized LAFA study has shown positive benefits when laparoscopic resection is optimized within an ERAS protocol.

The main goal of enhanced recovery strategy should not be based on the choice of laparoscopic vs. open, but less surgical invasiveness as the surgical technique should minimize wound trauma, tissue distraction and bleeding.

A recently updated Cochrane review comparing transverse with midline laparotomy incisions for abdominal surgery found less postoperative opiate analgesic use with transverse incisions but no differences in visual analogue pain scores reported by patients. Pooled data for spirometry after the operation showed that a transverse incision had less effect on vital capacity and FEV₁. However, these benefits on pulmonary function did not result in reduced pulmonary complications or hospital stay. A trend towards a lower incidence of wound dehiscence was shown in the transverse incision group. Finally there was a reduction in incisional hernias with transverse incisions, but the studies showed a high variety of time to follow-up.

A number of new minimally invasive surgical technologies have emerged over the past decade. A recent meta-analysis of non-randomized controlled trials has indicated that robotic total mesorectal excision (TME) did not reduce opera-
tion time, length of hospital stay, time to resume regular diet, postoperative morbidity or mortality, and is a technique that requires evaluation through high-quality randomized research. While single-incision laparoscopic resections may improve recovery, no robust data have yet appeared and these techniques are at an early stage in their development. Furthermore, transvaginal and transrectal specimen extraction to avoid abdominal wounds has been described, but with little data on short- and long-term results. At this stage, no recommendation can be made on these procedures. However, the negative intraoperative pathophysiological consequences (e.g. head-down-position, longer operation time) have to be balanced to the benefits of the minimal-invasive approaches and the use of an ERAS protocol.

**Summary and recommendation:** Laparoscopic surgery for gastrointestinal resections is recommended when the expertise is available. Transverse incisions for colonic resections should be preferred.

**Recommendation grade:**
- Laparoscopic approach: strong;
- Transverse incisions: low.

**Nasogastric intubation**

There is strong evidence that routine nasogastric decompression following elective laparotomy should be avoided. Prophylactic nasogastric tubes placed during surgery (to evacuate air) should be removed before reversal of anaesthesia. Fever, oropharyngeal and pulmonary complications are more frequent in patients with nasogastric tubes. Even death and other serious complications resulting from nasogastric tubes are reported. Avoidance of nasogastric decompression is associated with an earlier return of bowel function while gastrointestinal reflux is increased during laparotomy if nasogastric tubes are placed. Even in gastroduodenal and pancreatic surgery, there appears to be no evidence of a beneficial effect from the prophylactic use of nasogastric tubes. However, the incidence of vomiting has been shown to be higher in patients without nasogastric tubes. Nevertheless, the benefits of routinely avoiding nasogastric intubations overcome the risks.

Delayed gastric emptying can occur in a small proportion of patients, leading to vomiting and fatal aspiration if not treated promptly by inserting a nasogastric tube. The recognition and avoidance of this complication is essential. Teams should be taught to positively identify these changes, particularly when patients are failing to progress between 2 and 5 days after surgery.

**Summary and recommendation:** Prophylactic use of nasogastric tubes is not recommended for patients undergoing elective colorectal surgery, while its use in patients undergoing gastrectomy and oesophagectomy is still debatable. Patients with delayed gastric emptying after surgery should be treated by inserting a nasogastric tube.

**Recommendation grade:** strong.

**Intraoperative glycaemic control**

Blood glucose levels increase during and after elective surgery with the magnitude of hyperglycaemia depending upon the patient’s metabolic state (fasting, fed, diabetes), the type of anaesthesia and analgesia and the severity of surgical tissue trauma.

Strong evidence indicates that even moderate increases in blood glucose are associated with adverse outcomes. Patients with fasting glucose levels > 7 mmol/l or random blood glucose levels > 11.1 mmol/l on general surgical wards showed an 18-fold increased in-hospital mortality. More recent observations suggest that the quality of preoperative glycaemic control also is important. In fact elevated HbA1c levels have been found to be predictive of complications after cardiac and abdominal surgery.

Mere associations between two variables, i.e. glycaemia and clinical outcomes, do not prove a direct cause–effect relationship. At present there is insufficient evidence to demonstrate superiority of strict glycaemic control (blood glucose levels within a normal and narrow range) over conventional management in surgical patients. As in the ICU situation, it remains a balance...
between the benefits of bringing down glucose levels vs. the risks of hypoglycaemia. For the surgical patient on the ward, there is also the issue of the nursing staffing and their capacity to monitor patients on intensive insulin treatment to take into account. A review of the effect of glycaemic control on the incidence of surgical site infections was inconclusive, mainly because of the small number of studies \((n = 5)\), the heterogeneity in patient populations, the route of insulin administrations, the definition of outcomes measures and the fact that glycaemic targets were different and/or were not achieved.\(^{182}\) Hence, to date, the optimal glucose level for enhancing clinical outcomes is unknown.

This uncertainty is reflected by the diversity of recommendations issued by Medical Associations concerning blood glucose control in critically ill and surgical patients.\(^{64,183–185}\) Overall most of the Associations recommend treatment of random blood glucose concentrations \(> 10 \text{ mmol/l}\). A large randomized controlled trial of aggressive preservation of normoglycaemia vs. conventional glycaemic control is necessary to identify target blood glucose concentrations in patients undergoing major surgery.

In the meantime, it is important to emphasize that there are a range of elements in the ERAS protocol that will reduce insulin resistance and hence reduce the risk of hyperglycaemia and that should be employed.\(^{186}\) These include preoperative carbohydrates, an active mid thoracic epidural, early feeding and good pain control.

**Summary and recommendation:** Glucose concentrations should be kept as close to normal as possible without compromising safety. Employing perioperative treatments that reduce insulin resistance without causing hypoglycaemia is recommended.

**Recommendation grade:** strong.

**Perioperative haemodynamic management**

**Preoperative period:** preoperative hydration deficit can vary according to patients’ comorbidities, preoperative fasting and use of preoperative mechanical bowel preparation (MBP). The avoidance of prolonged preoperative fasting,\(^{80,81}\) MBP\(^{187,188}\) and as well the administration of preoperative carbohydrate (CHO) drinks\(^{83}\) have substantially reduced intraoperative fluid requirements. However, when MBP is indicated fluid and electrolytes derangements occur even if patients are encouraged to drink.\(^{74,189,190}\) The replacement of preoperative intravascular deficits should be based on individualized intraoperative fluid administration strategies\(^{75}\) rather than administering fluid based on anecdotal “textbook recipes”.

**Intraoperative period:** intraoperative fluid therapy aims to administer balanced crystalloid solutions to cover the needs derived from the salt–water homoeostasis. This is in contrast to volume therapy where goal-directed boluses of intravenous solutions are administered to treat objective evidence of hypovolaemia, and consequently improve intravascular volume and circulatory flow.

Intraoperative fluid therapy should aim to maintain a near-zero fluid balance\(^{191}\) and substantial weight gain of more than 2.5 kg should be avoided.\(^{192}\) Intraoperative fluid requirements can be met with a basal crystalloid infusion rate of \(3 \pm 2 \text{ ml/kg/h} \) (also called restrictive approach\(^{11}\)).\(^{192–194}\) Crystalloid excess increases the risk of pulmonary complications,\(^{193}\) prolonged ileus\(^{192,195,196}\) and delayed recovery.\(^{197}\)

Crystalloid isotonic balanced solutions should be preferred and 0.9% saline solutions avoided.\(^{198,199}\) Hyperchloraemia caused by the use of 0.9% saline solutions has been associated with kidney dysfunction\(^{200–202}\), prolonged hospital stay and increased 30-day mortality (OR = 1.58, 95% CI 1.25–1.98).\(^{200}\)

Intraoperative volume therapy should be performed by bolus administration of an intravenous solution based on objective measures of hypovolaemia. Goal-directed fluid therapy (GDFT) aims to maintain central normovolaemia by utilizing changes in stroke volume measured by a minimally invasive cardiac output monitor to optimize the patients on their individual Frank–Starling curve.\(^{96,203}\)

Trans-oesophageal Doppler (TOD)-guided GDFT has been shown to reduce the length of hospital stay and postoperative complications in several RCTs of patients undergoing non-cardiac surgery\(^{96,204–206}\) and in a hospital quality improvement project.\(^{207}\) Similarly, GDFT based on pulse contour analysis and aiming to minimize stroke volume variations during the respi-
ratory cycle of mechanically ventilated patients has also shown to decrease morbidity and accelerate recovery. These findings are in agreement with the results of 2 recent meta-analyses. However, the benefits of GDFT seem to be offset by the optimization of perioperative surgical care. In fact, in two recent RCTs, TOD-guided GDFT showed no benefits on postoperative outcomes in low-risk patients treated within an ERAS protocol. These results could be also explained by a judicious fluid management in patients not treated with GDFT, as the amount of intravenous fluid received in patients randomized in these patients was significantly less than the amount received by the same population in previous studies.

The benefits of GDFT become more clinically meaningful in high-risk patients, and in patients undergoing surgery associated with larger intravascular fluid loss (blood loss and protein/fluid shift). In the largest multicentre RCT (734 patients), Pearse et al. found a non-significant trend towards decreased complications (36% vs. 43.4% respectively, P = 0.07) and 180-day mortality (7.7% vs. 11.6% respectively, P = 0.08) in high-risk patients receiving GDFT compared with patients receiving usual care. Auditing internal data (amount of intraoperative fluid given, surgical loss, complications, mortality, length of stay and readmission rate) is essential to determine if GDFT should be implemented as routine strategy to improve postoperative outcomes.

Colloidal solutions have been mainly used to optimize stroke volume during GDFT. Colloids improve circulatory flow to a greater extent than crystalloids and could reduce the incidence of postoperative nausea and vomiting. Colloid boluses do not accelerate the recovery of bowel function, reduce complications or impair haemostasis compared with crystalloids. Recent data have suggested that the use of large volumes of colloids administered post-resuscitation in critically ill patients can increase the risk of death and acute kidney injury (AKI) in critically ill patients, but these results have not been consistently reproduced in the perioperative setting. A recent study has found a dose-dependent association between the volume of HES administered and the development of AKI. The Pharmacovigilance Risk Assessment Committee of the European Medicines Agency has recommended that HES should only be used for the treatment of hypovolaemia caused by acute blood loss when crystalloids alone are not considered sufficient and that it should be used at the lowest effective dose for the shortest period of time. It also states that treatment should be guided by continuous haemodynamic monitoring so that the infusion is stopped as soon as appropriate haemodynamic goals have been achieved. The committee also observed that there is a lack of robust long-term safety data in patients undergoing surgical procedures and in patients with trauma. Moreover, the use of large volumes of colloids (2605 ± 512 ml) hydroxyethyl starch (HES) 130/0.4 during major urological procedures has shown to impair haemostasis and increase surgical blood loss compared with crystalloids. Nevertheless, crystalloid-based GDFT can significantly increase the risk of fluid overload.

Arterial hypotension should be treated with vaspressors when administering intravenous fluid boluses fails to significantly improve the stroke volume (stroke volume > 10%). Inotropes should be considered in patients with reduced contractility (Cardiac Index < 2.5 l/min) to guarantee adequate oxygen delivery.

Postoperative period. Early oral intake of fluids and solids following abdominal surgery should be encouraged. If oral intake is tolerated, routine intravenous fluid administration should be discontinued after PACU discharge and restarted only if clinically indicated. In the absence of surgical losses to cover physiological needs patients should be encouraged to drink 25–35 ml/kg of water per day (1.75–2.75 l for an average person). After ensuring the patient is normovolaemic, hypotensive patients receiving epidural analgesia should be treated with vaspressors.

Summary and Recommendation: The goal of perioperative fluid therapy is to maintain fluid homeostasis avoiding fluid excess and organ dysfunction.
hypoperfusion. Fluid excess leading to perioperative weight gain more than 2.5 kg should be avoided, and a perioperative near-zero fluid balance approach should be preferred. The need of GDFT should be determined based on clinical and surgical factors. GDFT should be adopted especially in high-risk patients and in patients undergoing surgery with large intravascular fluid loss (blood loss and protein/fluid shift). Inotropes should be considered in patients with poor contractility CI < 2.5 l/min. 0.9% saline and saline-based solutions should be avoided, with balanced solutions preferred. Colloids should be used to treat objective evidence of hypovolaemia. In patients receiving epidural analgesia, arterial hypotension should be treated with vasopressors after ensuring the patient is normovolaemic. In the absence of surgical losses, postoperative intravenous fluid should be discontinued and oral intake (1.5 l/day) encouraged.

**Recommendation grade:** GDFT: Strong in high-risk patients and for patients undergoing surgery with large intravascular fluid loss (blood loss and protein/fluid shift)

GDFT: low in low-risk patients and in patients undergoing low-risk surgery

Perioperative near-zero fluid balance: moderate

Use of advanced haemodynamic monitoring; strong in high-risk patients and for patients undergoing surgery with large intravascular fluid loss (blood loss and protein/fluid shift)

**Balanced crystalloids vs. 0.9% saline**

Healthy volunteer studies have suggested that the excretion of an acute saline load is slower when compared with balanced crystalloid infusions, and saline tends to overload the interstitial space to a greater extent, with a tendency to result in more oedema than balanced crystalloids. Mechanisms for excreting this saline excess are inefficient, depending on a slow and sustained suppression of the renin–angiotensin–aldosterone axis. In addition, 0.9% saline produces a hyperchloraemic acidosis, which along with renal oedema, can lead to a reduction in renal blood flow and renal cortical perfusion, even in healthy human volunteers.

There are two relatively small randomized clinical trials in humans comparing 0.9% saline with Ringer’s lactate in the perioperative period, showing that 0.9% saline caused more side effects. One of these studies, involving patients undergoing renal transplantation, had to be stopped prematurely because, compared with none in those receiving Ringer’s lactate, 19% of patients in the saline group had to be treated for hyperkalaemia and 31% for metabolic acidosis. In the other study, involving patients undergoing abdominal aortic aneurysm repair, those receiving saline needed more blood products and bicarbonate therapy. Three recent large observational studies have suggested that 0.9% saline, because of the high chloride content, may cause harm, especially to the kidney. In a study using a validated and quality assured database, evaluation of outcomes in 2,788 adults undergoing major open abdominal surgery who received only 0.9% saline and 926 who received only a balanced crystalloid on the day of surgery and showed that unadjusted in-hospital mortality (5.6% vs. 2.9%) and the percentage of patients developing complications (33.7% vs. 23%) were significantly greater in the 0.9% saline group than in the balanced crystalloid group. Patients receiving 0.9% saline had significantly greater blood transfusion requirements and more infectious complications, and were 4.8 times more likely to require dialysis than those receiving balanced crystalloids. Another recent study provides support for chloride-restrictive fluid strategies in critically ill patients. In an open-label prospective sequential manner, 760 patients consecutively admitted to intensive care (30% of whom were admitted after elective surgery) received either traditional chloride-rich solutions (0.9% sodium chloride, 4% succinylated gelatin solution or 4% albumin solution) or chloride-restricted (Hartmann’s solution, Plasma-Lyte 148 or chloride-poor 20% albumin). After adjusting for confounding variables, the chloride-restricted group had decreased incidence of acute kidney injury [odds ratio 0.52 (95% CI 0.37–0.75), P < 0.001] and the use of renal replacement therapy [odds ratio 0.52 (95% CI 0.33–0.81), P = 0.004]. However, there were no differences in hospital mortality, hospital or ICU length of stay. A third study on 22,851
surgical patients with normal preoperative serum chloride concentration and renal function showed that the incidence of acute postoperative hyperchloraemia (serum chloride $> 110$ mmol/l) was 22%. Patients with hyperchloraemia were at increased risk of 30-day postoperative mortality (3.0% vs. 1.9%; odds ratio 1.58 (95% CI 1.25–1.98) and had a longer median hospital stay [7.0 days (IQR 4.1–12.3) vs. 6.3 days (IQR 4.0–11.3)] than patients with normal postoperative serum chloride concentrations. Patients with postoperative hyperchloraemia were also more likely to have postoperative renal dysfunction.

There is a strong signal suggesting that 0.9% saline is harmful, particularly in the perioperative period when compared with balanced solutions. However, there are currently no large-scale randomized controlled trials that confirm this finding. Nevertheless, it may be preferable to use balanced crystalloids in the perioperative period and restrict the use of saline to patients who have alkalosis or have a hyperchloraemia secondary to conditions such as vomiting or high nasogastric tube aspirates, and in neurosurgical patients because of the relative hyposmolarity of some of the balanced crystalloids.

Summary and Recommendations: 0.9% saline should be avoided and balanced crystalloids used in the preoperative period. The use of 0.9% saline should be restricted in hypochloremic and acidic patients.

Recommendation: strong

Pain management
Multimodal, evidence-based and procedure-specific analgesic regimens should be standard of care, with the aim to achieve optimal analgesia with minimal side effects and to facilitate the achievement of important ERAS milestones such as early mobilization and oral feeding (Table 2).

Thoracic epidural analgesia (TEA)
TEA (T6-T11) remains the gold standard for postoperative pain control in patients undergoing open abdominal surgery. It still remains unclear if epidural analgesia improves postoperative outcomes. Although the results of a large multicentre RCT failed to show a significant benefit of using epidural analgesia in association with general anaesthesia in reducing 30-day mortality and postoperative morbidity in high-risk patients, a recent meta-analysis of 9044 patients undergoing surgery with general anaesthesia and receiving epidural analgesia (4525 patients) found that epidural analgesia is associated with a 40% reduction of mortality. Initiation of neuroaxial blockade before surgery and its maintenance throughout surgery decreases the need for anaesthetic agents, opioids and muscle relaxants. Compared with parenteral opioids, epidural blockade has shown to provide better postoperative static and dynamic analgesia for the first 72 h, to accelerate the recovery of gastrointestinal function, to reduce insulin resistance and impact positively on cardiovascular and respiratory complications. However, hypotension, urinary retention pruritus and motor blockade are common side effects. Although detrusor function can be impaired in patients receiving TEA, a recent RCT has shown that early removal of a urinary catheter (on postoperative day 1) does not increase the risk bladder catheterization and urinary infection. Also TEA does not influence the duration of hospital stay.

The same benefits have not been observed after laparoscopic procedures, especially in a context of an ERAS programme. However, TEA might still be valuable in patients at risk of respiratory complications, in those with high probability of conversion to laparotomy, or requiring transverse or Pfannenstiel-like incisions. Furthermore, TEA may be useful to facilitate the recovery of bowel function even after laparoscopic colorectal surgery.

Clinical management
Epidural blockade should be tested before surgery or in the immediate postoperative period (post-anaesthesia care unit) to avoid non-functioning epidurals and unnecessary opioid administration. The addition of opioids to local anaesthetic has shown to improve postoperative analgesia. Although a paucity of studies have compared the analgesic efficacy of...
Epidural solutions combining local anaesthetic with lipophilic opioids vs. those containing local anaesthetic combined with hydrophilic opioids, epidural solution containing morphine increase the risk of urinary retention.\(^{257,258}\) However, the use of low dose of local anaesthetics (bupivacaine 0.1 mg/ml) and lipophilic opioids (e.g. fentanyl 3 \(\mu g/ml\)) seem to provide optimal analgesia with minimal side effects\(^{257}\). Epidural morphine (0.02 mg/ml) in adjunct to local anaesthetic can be preferred to lipophilic opioids to increase segmental analgesia spread and could be recommended for long midline incisions.\(^{259}\) Epidural infusions can be continued for 48-72, gradually reducing infusion rates and until the recovery of gastrointestinal function. Adding adrenaline (1.5–2.0 \(\mu g/ml\)) to epidural mixture of local anaesthetic and fentanyl improves postoperative analgesia, especially during mobilization and coughing, and reduces pruritus and nausea.\(^{248,256,260–262}\) Evidence on the analgesic efficacy of epidural cloni-

dine is inconclusive and the risk of hypotension and sedation is increased. Hypotension induced by epidural blockade should be treated with vasopressors as first choice provided the patient is not hypovolaemic. Orthostatic hypotension associated with postoperative epidural analgesia does not impair the ability to ambulate. Institutional policies on how to manage epidural side effects, terminate epidural infusions, and how transition to oral multimodal analgesia are recommended.

Intrathecal (IT) analgesia. IT morphine is a valuable analgesic technique to improve early postoperative analgesia and facilitates surgical recovery. However, compared with systemic opioids, the incidence of pruritus (OR 3.85, 95% CI 2.40–6.15) and respiratory depression (although rare) is increased (OR 7.86, 95% CI 1.54–40.3). Postoperative urinary retention is also slightly more frequent (OR 2.35, 95% CI 1.00–5.51). Hypotension in the first 12 h, especially in a context of an enhanced recovery pathway and a restrictive fluid management, has been also associated with the use of intrathecal hydromorphone (with bupivacaine or clonidine).

In the light of these side effects, in the context of an multimodal analgesic regimen other regional anaesthesia technique could be favoured especially in elderly patients. Behind providing excellent analgesia, IT morphine seems an appealing technique to shorten hospital stay in low-risk patients undergoing laparoscopic colorectal surgery with an ERAS protocol.

Clinical management
Reported IT morphine dosage range between 200 and 250 μg in patients aged ≤ 75 years to μg 150 in patients > 75 years of age. Isobaric or hyperbaric bupivacaine (10–12.5 mg) have been used in conjunction with IT morphine.

Intravenous lidocaine (IVL) infusion
In view of its antinociceptive and anti-inflammatory properties, systemic administration of IVL as adjuvant to systemic opioids has been shown to improve postoperative analgesia, reduce opioid consumption and speed surgical recovery. Similar benefits have been observed after laparoscopic abdominal surgeries when compared with systemic opioids, but not when compared with TEA, and especially in the absence of an ERAS programme.

Clinical management
A loading dose of 1.5 mg/kg (IBW) should be initiated 30 min before or at the induction of anaesthesia and continued until the end of surgery or in the recovery room (2 mg/kg/h IBW). The exact duration of the infusion providing optimal analgesia and facilitating also recovery remains unknown. Systemic toxicity is rare, but continuous cardiovascular monitoring is required.

Continuous wound infusion (CWI) of local anaesthetic. CWI of local anaesthetic after open abdominal surgery has been shown to improve postoperative analgesia and reduce opioid consumption, however the effect on the recovery of bowel function is unclear. Two recent RCTs have compared the analgesic efficacy of CWI of local anaesthetic with TEA but the results are contrasting. A recent feasibility study has compared the analgesic efficacy of CWI of local anaesthetic with epidural analgesia after laparoscopic abdominal surgery. Pain intensity was similar among patients receiving epidural and CWI of local anaesthetic. Despite promising results the analgesic efficacy of CWI of local anaesthetic remains inconclusive and several aspects related to this techniques need to be clarified. For example, although preperitoneal multihole catheters have consistently provided satisfactory analgesia, and subfascial catheters have provided better results than suprafascial catheters, the anatomical location associated with optimal recovery remains undetermined. Furthermore, it remains to be established if the analgesic effect observed in different trials is mainly driven by the bolus of local anaesthetic commonly given at the end of surgery or by the infusion of local anaesthetic during the postoperative period.
Clinical management

Preperitoneal continuous infusion of ropivacaine 0.2% (10 ml/h) for 48–72 h has been used in the majority of the studies. Other amide-local anaesthetics have also been used. Systemic opioids are still required to control visceral pain.

Abdominal trunk blocks: transversus abdominis plane (TAP) block and rectus sheath block. Significant reduction of pain intensity and opioid consumption after ultrasound-guided single-shot TAP blocks has been observed but it is limited to the first 24 h after surgery. TAP blocks can also be performed by surgeons from the peritoneal cavity before closing the abdominal wall, or laparoscopic guided. Few studies have reported a reduction of some of the opioids side effects such as nausea and vomiting, but these results have not been reproduced consistently. Continuous infusion or intermittent administration of local anaesthetics through multihole catheters placed in the transversus abdominis plane have been used to improve and prolong opioid-based postoperative analgesia up to 48–72 h after abdominal surgery, but the evidence supporting the analgesic efficacy of TAP-infusion of local anaesthetic remains scarce and inconclusive.

Niraj et al. found that epidural analgesia did not provide better visual analogue scores during coughing than intermittent local anaesthetic boluses through bilateral subcostal TAP catheters in the first 72 h after upper abdominal surgery. However, epidural failure rate were high (22%) and almost half of the TAP catheters had to be replaced in the postoperative period.

Similar benefits have been reported in abdominal laparoscopic procedures and in a context of an ERAS programme. Despite facilitating hospital discharge, bilateral single-shot TAP blocks seem to do not reduce hospital stay after laparoscopic colorectal surgery. A recent RCT has shown that the analgesic efficacy of four-quadrant TAP blocks in adjunct to bilateral posterior continuous TAP blocks, was not inferior to TEA after laparoscopic colorectal surgery.

Clinical management

Optimal timing, choice of local anaesthetic, dosing and volumes remain unknown. However, it seems that a minimal volume of 15 ml is required to achieve satisfactory analgesia with single-shot TAP block. Ropivacaine 0.2% (8–10 ml/h) can be infused for 48–72 h trough a multihole catheter. A bilateral infusion (8–10 ml/h each side) is required with a midline incision. Systemic opioids are needed to control visceral pain.

More studies that further validate the analgesic efficacy of TAP blocks are warranted.

Intraperitoneal local anaesthetic (IPLA). The results of a meta-analysis including eight RCTs have shown that IPLA after open abdominal surgery reduce postoperative pain scores but not opioid consumption. However, in the latest randomized control trial conducted in a context of an enhanced recovery programme, IPLA improved surgical recovery, reduced postoperative pain and opioid consumption in patients undergoing open colectomy and receiving thoracic epidural analgesia. IPLA has been shown to improve postoperative analgesia, reduce shoulder pain and opioid consumption after laparoscopic gastric surgery.

Multimodal analgesia (MMA). A MMA regimen based on routine use of NSAIDs, COX-2 and acetaminophen (paracetamol) (PO or intravenously when available) should adopted if not contraindicated in patients undergoing open and laparoscopic abdominal procedures with the aim to reduce opioid consumption and their dose-dependent side effects that impair recovery. NSAIDs and COX-2 inhibitors have been shown to improve postoperative analgesia, reduce opioid consumption and some of their side effects by 30%. There have been recent concerns about the risk of anastomotic leakage and the use of NSAIDs or COX-2 inhibitors after colorectal surgeries based on experimental, retrospective and case-series studies. Large RCTs are needed to confirm these results. The risk of anastomotic leakage after bowel surgery
was not significantly increased in a recent meta-analysis of six RCTs (480 patients) of patients receiving at least one dose of NSAIDs or COX-2 inhibitors within 48 h of surgery (Peto OR 2.16 [95% CI 0.85–5.53, \(P = 0.11\)]\(^{303}\). This effect seems to be molecule-specific (diclofenac is associated with the highest risk)\(^{302}\) and class-specific (risk of anastomotic leakage with NSAIDs, OR 2.13 [95% CI 1.24–3.65], \(P = 0.006\), risk of anastomotic leakage with selective COX-2 inhibitors OR 1.16 [95% CI 0.49–2.75] \(P = 0.741\)]\(^{304}\). Furthermore, the risk varies with duration of the treatment, and it is higher after 3 days or more of NSAIDs than after 1 or 2 days only\(^{304}\). Acetaminophen (paracetamol) has shown to improve postoperative analgesia, have an opioid-sparing effect, but not reduce opioids side effects.\(^{305}\) However, a recent meta-analysis has demonstrated that intravenous paracetamol reduces the risk of postoperative nausea and vomiting, but this effect seems more related to an improvement in postoperative pain rather than to a reduction in opioid consumption.\(^{306}\) Concerns have been raised about the cardiovascular risk and delayed bone healing associated with the use of NSAIDs and COX-2 inhibitors\(^{307}\). Overall, the evidence is inconclusive\(^{307}\) and does not support the avoidance of short perioperative NSAIDs and COX-2 inhibitors treatment in patients with low cardiovascular risk.\(^{307,308}\) High-dose of systemic steroids have also shown promising results\(^{309,310}\), also in patients not undergoing gastrointestinal surgery.\(^{311,312}\) Perioperative intravenous ketamine and gabapentinoids have also shown opioid-sparing properties.\(^{313,314}\) However, the risk of side effects such as dizziness and sedation should be considered. An opioid-free multimodal analgesic strategy based mainly on analgesic adjuvants would be appealing but more studies are warranted to establish the feasibility, efficacy and safety of such analgesic approaches.\(^{315}\) Wound infiltration with long-acting multivesicular liposome formulation of bupivacaine as part of multimodal analgesic regimens has also shown promising results.\(^{316,317}\) It must be acknowledged that most of the following recommendations come from studies not using enhanced recovery after surgery (ERAS) programmes. It might be possible that the well-proven benefits of ERAS programmes might offset the reported advantages of different analgesic techniques.\(^{242}\) The synergistic effect of combining different analgesic medications remains unknown and the impact of MMA on long-term outcomes still remains to be determined\(^{318}\).

**Summary and Recommendation:** Analgesic techniques should aim to not only provide optimal pain control but also to facilitate the achievement of important milestones such as tolerance of oral intake, and early mobilization. Opioid side effects are dose-dependent and delay recovery. Opioid-sparing analgesic strategies, including regional analgesia techniques, should be implemented in a context of a multimodal analgesic regimen. Postoperative pain management should be procedure-specific.

**Recommendation grade:** MMA: strong

**Open abdominal surgery.** TEA: strong for using it

IVLI: moderate for using it

CWI: weak for using it

TAP blocks: moderate for using it

**Laparoscopic abdominal surgery.** TEA: weak for using it

IVLI: moderate for using it

Intrathecal morphine: moderate for using it

TAP blocks: moderate for using it

**Postoperative delirium**

Postoperative delirium is increasingly recognized in surgical practice, particularly in the elderly population who have pre-existing cognitive dysfunction. While delirium can be a symptom of a surgical or medical complication it is important to be recognized instantly.

The prevalence is underestimated and underdiagnosed if no systematic monitoring is applied.\(^{319}\) It is defined as a condition of altered consciousness, orientation, memory, thought, perception, behaviour and possibly sleep pattern which develops acutely and shows a fluctuating clinical course.\(^{320}\) Delirium can be classified into three subtypes: the hyperactive delirium, the hypoactive delirium and a
Delirium as a symptom of acute cerebral dysfunction should not solely be perceived as a strictly binary phenomenon which is either present or absent. Detection of delirium also at pre-delirium or sub-syndromal levels could prevent further deterioration of cerebral function.

Undetected and untreated or delayed treatment of delirium does increase the rate of complications, the length of hospital stay as well as mortality and is associated with long-term cognitive dysfunction.

Early detection in the postoperative setting is a prerequisite for finding and treating the underlying causes. Numerous validated Delirium Instruments have been validated for clinical use.

Delirium promoting factors such as prolonged preoperative fluid fasting times, deep anaesthesia time as well as disturbing the sleep–wake cycle and the use of sedatives and other delirogenic medications should be avoided.

If postoperative delirium is detected, the early symptomatic therapy based on pharmacological and non-pharmacological measures, is associated with a decreased mortality. Psychotic symptoms should be treated with neuroleptics. A systematic review that a low-dose haloperidol therapy compared with a therapy with atypical neuroleptics has a similar effectiveness and side effect rate.

If there is the necessity to apply substances with sedative properties, non-benzodiazepines should be preferred (e.g. alpha-2-agonists) due to international guidelines for sedation. Benzodiazepines are known to be an independent risk factor for delirium and should therefore be avoided if possible.

Summary and recommendation: Preventive measure as avoidance of prolonged fasting, deep anaesthesia, disturbance of sleep–wake cycle or delirogenic medications like benzodiazepines, atropine should be implemented. Systematic delirium screening and symptom-oriented treatment should be performed and potential underlying medical causes should be ruled out.

Recommendation grade: strong.

Attenuation and treatment of postoperative ileus

Postoperative ileus (POI) is defined as a transient reduction of bowel motility that prevents effective transit of bowel content and tolerance of oral intake following surgical interventions. POI has been associated with prolonged hospital stay and higher risk of complications. POI can be classified in primary POI that occurs in the absence of surgical complications, and in secondary POI in the presence of surgical complications such as anastomotic leakage, abscess, peritonitis, etc. Primary POI is considered an inevitable consequence after abdominal surgery. However, its clinical presentation and duration can significantly vary among patients depending on the severity of the gastrointestinal dysfunction. Some patients can be totally asymptomatic and tolerate oral intake in the immediate postoperative period, while others experience gastrointestinal symptoms, cannot tolerate any oral intake for several days and might require insertion of a nasogastric tube (NGT).

The definitions of primary POI remains elusive and many clinical trials still utilize personal definitions in view of the difficulty on how to clinically identify patients with a clinically relevant impairment of gastrointestinal function. In a recent study measuring the gastrointestinal transit after colorectal surgery, Van Bree et al. showed that the combination of tolerance of solid food and passage of stool best correlates with the recovery of gastrointestinal function (area under the curve 0.9, SE 0.04, 95% CI 0.79–0.95, P < 0.001), with a positive predictive value of 93% (95% CI 78–99). Others clinical indicators commonly used to assess POI, such as the time to first flatus, poorly correlate with the recovery of the gastrointestinal function. A list of clinical indicators commonly used in clinical practice to evaluate the recovery of the gastrointestinal function is reported in Fig. 1. Non-ileus-related nausea and intra-abdominal surgical complications leading to secondary POI should be excluded.

Due to its multifactorial pathogenesis several perioperative preventive strategies can be implemented to reduce the severity and duration of primary POI. Based on the results of a large
A retrospective study, it should be also considered that some patients might have a higher risk to develop prolonged primary POI (Table 3). These results need to be confirmed when adopting multiple interventions to attenuate postoperative gastrointestinal dysfunctions as in a context of an ERAS programme. Nasogastric decompression should be considered to prevent complications such as pulmonary aspiration and arrhythmias.

**Summary and recommendation:** Primary POI is an inevitable consequence after gastrointestinal surgery and its pathogenesis is multifactorial. Multimodal preventing strategies should be adopted to facilitate the recovery of gastrointestinal function.

**Recommendation grade:** moderate

### Early mobilization

Although the tradition of prolonged postoperative bed rest was abandoned over 75 years ago and the dangers of staying in bed acknowledged, modern surgical patients actually spend very little time out of bed. Early “enforced” or “structured” mobilization is a key component of virtually all ERAS programmes. Patients cared for with the ERAS paradigms mobilize more and achieve independent mobilization earlier than those cared for without ERAS. Mobilization helps preserve

muscle function and prevent complications associated with bed rest, but also aligns with the message of empowerment of patients to play an active role in their own recovery after surgery; this term is used instead of “convalescence”, which implies a passive process.

Protocols differ between pathways and there is no standard definition of early mobilization which may include exercising in bed, sitting out of bed, standing, walking in the room, walking in the hallway or exercising. Different successful pathways set different mobilization goals using different benchmarks such as time (hours out of bed, hours sitting or walking) or distance (e.g. number of times to walk a hallway or ward). These begin early, on the day of surgery, and increase each day to reach predetermined targets. There are no data to support the use of one plan over another or suggestion of a “dose–response” curve related to outcomes.

Unfortunately, there is little evidence available to guide how to best achieve early mobilization and even within established ERAS programmes adherence to mobilization targets may be quite low, suggesting a need for specific studies in this area. A review of the impact of early mobilization for medical and surgical patients found that the use of a more standardized and structured approach beginning as early as possible had the most favourable results. This begins in the preoperative setting with clear and explicit instructions detailing daily mobilization goals. These instructions are reinforced with written material which improves recall and which is brought by the patient to the hospital. Posters on the ward may help reinforce daily goals. Patients who begin an exercise programme in the preoperative period may also be more likely to be physically active postoperatively. Compliance may be improved by the use of a patient diary or when a pedometer is worn, which has been shown in other contexts to be associated with increased physical activity. Creation of separate ERAS “rehabilitation” wards or having a separate ward dining room may help but are not feasible in all settings. The absence of an in-room entertainment system may promote increased walking. Having an audit tool available recording compliance with mobilization is important to identify and address barriers.

Achieving early mobilization on the ward requires integration between the patient and the various health care providers working in a multidisciplinary fashion form the beginning. Pain and drains inhibit ambulation. Ideally a dedicated pain service is involved in the ERAS team to optimize pain control and reduce side effects. Epidural analgesia provides excellent analgesia after open abdominal or thoracic surgery but it is associated with postoperative hypotension and with lower limb weakness if the epidural block is extended to the lumbar nerve roots. Epidural systems that reduce interference with ambulation should be used if possible. There is a tendency to bed rest patients experiencing orthostatic intolerance or hypotension, and to consider the epidural responsible for this effect. However, in patients with thoracic epidural analgesia hypotension is a relatively common side effect on postoperative day 1 but is often asymptomatic and does not predict the ability to walk. Furthermore, epidural analgesia is not associated with higher risk of orthostatic intolerance or hypotension than systemic opioids. Orthostatic intolerance seems to be more related to an impairment of the autonomic system and to an alteration of the baroreceptor reflex rather than to other factors such as hypovolaemia, anaemia and pain. The underlying mechanisms are not yet fully understood.

Most pathways rely on nurses to assist with “enforcing” mobilization with physiotherapists involved in some programmes, suggesting an increased need for resources. Nurses should be involved in the creation of the mobilization plan from the beginning in order for the team to understand potential barriers to ambulation. Although there may be concern from nurses that ERAS will increase their daily workload related to these physical tasks, this has not been shown to be the case, perhaps because of increased patient independence.

Summary and recommendation: Achievement of mobilization goals requires a multidisciplinary approach. Patients should be given written information setting daily targets for ambulation in hospital. Patients should be encouraged to increase their physical activity in the preoperative period. Patients should use a diary or pedometer to record their daily physical activity.

Comment

The practice of surgery and anaesthesia is continuously evolving and there is a need to offer the knowledge base for continuous training of those involved in the treatment of surgical patients. The ERAS Society (www.erassociety.org) was initiated by the former ERAS Study Group and was formed in 2010 to support these processes. The multidisciplinary Society participates in the improvement of perioperative care by developing new knowledge through research, education and also by being involved in the implementation of best practice.

The current manuscript presents a consensus review from the ERAS Society, discuss clinical considerations, and provide recommendations, for optimal anaesthesia care within the ERAS programme for patients undergoing gastrointestinal surgery. The quality of evidence supporting each ERAS element has been already evaluated according to the GRADE system and previously published15–19. The evidence-based recommendations present the ERAS protocol interventions separately and overall, and are intended to be used by units undertaking to implement and upgrade to what the current literature shows to be best practice: the ERAS protocol. It must be acknowledged that, not being a systematic review, all articles quoted in the manuscript have been selected by the expert in each area, resulting in potential bias. Clinical considerations and recommendations for each of the ERAS elements are listed in Table 4.
