I. INTRODUCTION AND MOTIVATION

Vector meson electro- and photoproduction have played an important role in our understanding of photon-hadron interactions in QCD. Sakurai [1] first proposed that during interactions with hadrons, the photon (either real or virtual) behaves like an on-shell vector meson \( V = \{\rho, \omega, \phi\} \). This is possible because the photon and the vector mesons share the same set of quantum numbers (see Ref. [2] for a review on the hadronic properties of the photon). Following Feynman [3], if the real or virtual photon momentum is \( q \), we can write the photon-hadron interaction amplitude in terms of a current \( J_\mu(q^2) \) as \( \langle \text{hadrons} | J_\mu(q^2) | 0 \rangle \), and one sees “resonances” at the values \( q^2 = m_V^2 \).

In the so-called vector meson dominance (VMD) model for photoproduction, a real photon can fluctuate into a virtual vector meson, which subsequently scatters off the target proton. Therefore, the amplitude \( A_{\gamma p \rightarrow V' p'} \) is related to \( A_{\gamma p \rightarrow V' p'} \) as

\[
A_{\gamma p \rightarrow V' p'} = \sum_{V_T} \epsilon_{V' V} A_{\gamma p \rightarrow V' p'},
\]

where \( V_T \) indicates that the summation is only over the transverse polarization states of the vector meson (a real photon has no longitudinal polarization), \( \gamma_V \) is the \( V-\gamma \) coupling constant and \( \epsilon \) is the electric charge. Traditionally, the \( \phi \) vector meson has played a special role in our understanding of this VMD picture. Since the SU(6)-based quark model assigns an almost pure \( |s\bar{s}\rangle \) configuration to the \( \phi \), assuming the strangeness component of the proton to be small, the OZI rule [4] suppresses direct exchanges of quarks between the \( \phi \) and the proton. Therefore, \( \phi \) photoproduction is predicted to proceed by the exchange of color singlet gluonic objects. From quite early on, several authors [5] gave very general arguments that \( \phi p \) scattering should proceed by the exchange of the universal Pomeron (\( IP \)) trajectory which has the same quantum numbers as the vacuum and the maximal Regge intercept of \( \alpha_0 \approx 1 \) (the Froissart bound [6]). In terms of Regge theory, for \( pp \) or \( \pi N \) scattering at low energies, \( t \)-channel \( \rho \) and \( \omega \) exchanges can occur and the forward-angle differential cross sections exhibit “shrinkage”. However, at very high energies, both the total and the differential cross section show only a slow (logarithmic) variation with the total energy and almost no shrinkage. This is also known as “diffractive” scattering at \( s \rightarrow \infty \) and \( t \rightarrow 0 \), where \( s \) and \( t \) are the squares of the total center-of-mass (c.m.) energy and the exchanged momentum, respectively. The shape of the differential cross section \( (d\sigma/dt) \) plotted against \( t \) resembles the intensity distribution in ordinary diffraction of light around a small object. For diffractive scattering with Pomeron...
exchange, the total cross section stays almost constant with energy and the width of the forward peak decreases only logarithmically with energy. That is, there is only a very slow shrinkage.

In the case of $\phi p$ scattering, since meson exchanges are suppressed, diffractive Pomeron exchange dominates even at low energies. The early (1972) SLAC beam-asymmetry measurements for $\phi p$ photoproduction by Halpern et al. [7] confirmed the dominance of natural-parity (Pomeron) exchange over unnatural-parity ($\pi$) exchange. It is this decoupling from the light quark ($u$ and $d$) sector that makes the $\phi$ a very "clean" system to study gluonic interactions, the gluonic structure of the Pomeron, for example. There is also speculation that at near threshold and forward angles, the $\phi$ channel will give access to the $0^{++}$ glueball $f_0(1710)$ [8,9].

Experimentally, most of the world data exist in the high energy diffractive region. These include results from DESY [10–12], Cornell [13,14], SLAC [15–17], Fermilab [18,19], Daresbury [20,21], and HERA [22,23]. Due to the inherently small $\phi$ cross sections, these data are generally sparse with wide energy bin-widths and limited statistical precision. Also, since $d\sigma/dt$ drops exponentially with increasing $|t|$ and variations with the total c.m. energy ($\sqrt{s}$) are logarithmic, the "natural" scale for comparison purposes at these high energies seems to be logarithmic and not linear.

The earliest low energy near-threshold measurement (the ABHBM results [10] had some low energy data as well) was at Bonn [24], with more recent results coming from SAPHIR [25] and LEPS [26]. Although both the Bonn and SAPHIR results covered the $E_\gamma = 2.0$ GeV (or $\sqrt{s} \approx 2.15$ GeV) energy region, it was the LEPS 2005 paper that first took note of a localized "bump" around $E_\gamma = 2.0$ GeV, when a simple Pomeron exchange model predicts a smooth rise from threshold. To explain this nonmonotonic behavior, theoretical groups have put forward two different explanations. First, the works by Ozaki et al. [27] and Ryu et al. [28] relate this to a coupling between the $\phi$ and $K^+\Lambda(1520)$ channels. In the kinematic regime 2 GeV $\lesssim \sqrt{s} \lesssim 2.2$ GeV, the $\phi \to K^+K^-p$ charged mode and the $K^+\Lambda(1520) \to K^+pK^-$ decay mode have the same final states. Therefore, rescattering effects can occur between the two channels. Our neutral-mode ($\phi \to K_S^0\bar{K}_S^0$) results can play a critical role in this situation, since the $\phi$ neutral mode does not share the same final states with $K^+\Lambda(1520)$. Second, Kiswandhi et al. [29,30] have attempted to explain this as a $J = \frac{3}{2}$ resonance of mass around $\sqrt{s} \sim 2080$ MeV. Ultimately, the resolution could come from a combination of both approaches and would require a coupled-channel analysis of the $\phi$, $\Lambda(1520)$ and $\omega$ channels.

The first CLAS measurements at $E_\gamma = 3.6$ GeV [31,32] also noted an interesting feature, a slight rise in the cross section at the backward angles from nucleon exchanges via the $u$ channel. As mentioned earlier, the strangeness content of ordinary nucleons is usually assumed to be very small. However, the $u$-channel nucleon exchanges points directly towards an appreciable strangeness content (possibly sea quarks) of the nucleon, or a violation of the OZI rule. We also note that a related CLAS analysis [33] has presented differential cross sections for the purely neutral mode of $\phi$ photoproduction that are consistent with the more extensive results presented here.

In this work, we report on a precision study of $\phi$ photoproduction using a high statistics data set. The $\phi$ mass ($\approx 1.0195$ GeV) is close to the the $K\bar{K}$ production threshold. Therefore, the natural line-shape deviates from a relativistic-Breit-Wigner (rBW). We approximate the lineshape as a mass-dependent rBW with a $P$-wave barrier factor. Further, the $\phi$ natural width ($\Gamma_0 \approx 4.26$ MeV) is comparable to the CLAS resolution (1–2 MeV, see Fig. 7). In general, the resolution can be a complicated mass-dependent function by itself (see Ref. [34] for example). We approximate the resolution function as a single Gaussian and convolve it with the natural rBW lineshape to give the measured signal lineshape. We incorporate three different $K\bar{K}$ topologies that have different resolutions, and calibrate them against each other, to reduce systematic uncertainties on the $\phi$ lineshape. We also dwell on the issues pertaining to $K^+\Lambda^+$ backgrounds.

For the spin-density matrix elements (SDME), it has long been observed that diffractive vector meson photoproduction sharply follows $s$-channel helicity conservation (SCHC), while $t$-channel helicity conservation (TCHC) is broken. Helicity nonconservation in any frame refers to the deviation of the $\rho_0$ SDME from zero in that frame (see Sec. XII C). SCHC indicates that in one particular reference frame (the helicity frame), the outgoing vector meson has the same helicity as the incident photon. Gilman et al. [35] observed that even though in the Regge picture, the Pomeron acts like a spin-1 trajectory in the diffractive limit ($t \to 0$), its coupling is not well known. Naively, one ascribes the quantum numbers of the vacuum, $J^{PC} = 0^{++}$, to the Pomeron. This means that the coupling for the Pomeron in the $t$-channel is the same as the exchange of a spin-0 (scalar) particle. If so, one expects TCHC (no helicity flip in the $t$ channel), while experiments show violation of TCHC, and instead, support for SCHC. Phenomenologically, Gilman et al. showed that (in a sufficiently high energy limit) the spin-flip and nonflip components of the Pomeron in the $t$-channel exchange have to be related in a special manner to conserve helicity in the $s$ channel. However, there is no fundamental principle that predicts SCHC. With a fine binning in both $\sqrt{s}$ and $\cos \theta_{\phi,m}$, where $\theta_{\phi,m}$ is the meson production angle in the c.m. frame, our new precision results show that TCHC and SCHC are both violated.

With an unpolarized beam, one has access to only the $\rho^0$ elements, while $\rho^1$ and $\rho^2$ require a linear polarized beam, and $\rho^3$, a circularly polarized beam. Recently, the LEPS Collaboration [36] has published near-threshold measurements for the $\rho^1$ and $\rho^2$ SDME’s. From their $\rho^1_{-1}$ measurements in the Gottfried-Jackson frame, they have estimated a nonzero contribution from unnatural-parity ($\pi$, $\eta$) exchanges in the $t$ channel, at these low energies. With the beam and target both polarized, the FROST experiment [37] at Jefferson Lab will give access to several of the double polarization observables [38] as well.

II. EXPERIMENTAL SETUP

The data that we use in this analysis were obtained using real photons produced via bremsstrahlung from a 4.023-GeV electron beam produced by the Continuous Electron Beam Accelerator Facility (CEBAF) at Jefferson Lab. The photons
were energy-tagged by measuring the momenta of the recoiling electrons with a dipole magnet and scintillator hodoscope system [39]. A separate set of scintillators was used to make accurate timing measurements. The photon energy resolution was about 0.1% of the incident beam energy and the timing resolution was 120 ps. These tagged photons were then directed toward a 40-cm-long cylindrical liquid-hydrogen cryotarget inside the CEBAF Large Angle Spectrometer (CLAS) detector system. Immediately surrounding the target cell was a “start counter” scintillator, used in the event trigger.

Both the start counter and the CLAS detector were segmented into sectors with a sixfold azimuthal symmetry about the beam line. A nonuniform toroidal magnetic field with a peak strength of 1.8 T was used to bend the trajectories of charged particles and a series of drift chambers was used for charged particle tracking. In this manner, CLAS could detect charged particles and reconstruct their momenta over a large fraction of the 4π solid angle. The overall momentum resolution of the detector was ∼0.5%. A system of 342 scintillators placed outside the magnetic field and drift chamber regions provided timing information by measuring the time of flight (TOF) for each charged particle trajectory. A fast triggering and fast data-acquisition system (capable of running at ∼5k events/s) allowed for operating at a photon flux of a few times 10^7 photons/s. Further details of CLAS can be found in Ref. [40].

### III. DATA

The specific data set that we analyze in this work was collected in the summer of 2004, during the CLAS “g11a” run period. Roughly 20 billion triggers were recorded during this time, out of which only a small fraction corresponded to pφ events. Each event trigger required a coincidence between the photon tagger master OR (MOR) and the CLAS Level 1 trigger. The MOR consisted of a logical OR of the signals from the 40 tagger counters corresponding to the high-energy part of the tagged photon beam. The Level 1 trigger required that two tracks be present in the CLAS detector. A single track was defined on a sector-wise basis and required a coincidence between the start counter and the TOF counters within the given sector. The two-track trigger required that at least two sectors in CLAS satisfied the single-track trigger within a 150 ns window of each other. In addition to the MOR and Level 1 trigger, we required the tagger MOR and an OR of all the start counter hits occurs within 15 ns of each other. This constraint was used to reduce out-of-time contamination. The beam structure contained one or a few photons within bunches separated by 2.0 ns.

During offline processing, before any physics analysis began, the CLAS detector sub-systems had to be calibrated. This included determining the relative offsets between the photon tagger, start counter, and TOF counter times, as well as calibration of the drift times in the drift chambers and the pulse heights of the TOF scintillators. Energy and momentum corrections were made for individual particles to account for their energy and momentum losses during passage through several layers of the detector subsystems. Corrections were also made to the incident photon energy (E_γ) to account for mechanical sagging in the tagger hodoscope. A discussion of the collection and calibration of this data set can be found in Ref. [41]. Several meson photoproduction channels (opp [42,43], ηp [44], K^+Λ [45], K^+Σ^0 [46], K^+Y^* [47,48]) have already been analyzed using this data set. In the vector meson sector, the present work extends our recently published ω results [42] to the φ channel.

### IV. REACTION TOPOLOGIES AND EVENT SELECTION

In the reaction γp → φp, the φ subsequently decays most of the time into two kaons: K^+K^- (charged mode) and K^0_LK^0_S (neutral mode). For the neutral mode, the daughter K^0_L further decays into π^+π^- (60.2%) and π^0π^0 (39.7%). Since CLAS is optimized for detecting charged particles, we only employed K^0_L → π^+π^- decay in this analysis.

The “charged-two-track” topology was then defined as γp → K^+(K^-)p, where only the proton and the K^- were detected and the undetected K^- was reconstructed as the missing four-momentum using a 1-C kinematic fit to a total missing mass of m_K^- = 0.493 GeV. The polarity setting of the drift chamber magnets inside CLAS bent negatively charged particles like K^- inwards towards the beam line, where the detector acceptance was the lowest. Therefore, not detecting the K^- led to a substantial increase in the overall statistics, allowing for a fine energy binning (10-MeV-wide √s bins) and wide kinematic coverage for this topology. The main bulk of our results derives from this mode.

The “charged-three-track” topology was a subset of the charged-two-track data sample where all three final-state charged tracks were required to be detected. A 4-C fit to zero missing four-momentum and subsequent confidence level (CL) cut was used to remove background. Due to the 4-C fit, this topology had a very high purity of K^+K^- final states and the highest resolution in the reconstructed φ lineshape, but with very low acceptance. It is mainly used for understanding some of the systematics and our final set of results do not include this topology.

As mentioned in the Introduction, it is also important to examine the neutral decay mode of the φ, since this is relatively immune (see discussion in Sec. XII B) to effects from the K^+Λ^* final states. We defined the “neutral-mode” topology as γp → π^+π^-p(K^0_L), where only the π^+, the π^-, and proton were detected, and the undetected K^0_L was reconstructed as the missing four-momentum using a 2-C kinematic fit to m_K^0 = 0.497 GeV total missing mass and M(π^+π^-) = m_K^0. Since this topology required detection of a negatively charged π^-, the acceptance was substantially lower compared to the charged-two-track mode, especially at high energies and backward-angles. To bolster statistics, therefore, we employed wider 30-MeV-wide √s bins for this case.

Each event trigger recorded by CLAS consisted of one or more tagged photons. To begin the event selection process, at least two positively charged particle tracks were required to have been detected. These were hypothesized as a proton and a K^+ for the charged modes, and as a proton and a π^+ for the neutral mode. The charged-two-track (neutral-) mode topology required an extra negatively charged particle track.
that was assumed to be a $K^− (π^−)$. To minimize bias, all possible photon-particle combinations allowed by the given topology were taken to be a candidate signal event. Events with incorrectly assigned photons or particle hypotheses were removed by subsequent cuts. In the following subsections, we describe each of these event selection cuts, referring the interested reader to Ref. [41] for further details. Since the two topologies followed significantly different analysis chains, to avoid confusion, we list the various cuts as applicable to each of the charged- and neutral-mode topologies in Table I.

### A. Confidence level cut

Each event candidate in the charged-two-track data set was kinematically fit [41] to an overall $m_{K^0}$ missing mass hypothesis for the undetected $K^−$. For every event recorded by CLAS, both $\text{“} K^+: p \text{”}$ and $\text{“} p : K^+ \text{”}$ combinations were treated as independent event hypotheses, where the two-particle assignment (separated by the colon) corresponds to the two detected positively charged particles. Similarly, for the neutral mode, every event was kinematically fitted to an overall $m_{K^0}$ missing mass hypothesis for the undetected $K^0_L$. Both $\text{“} π^+: p : π^− \text{”}$ and $\text{“} p : π^+ : π^− \text{”}$ combinations, corresponding to different particle assignments to the two positively charged tracks, were taken as independent event hypotheses. For the charged-three-track mode, both $\text{“} K^+: p : K^- \text{”}$ and $\text{“} p : K^+: K^- \text{”}$ combinations were allowed as event candidates. Incorrect particle hypothesis assignments were removed by subsequent timing cuts. The kinematic fitter adjusted the momentum of each individual detected particle, while constraining the total missing mass to be either $m_{K^0}$ (charged-two-track mode) or $m_{K^0}$ (neutral mode), and the total missing four-momentum to be zero for the charged-three-track mode. The shifts in the momenta, combined with the known detector resolution within the current experiment, gave a CL for the event to be the desired reaction. For the charged-two-track and neutral-mode topologies, only events with a CL greater than 5% were retained for further analysis. For the charged-three-track mode, we required the CL to be greater than 1%.

Figure 1 demonstrates the effect of kinematic fitting for the neutral-mode topology. After kinematic fitting, both $K^0$'s were mass constrained, so that the threshold value of $M(K\bar{K})$ min = $2m_{K^0}$ was enforced. The reconstructed $\phi$ mass lineshapes were markedly different before (blue dashed histogram) and after (red histogram) kinematic fitting. In topologies with the initial four-momenta known and a single missing particle in the final states, kinematic fitting amounts to measurement of the missing particle’s four-momentum. In particular, the present analysis is very sensitive to the reconstructed $\phi$ mass resolution relative to the $\phi$ natural linewidth $Γ_0 ≈ 4.26$ MeV (see also Sec. VI A for a discussion). Therefore kinematic fitting plays a critical role here.

### B. Timing cuts

Track reconstruction through the different CLAS detector segments yielded both the momentum $\vec{p}$ and the path length $l$ from the reaction vertex to the TOF scintillator wall. The expected time of flight for a track hypothesized to be a particle of mass $m$ was then given by

$$t_{\text{exp}} = \frac{l}{c} \sqrt{1 + \left(\frac{m}{|\vec{p}|}\right)^2}.$$  \hspace{1cm} (2)

CLAS also measured the time-of-flight $t_{\text{meas}}$ as the difference between the tagged photon’s projected arrival time at the reaction vertex for the given event and the time the given particle track hits the TOF scintillator wall. The difference between these two time-of-flight calculations gave $Δt_{\text{of}} = t_{\text{meas}} − t_{\text{exp}}$. For each track there was also a calculated mass $m_c$, given by

$$m_c = \sqrt{\left|\vec{p}\right|^2(1 − β^2)} \frac{1}{β^2c^2},$$  \hspace{1cm} (3)

where $β = 1/(ct_{\text{meas}})$.

Timing information in the form of $Δt_{\text{of}}$ or $m_c$ was used to place particle identification cuts on the proton and $K^+$ tracks for the charged mode, and the proton and $π^+$ tracks for the neutral mode. As mentioned earlier, for each pair of positively charged particle tracks, all possible combinations of particle assignments were considered and treated as independent event hypotheses. Figures 2(a) and 2(c) show our $Δt_{\text{of}}$ cuts placed on

FIG. 1. (Color online) The dotted blue and the continuous red histograms represent the reconstructed $\phi$ mass prior to and after kinematic fitting, respectively, for the neutral mode. The resolution is markedly improved due to the kinematic fit.

DATA ANALYSIS TECHNIQUES, DIFFERENTIAL CROSS . . . PHYSICAL REVIEW C 89, 055208 (2014)
proton-$K^+$ (charged-two-track mode) and proton-$\pi^+$ (neutral mode) tracks, respectively, where events outside the “iron-cross” shaped quadruplet of black curves were rejected. The clusters along the diagonal in the $\Delta$tof plots, more prominent in Fig. 2(c), were due to accidental coincidences with events in different beam bursts corresponding to the 2 ns radiofrequency pulses used by the CEBAF electron accelerator.

For the charged mode, even after the application of the $\Delta$tof iron-cross cut, a remnant pion leakage was still visible, as seen in the left hand side “blob” in Fig. 2(b). To further remove this pion background, we placed an additional cut on the calculated mass of the proton and $K^+$ tracks by rejecting events that lie on the left of the curve in Fig. 2(b).

C. Overlap with $K^+\Lambda^*$

Consider the process $\gamma p \rightarrow M(\sqrt{s}) \rightarrow K^+K^-p$ from the perspective of a three-body decay, where $M(\sqrt{s})$ denotes a general $s$-channel state with total invariant mass $\sqrt{s}$. If $M(K^+K^-)$ is fixed at $m_\phi = 1.02$ GeV, $M(pK^-)$ is bound between a minimum ($M_{pK,\text{min}}$) and a maximum ($M_{pK,\text{max}}$). The specific values of $M_{pK,\text{min}}$ and $M_{pK,\text{max}}$ depend on $\sqrt{s}$, and the masses of the $\phi$, the proton and the kaon. Figure 3 shows the variation of $M_{pK,\text{min}}$ and $M_{pK,\text{max}}$ with $\sqrt{s}$.

In the region $2 \text{ GeV} \leq \sqrt{s} \leq 2.2$ GeV, $M(pK^-) = 1.52$ GeV lies within these bounds. This implies that in this energy regime, the kinematics for production of $\phi p$ and $K^+\Lambda(1520)$ overlap in phase-space. Figures 4(a) and 4(b) show plots of $M(pK^-)$ vs. $M(K^+K^-)$ at two different energies for the charged-two-track mode. The $\phi$ and $\Lambda(1520)$ “bands” are clearly visible in both figures. Above $\sqrt{s} \approx 2.2$ GeV there is no overlap between the $\phi$ and the $\Lambda(1520)$. To reduce the $\Lambda(1520)$ contamination in the charged modes, we keep the additional option of placing a hard cut around the $\Lambda(1520)$ mass as

$$|M(pK^-) - 1.52| \geq 0.015 \text{ GeV}. \quad (4)$$

Similarly, there are several broad $\Lambda^*$ states around 1800 MeV that overlap with the $\phi$ in the region $2.3 \text{ GeV} \leq \sqrt{s} \leq 2.8$ GeV. Figures 5(a) and 5(b) show the $M(pK^-)$ vs $M(K^+K^-)$ distributions in this $\sqrt{s}$ region for the charged two- and three-track topologies, respectively. Given that these higher $\Lambda^*$ states have large widths, it is difficult to place hard cuts without significant signal loss in the $\phi$. Moreover, from Fig. 5, the poorer resolution in the two-track compared to the three-track means that the $M(pK^-)$ cuts have to be tighter, for the former case. We consider the cuts

$$|M(pK^-) - 1.8| \geq \delta_{1800}. \quad (5)$$

where $\delta_{1800} = 0.04$ GeV for charged-two-track and 0.02 GeV for the charged-three-track mode.

D. Effectiveness of cuts

The effectiveness of these cuts can be gauged by the percentage of signal events lost due to them. The $M(K\overline{K})$ distributions were fit to a signal lineshape (see Sec. V) plus a quartic background function before and after placing the

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure3.png}
\caption{(Color online) $\phi$-$\Lambda^*$ overlap for the charged-mode topology: if the $M(K^+K^-)$ invariant mass is fixed at $m_\phi = 1.020$ GeV, $M(pK^-)$ is bounded between an upper and lower limit depending on $\sqrt{s}$. Phase-space overlaps with different $K^+\Lambda^*$ production channels occur in different $\sqrt{s}$ ranges.}
\end{figure}
FIG. 4. (Color online) $\phi$-$\Lambda(1520)$ overlap for the charged-two-track mode topology: between $\sqrt{s} = 2$ and 2.2 GeV, the $\Lambda(1520)$ mass lies within the allowed $M(pK^-)$ bounds and the $\phi p$ and $K^+\Lambda(1520)$ channels overlap in phase space. A plot of $M(pK^-)$ vs. $M(K^+K^-)$ is shown in (a) and (b) for two different energies in the charged-two-track mode. (a) Shows the overlap for the $\sqrt{s} = 2.105$ GeV bin, while (b) shows that above $\sqrt{s} \approx 2.2$ GeV, the $\phi$ and $\Lambda(1520)$ “bands” are separated.

E. Fiducial cuts

In addition to the above particle identification cuts, fiducial volume cuts were required to remove events belonging to regions where our understanding of the detector performance was relatively poor. These cuts were motivated by differences in an empirical efficiency calculation between the actual data and Monte Carlo which indicated discrepancies in the forward-angle region and at the boundaries of the six sectors of the CLAS detector due to edge effects in the drift chambers.

FIG. 5. (Color online) $\phi$-$\Lambda(1800)$ overlap for the charged-track mode topology: between $\sqrt{s} = 2.3$ and 2.8 GeV, several broad $\Lambda^*$ states with masses around 1800 MeV within the allowed $M(pK^-)$ bounds. A plot of $M(pK^-)$ vs $M(K^+K^-)$ is shown for the charged (a) two-track and (b) three-track mode.

Therefore, events with any particle trajectory falling near the sector boundary regions were removed. A $\phi_{lab}$-dependent cut on $\cos\theta_{lab}$ along with a hard cut at $\cos\theta_{lab} \geq 0.985$ removed extremely forward-going particles that coincided with the beam-dump direction. Localized inefficiencies within the CLAS detector volume such as inside the drift chambers were accounted for by placing trigger efficiency cuts on the Monte Carlo data as functions of $\phi_{lab}$, $\theta_{lab}$, and $|\vec{p}|$ for each particle track. Additional cuts were placed on backward-going tracks ($\cos\theta_{lab} \leq -0.5$). A minimum proton momentum cut at 375 MeV removed slow moving protons, whose energy losses were difficult to model in the detector simulation. Events with particles corresponding to poorly performing TOF scintillator counters were removed as well.

V. THE $\phi$ LINESHAPE

We first define our notation for the two-body breakup momentum of a parent particle of mass $m$ decaying into two
daughters of masses \( m_1 \) and \( m_2 \) as
\[
p_{m \rightarrow m_1m_2} = \frac{\sqrt{(m^2 - (m_1 + m_2)^2)(m^2 - (m_1 - m_2)^2)}}{2m}.
\]
The phase-space element contribution from each such decay is
\[
d\frac{N}{d^2m} \propto \left( \frac{p_{m \rightarrow m_1m_2}}{m} \right).
\]
The phase-space factor for the c.m. is as follows.
\[
\frac{p_{m \rightarrow m_1m_2}}{m} \propto \frac{1}{\sqrt{1 + p^2R^2}}.
\]
The total mass-dependent, \( \Gamma_{\text{total}} \), comprises four parts
\[
\Gamma_{\text{total}} = \Gamma_{KK^0} + \Gamma_{KK_L} + \Gamma_{3\pi} + \Gamma_4,
\]
corresponding to the different decay modes of the \( \phi \) (\( \Gamma_4 \) accounts for any mode other than \( KK \) and \( 3\pi \)). For each of the \( KK \) modes, the contribution is
\[
\Gamma_{KK} = \Gamma_0 B_{KK} \frac{p^3}{p_{0}} \frac{m_0}{m} \frac{1 + p_0^2R^2}{1 + p^2R^2},
\]
where \( B_{KK} \) denotes the branching fraction of \( \phi \) into a particular final state \( X \). The dynamics of the \( \phi \rightarrow 3\pi \) decay is more complicated and beyond the scope of this work; we assume the corresponding amplitude to be approximately constant in the small range of \( M(KK) \) that we are interested in. To incorporate the mass-dependence from the three-body phase-space factor, we consider \( m_{12} \) as the mass of the \( (\pi^+,\pi^-) \) system. The two-body phase-space element is then
\[
d\frac{N}{d^2m_{12}dm} \sim \left( \frac{p_{m \rightarrow m_{12}m_0}}{m} \right) \times \left( \frac{p_{m_{12} \rightarrow m_1m_2}}{m_{12}} \right),
\]
which gives
\[
d\frac{N}{dm} \sim \int_{2m_\phi}^{m_{12}} \left( \frac{p_{m \rightarrow m_{12}m_0}}{m} \right) \left( \frac{p_{m_{12} \rightarrow m_1m_2}}{m_{12}} \right) dm_{12}.
\]
This integration is performed numerically. The \( \phi \rightarrow 3\pi \) contribution to \( \Gamma_{\text{total}} \) is then
\[
\Gamma_{3\pi} = \Gamma_0 \times B_{3\pi} \times \frac{dN/dm}{[dN/dm]_0},
\]
where \([dN/dm]_0 \) corresponds to computation at \( m = m_0 \). The fourth component, we simply take as a constant:
\[
\Gamma_4 = \Gamma_0 (1 - B_{KK} - B_{K_k^0 K_L^0} - B_{3\pi}).
\]
The mass-dependent natural lineshape in each \( \sqrt{s} \) bin is then
\[
S(m) \sim \frac{p_{\sqrt{s} \rightarrow m_{pp}} |A|^2}{\sqrt{s}} \times \left( \frac{p}{m} \right) \sim p_{\sqrt{s} \rightarrow m_{pp}} \frac{p^3}{m} \frac{1}{1 + p^2R^2} \frac{1}{(m_0^2 - m^2)^2 + (m_0\Gamma_{\text{total}})^2}.
\]
where \( p_{\sqrt{s} \rightarrow m_{pp}}/\sqrt{s} \) is the phase-space factor for the c.m. mass pseudoparticle decaying into a \( \phi \) and a proton. Near production threshold, this factor suppresses events with large values of \( m \).

We next convolve the natural lineshape with a Gaussian function to obtain our ansatz for the measured signal lineshape
\[
S(m) = \int_{m-5\sigma}^{m+5\sigma} \tilde{S}(m') \frac{e^{-\left(\frac{m-m'}{2\sigma}\right)^2}}{\sqrt{2\pi}\sigma} dm',
\]
where \( \sigma \) represents the smearing due to the detector resolution. Ideally, \( \sigma \) should incorporate any possible \( m \) dependence as well. However, since our \( \phi \) mass window is narrow enough, we neglect this effect, and treat \( \sigma \) as a constant for each fit. However, the resolution can depend on kinematics and this is appropriately accounted for during our signal background separation procedure, by performing independent fits in small phase-space regions (see Sec. VI).

VI. SIGNAL BACKGROUND SEPARATION

The event selection cuts were very effective in cleaning the data sample for both topologies. Further removal of background, non-\( \phi \) events is done by an event-based technique that preserves correlations between all independent kinematic variables [41,49]. The motivation behind this approach, as opposed to a more conventional sideband-subtraction method, is as follows.

For a reaction with multiple decays, such as in the present case, there are several independent kinematic variables (decay angles, for instance). To perform a background subtraction, one typically bins the data in a particular variable, such as the production angle \( \cos \theta_{\phi,m} \). This is because both the background shape and scale can vary widely within the range of the kinematic variable chosen. However, this binning in a single variable generally does not preserve correlations present in the other independent kinematic variables of interest. Therefore, one needs to bin the data in multiple kinematic variables, such that in any particular bin, the background level (both shape and scale) remains roughly the same. Finally, the event-based fits using partial wave amplitudes and Monte Carlo simulation, to calculate the detector acceptance (see Sec. VII), are specifically intended to reproduce the correlations present in the data. Thus, the need for a more sophisticated background separation approach that preserves
multi-dimensional correlations in the signal component of the data.

To execute this technique for a given event, first, an \( N_c \) number of “closest neighbor” events are chosen in the phase space of all independent kinematic variables. \( N_c \) is typically of the order of a hundred. These \( N_c + 1 \) events are then fitted to a signal function \( s(m) \) plus a background function \( b(m) \) using an event-based, unbinned maximum likelihood method [the fit variable \( m \) being \( M(K\bar{K}) \)]. Once the functions \( s_i(m) \) and \( b_i(m) \) have been obtained from this fit for the \( i \)th event, the event is assigned a signal quality factor \( Q_i \) given by

\[
Q_i = s_i(m_i)/(s_i(m_i) + b_i(m_i)).
\]  

(18)

The \( Q \) factor is then used to weight the event’s contribution for all subsequent calculations. In particular, the signal yield in a kinematic bin with \( N \) events is obtained as

\[
Y = \sum Q_i.
\]  

(19)

**A. Specific issues for the \( \phi \) channel**

The above-mentioned procedure has already been employed for several other photoproduction channels [42–46] from the same data set, with excellent results. For the \( \phi \), however, there are some unique issues which need to be carefully dealt with. The main source of the problem is that the \( \phi \) mean mass (\( m_\phi \approx 1.019 \) GeV) is very close to the \( K\bar{K} \) threshold (\( \approx 0.99 \) GeV). Therefore, conventional side-band subtraction is difficult to perform, since there are fewer events on the low mass side. Furthermore, the natural width of the \( \phi \) (\( \Gamma_\phi \approx 4.26 \) MeV) is non-negligible, leading to two complications. First, there are theoretical difficulties associated with determining the exact lineshape when multiple channels [in this case, the \( \phi \) and \( f_0(980) \)] open up close to each other near threshold [50]. Second, \( \Gamma_\phi \) is of the same order as the detector resolution term [\( \mathcal{O}(1 \text{MeV}) \)]. The convolution of the resolution function with an asymmetric natural lineshape can result in a complicated measured lineshape.

Previous experiments often used a Gaussian function to represent the \( \phi \) signal. In this analysis, we use an asymmetric relativistic Breit-Wigner appropriately convolved with a Gaussian (as described in Sec. V) to better characterize the measured \( \phi \) lineshape. The next issue involves the background function shape and scale. The general scheme found in previous \( \phi \) analyses [25,26,31] has been to assume various “template” shapes arising from an underlying \( K\bar{K} \) phase-space, \( a_0/f_0 \), and the \( K^+\Lambda^* \) channels (for the charged mode). Several problems arise from this approach. First, all three of the above physics backgrounds correspond to a \( pK\bar{K} \) final-state topology, which in turn implies that the particle identification procedure has cleanly separated any pion leakage, a highly improbable prospect. Second, the use of the \( a_0/f_0 \) or \( K^+\Lambda^* \) template shapes require a good understanding of the production mechanism of these channels themselves, which we do not have as yet. This is especially true of the \( S \)-wave \( a_0/f_0 \), which remains poorly understood. Third, we have found that the background underneath the \( \phi \) is dependent on the phase-space region one is examining, and fits to cumulative yields are almost certainly bound to be incorrect. The only proper way of performing signal-background separation for the \( \phi \) is to bin the data in all independent kinematic variables \( \{\sqrt{s}, \cos\theta^*_{\phi m}, \cos\xi, \phi\} \) (\( \xi \) and \( \phi \) are the polar and azimuthal decay angles for \( \phi \to K\bar{K} \)) and perform independent fits in each phase-space volume.

In this work, therefore, we have specifically avoided the use of such templates for the background. Instead, we perform independent fits for each event in a suitably small volume of phase-space denoted by the \( N_c \) number of closest-neighbor points. We assume a core linear background function (corresponding to a flat production amplitude), but include the phase-space factors corresponding to the two-body decays \( M(\sqrt{s}) \to p\phi \) and \( \phi \to K\bar{K} \), as described in Sec. V. The signal lineshape is given by Eq. (17).

Figure 6 shows a global fit in the near-threshold \( \sqrt{s} = 1.995 \) GeV for the charged-two-track data set. The dwindling phase space at higher \( M(K\bar{K}) \), applicable to both the signal and background lineshapes is clearly visible here. Figure 7 shows the energy dependence of the detector resolution term \( \sigma \) in Eq. (17), extracted via such global fits (integrated over all angles) in each \( \sqrt{s} \) bin. The resolutions worsen with increasing track momenta at higher \( \sqrt{s} \). The charged-two-track and charged-three-track data sets shown in Figure 8 were analyzed using the same procedure as the charged-two-track data set. The background results are similar for all three topologies.

**FIG. 6.** (Color online) Sample global fit for in the charged-two-track data set in the near-threshold \( \sqrt{s} = 1.995 \) GeV bin. The phase-space suppression in the high-mass side is clearly visible.

**FIG. 7.** (Color online) Energy dependence of the detector resolution term \( \sigma \) in Eq. (17) extracted via such global fits (integrated over all angles) in each \( \sqrt{s} \) bin. The charged-two-track and charged-three-track data sets shown in Figure 8 were analyzed using the same procedure as the charged-two-track data set. The background results are similar for all three topologies.
and neutral topologies have almost the same resolution in the entire $\sqrt{s}$ range, while the charged-three-track has a markedly better resolution due to all final-state tracks being detected directly, which enables the use of the 4-C kinematic fit. Since the detector resolution and the $\phi$ natural linewidth are of same order of magnitude, the measured signal lineshape is highly sensitive to the resolution. By improving the reconstructed $\phi$ mass resolution, kinematic fitting plays an important role in this analysis.

We note that since fits are done for individual events in small phase-space bins, the assumed linearity of the background is local. The start values of the signal and background lineshapes are taken from the global fits, but, event-by-event, both the signal and the background functions in Eq. (18) can be different. Fits with several different values of $N_c$ were tried out and were seen to give stable results. Our final results are present with $N_c = 100$ and $\phi$ mass range $M(K\bar{K}) \in [1.0, 1.06]$ GeV.

**B. Results**

Figure 8 shows the signal-background separation quality checks for the charged-two-track topology in the $\sqrt{s} \in [2.12, 2.15]$ GeV and $\cos \theta_{c.m.} > 0.33$ kinematic regime. Events are further categorized into nine phase-space volumes in the $\phi \rightarrow K\bar{K}$ decay angles. The red dashed and blue dot-dashed histograms represent the extracted signal and background components, respectively. The y-axis units are number of events per 10-MeV-wide $\sqrt{s}$ bin. The dependence of the background (both in shape and size) on phase space is clearly borne out. Figure 8 corresponds to the forward-angle regime in $\cos \theta_{c.m.}$. The background levels were found to be different in the mid- and backward-angles. This strong phase-space dependance arises because the composition and dynamics of the background components vary in phase-space. Similar checks were performed in other kinematic regions and topologies as well.

**C. Further discussion**

Seen in one way, there is some difference in philosophy between our approach and that in some of the previous analyses—instead of “subtracting away the background”, we are “pulling out the signal”. Furthermore, by performing independent fits in very small regions of phase-space for each event (where the background shape is assumed to be roughly constant), we are not making any a priori guesses about the global features of the background. Even if there...
is an $f_0/a_0$ or $\Lambda^*$ underneath the $\phi$, unless this background interferes strongly with the $\phi$, our method should work properly and provide a much better handle on the systematics of the signal-background separation process than in the older methods. While there is certainly an $S$ wave underneath the $\phi$, the extent of the $S$-wave contribution is usually estimated to be small, the presently accepted value being at the percent level [51,52]. We leave the $S$-$P$-wave interference issue as beyond the scope of this work.

VII. DETECTOR ACCEPTANCE

Detector efficiency was modeled using GSIM, a GEANT-based simulation package of the CLAS detector. A Monte Carlo sample containing $10^8 \gamma p \rightarrow \phi p$ events were pseudorandomly generated according to phase-space distributions and allowed to propagate through the simulation. The simulator also handled the decay of the $\phi$ into the $K\bar{K}$ charged- and neutral-modes according to the corresponding branching fractions. An additional momentum smearing algorithm was applied to better match the resolution of the Monte Carlo with the real data. After processing, the “raw” (i.e., original phase space generated) events yielded a set of “accepted” Monte Carlo events. The “accepted” Monte Carlo data then underwent the exact same series of event reconstruction, analysis cuts and energy-momentum correction steps as applied to the real data events.

To account for the characteristics of the event trigger used in this experiment, an additional correction for the Monte Carlo came from a trigger efficiency study using the $\gamma p \rightarrow p\pi^+\pi^-$ channel (see Refs. [41,53] for details). This study computed the probability that an individual particle trajectory did not fire the trigger, when the reaction kinematics strongly demanded (via total missing mass) that the particle should have been there. The average effect of this correction was found to be 5–6 %.

To form a more accurate characterization of the detector acceptance pertaining to the kinematics of the reaction of interest, one should use a Monte Carlo event generator based on a physics model, instead of a simple phase-space generator. Typically, this is achieved in an iterative fashion; one starts with phase-space generated Monte Carlo events, extracts the differential cross sections, fits these cross sections to a model and uses the model to generate new Monte Carlo events for the next iteration. After several such iterations, the accepted Monte Carlo and data distributions are expected to resemble each other to a fair degree.

However, the above procedure assumes that one has a very good handle on the signal-background separation. For a complicated reaction with multiple decay angles, the detector acceptance can depend on several kinematic variables and it becomes more difficult to disentangle the effect of the detector acceptance on signal events from that on the background. Our signal-background separation procedure, as described in the previous section, specifically addresses this issue. By weighting every event by its $Q$ value, we are able to produce distributions of any particular kinematic variable that include only signal events.

In the next step, we expand the scattering amplitude $\mathcal{M}$ for the complete reaction $\gamma p \rightarrow \phi p$ in a basis of $s$-channel production amplitudes $A^{i'}$:

$$\mathcal{M}_{\alpha}(\vec{x},\vec{\alpha}) \approx \sum_{j=1}^{J} \sum_{P=\pm}^{M} A_{ij}^{\alpha}(\vec{x},\vec{\alpha}), \quad (20)$$

where $\vec{m} = \{m_\gamma, m_\phi, m_p, m_f\}$ denotes spin projections quantized along the beam direction for the incident photon, target proton, intermediate $\phi$, and final-state proton, respectively. The vector $\vec{x}$ represents the set of kinematic variables that completely describes the reaction, while the vector $\vec{\alpha}$ denotes a set of 56 fit parameters, estimated by a fit to the data distribution using the method of extended unbinned maximum likelihoods. The only assumption made here is that any distribution can be expanded in terms of partial waves (denoted by the spin-parity combination $J^P$). Ideally, one needs to use a “complete” basis of such $J^P$ waves, but we found that a “large-enough” ($J^P = 1^\pm, 3^\pm, \ldots, 11^\pm$) set of waves was sufficient to fit the data very well. The $s$-channel $J^P$ waves were constructed using the relativistic Rarita-Schwinger formalism [54] and numerically evaluated using the qft++ software package [55].

A full description of the amplitude construction and fitting procedure can be found in Refs. [41,42], but a salient feature was a $Q$ value weighted contribution of each data event to the total negative log likelihood

$$-\ln L = \sum_{i}^{N_{data}} Q_i \ln I_i + N,$$ \quad (21)

where the intensity $I_i$ corresponds to the differential rate calculated using the $\mathcal{M}$ amplitudes and the normalization integral $N$ that ensures that all probabilities are normalized to unity, is numerically calculated using the Monte Carlo. This function is then minimized with respect to the parameters $\vec{\alpha}$ to obtain the fit results.

Based on these fit results, each accepted Monte Carlo event was assigned a weight $I_i$ given by

$$I_i = \frac{\sum_{m_p,m_\phi,m_f} \left| \sum_{m_{\gamma}} \mathcal{M}_{\vec{m}}(\vec{x}_i,\vec{\alpha}) \times \mathcal{M}_{\phi\rightarrow K\bar{K}} \right|^2 \Delta \Phi_i}{\sum_{j}^{N_{raw}} I_j}, \quad (22)$$

where we have coherently summed over the intermediate $\phi$ spins and $\Delta \Phi_i$ is the phase-space element. The accepted Monte Carlo, weighted by the fits, matched the data in all physically significant distributions and correlations. Figure 9 shows comparisons between the data and the accepted MC weighted by the fit results in the production angle for the charged-mode $\sqrt{s} = 2.155$ GeV bin. The detector acceptance as a function of the kinematic variables $\vec{x}$ was then calculated as

$$\eta_{\text{word}}(\vec{x}) = \left( \frac{\sum I_i}{\sum_{j}^{N_{raw}} I_j} \right), \quad (23)$$

where $N_{raw}$ and $N_{acc}$ denote the number of events in the given kinematic bin for the raw and the accepted Monte Carlo data sets, respectively.

We emphasize that the $J^P$ waves in the expansion in Eq. (20) are not to be interpreted as physical $s$-channel multipoles contributing to the scattering process.
Data

Accidental events corresponding to tagger counters 41–61 of the photon tagger counters (1–40) went into the trigger. Required to account for the fact that only the first two-thirds losses along the beam line and the detector dead-time.

VIII. NORMALIZATION

To calculate differential cross sections, the data yields were normalized by the photon flux and the target factors as

$$\frac{d\sigma}{d \cos \theta_{\text{c.m.}}^\phi} = \frac{A_i}{\mathcal{F}(\sqrt{s}) \rho_i \ell_i N_A} \frac{\mathcal{Y}(\sqrt{s}, \cos \theta_{\text{c.m.}}^\phi)}{(\Delta \cos \theta_{\text{c.m.}}^\phi) \eta(\sqrt{s}, \cos \theta_{\text{c.m.}}^\phi)},$$  

(24)

where $A_i$, $\rho_i$, and $\ell_i$ are the target atomic weight, density, and length, respectively, $N_A$ is the Avogadro constant, $\mathcal{F}(\sqrt{s})$ is the photon flux incident on the target for the given $\sqrt{s}$ bin, $\Delta \cos \theta_{\text{c.m.}}^\phi$ is the angular binning width, and $\mathcal{Y}(\sqrt{s}, \cos \theta_{\text{c.m.}}^\phi)$ and $\eta(\sqrt{s}, \cos \theta_{\text{c.m.}}^\phi)$ are the number of data events and the acceptance for the given kinematic bin, respectively.

Photon flux normalization for this analysis was carried out by measuring the rate of out-of-time electrons at the photon tagger, that is, hits that did not coincide with any event recorded by CLAS \[56\]. Corrections were made to account for photon losses along the beam line and the detector dead-time.

A separate correction to the photon flux normalization was required to account for the fact that only the first two-thirds of the photon tagger counters (1–40) went into the trigger. “Accidental” events corresponding to tagger counters 41–61 could trigger if a simultaneous hit occurred in the lower (1–40) counters within the same time window. Such “accidental” events would be triggered as usual and recorded by CLAS just as any other “normal” event. However, the photon flux calculation would not incorporate the associated photon corresponding to an invalid tagger counter. By utilizing the trigger rates in counters 1–40 and assuming a Poisson distribution for the probability of occurrence of such “accidental” events, we were able to correct for this feature. Faulty tagger electronics prevented accurate electron rate measurements for photons in the energy bins $\sqrt{s} = 2.735$ and 2.745 GeV \[41\]. Differential cross sections are therefore not reported at these two energies. However, polarization measurements do not depend on flux normalizations and are reported in these two bins.

IX. UNCERTAINTIES

The statistical uncertainties for the differential cross sections were comprised of the uncertainty in the data yield and the acceptance calculation. For the $i$th event, the covariance matrix from the signal-background fit described in Sec. VI gave the uncertainty $\sigma_i$, in our estimate of the signal quality factor $Q_i$. Summing up these uncertainties, assuming 100% correlation for events in a given $(\sqrt{s}, \cos \theta_{\text{c.m.}}^\phi)$ bin, the

The $z$ axis for the c.m. frame points along the beam direction and coincides with $z_{\text{Ad}}$. Since $z_{\text{Hel}}$ points along the direction of the $\phi$ meson, the angle between the helicity and Adair frames is $\theta^\phi_{\text{c.m.}}$. The Gottfried-Jackson frame is defined as the direction of the incoming photon, as seen in the rest frame of the $\phi$ meson. The angle between the helicity and Gottfried-Jackson frame is given by Eq. (42b).](image)
FIG. 12. (Color online) \(\frac{d\sigma}{d\cos\theta^\phi_{\text{c.m.}}} (\mu b)\) vs \(\cos\theta^\phi_{\text{c.m.}}\): Differential cross section results for the charged-mode topology in the energy range 1.98 GeV \(\leq \sqrt{s} < 2.3\) GeV. The centroid of each 10-MeV-wide bin is printed on the plots. The y-axis range is constant over each horizontal row and is shown in the left-most column for every row. All error bars represent statistical uncertainties only.

Statistical uncertainty in the data yield was given by

\[
\sigma^2_{\text{data}} = Y + \left( \sum_i \sigma_{Q_i} \right)^2. \tag{25}
\]

The relative statistical uncertainty in the acceptance calculation was computed using the expression for binomial errors

\[
\frac{\delta\eta}{\eta} = \sqrt{\frac{1}{N_{\text{raw}}} - 1}. \tag{26}
\]

An overall detector acceptance uncertainty between 4 to 6 %, depending on \(\sqrt{s}\) was estimated based on previous studies [42,46] on the same data set. A study of the cross sections for three different reactions (\(\omega p\), \(K^+\Lambda\), and \(\eta p\)) using the same (present) data set in comparison with other experiments gave a flux normalization uncertainty of 7%. Data collection for the present experiment occurred in bunches of about 10 million event triggers (called “runs”). Our estimated photon flux normalization uncertainty from a “run”-wise comparison of flux-normalized yields was 3.2% [46]. Combining these in quadrature with the contributions from photon transmission efficiency (0.5%), a current-dependent normalization (3%) and target density and length (0.2%), we quote an overall normalization uncertainty of 8.3%. The other contributions...

come from the $\phi \to KK$ branching fractions (0.5% and 0.4% [57] for the charged and neutral modes, respectively) and $\phi$ full width (0.9%) [57]. A list of all the systematic uncertainties pertaining to $d\sigma/d\cos\theta^\phi_{c.m.}$ measurements for each of the two topologies is given in Table II.

X. SPIN DENSITY MATRIX ELEMENTS

A massive vector boson like the $\phi$ meson has three physical spin components. As in Eq. (20), we take the beam direction as our spin quantization axis, as well as the positive $\hat{z}$ direction. The $\hat{y}$ direction is the normal to the production plane (i.e., along $\vec{p}_\gamma \times \vec{p}_\phi$), and $\hat{x} = \hat{y} \times \hat{z}$. This is schematically shown in Fig. 10. The three spin operators are
and a pure spin-state $|\alpha\rangle$ is an eigenstate of the full $\vec{S}$ operator. For a classical ensemble of states, the spin of the vector particle is described by the density matrix $\rho = \sum w_{\alpha}|\alpha\rangle\langle\alpha|$, where the sum is over a complete basis of states and $w_{\alpha}$ is the classical probability of finding the particle in the state $|\alpha\rangle$. For the general case, however, $\rho$ will not be diagonal and the different polarization states will be correlated. A general $3 \times 3$ complex matrix $\rho$ has $2 \times 3^2$ real elements. Hermiticity constrains the diagonal elements of $\rho$ to be real (three real elements) and the off-diagonal elements to be conjugate transpose of each other (three complex elements or six real elements). The unit trace constraint further reduces the number of independent elements by 1. Therefore, in all, the most general $3 \times 3$ density matrix will have 8 real and independent elements. A convenient basis to expand the density matrix is given by three rank-1 tensors, $S_i$ ($i = x, y, z$) and five rank-2 tensors $\tau_{ij}$ given by

$$\tau_{ij} = \frac{1}{2}(S_i S_j + S_j S_i) - 2\delta_{ij}. \quad (28)$$

Therefore, by construction, in the tensorial space indexed by the two rank-1 tensors $S_i$ and $S_j$, $\tau_{ij}$ is symmetric and traceless.

The above tensors were written in the Cartesian basis. Following Ref. [58], we switch to the helicity basis where the spin-1 operators are written as [38]

$$S_{1\pm 1} = \pm \frac{S_i \pm i S_j}{\sqrt{2}}, \quad S_{10} = S_z. \quad (29)$$

Explicitly, they are

$$S_{10} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \quad (30a)$$

$$S_{11} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} \quad (30b)$$

$$S_{1-1} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (30c)$$

FIG. 14. (Color online) $\frac{d\sigma}{d\cos\theta_{c.m.}}$ (µb) vs $\cos\theta_{c.m.}$: Differential cross section results for the charged-mode topology in the energy range 2.62 GeV $\leq \sqrt{s} < 2.84$ GeV. The centroid of each 10-MeV-wide bin is printed on the plots. The $y$-axis range is constant over each horizontal row and is shown in the left-most column for every row. No results are presented for the bins $\sqrt{s} = 2.735$ and 2.745 GeV due to the normalization issues, as described in Sec. VIII. All error bars represent statistical uncertainties only.
In the helicity basis, the rank-2 operators $\tau_{2\mu}$ are given by the tensor products $[S_1 \otimes S_1]_{\mu}$, $\mu = \{0, \pm 1, \pm 2\}$. Substituting the appropriate Clebsch-Gordan coefficients, the tensor polarization operators are

\begin{align}
\tau_{22} &= S_{11}S_{11}, \\
\tau_{2-2} &= S_{1-1}S_{1-1}, \\
\tau_{21} &= \frac{1}{\sqrt{2}}(S_{11}S_{10} + S_{10}S_{11}), \\
\tau_{2-1} &= \frac{1}{\sqrt{2}}(S_{1-1}S_{10} + S_{10}S_{1-1}), \\
\tau_{20} &= \frac{1}{\sqrt{6}}(S_{11}S_{-1} + 4S_{10}S_{10} + S_{1-1}S_{11}).
\end{align}

For the sake of completeness, we give the explicit form of these five matrices:

\begin{align}
\tau_{22} &= \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \\
\tau_{2-2} &= \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \\
\tau_{21} &= -\frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{pmatrix}.
\end{align}
Fig. 16. (Color online) Comparison of the charged- and neutral-mode $d\sigma/d\cos \theta_{c.m.}$ results in $0.1$-cos $\theta_{c.m.}$ bins, at mid and backward angles. The charged-mode results comprise the two-track data set with additional $\Lambda^*$ cuts as explained in the text. The $y$-axis range is constant over each horizontal row and is shown in the left-most column for every row. All error bars represent statistical uncertainties only.

The full expression of the density matrix is then given as

$$\rho = \frac{1}{2} \left[ I + \frac{3}{2} \vec{S} \cdot \vec{P} + \sqrt{3} \tau \cdot T \right],$$

with the vector polarizations defined as

$$P_{1\pm1} = \frac{P_\pm \pm i P_y}{\sqrt{2}}, \quad P_{10} = P_z,$$

and the sum over the tensor polarizations defined as

$$\tau \cdot T = \sum_{\mu=0,\pm1,\pm2} (-1)^\mu \tau_{2-\mu} T_{2\mu}.$$
FIG. 17. (Color online) Comparison of the charged- and neutral-mode \( d\sigma/d\cos \theta^{c.m.} \) results in 0.05-\( \cos \theta^{c.m.} \) bins, at forward angles. The charged-mode results comprise the two-track data set with additional \( \Lambda^{+} \) cuts as explained in the text. The y-axis range is constant over each horizontal row and is shown in the left-most column for every row. All error bars represent statistical uncertainties only.

Therefore, the density matrix can be written as

\[
\rho_{\lambda\lambda'} = \begin{pmatrix} \rho_{-1-1} & \rho_{-10} & \rho_{-1-1} \\ \rho_{0-1} & \rho_{00} & \rho_{01} \\ \rho_{1-1} & \rho_{10} & \rho_{11} \end{pmatrix} = \frac{1}{3} \begin{pmatrix} 1 + \frac{3}{2} P_{1-1} + \sqrt{3} T_{20} & -\frac{3}{2} P_{11} + \sqrt{3} T_{2-1} & \sqrt{3} T_{22} \\ \frac{3}{2} P_{1-1} - \frac{1}{2} T_{21} & 1 - \sqrt{2} T_{20} & -\frac{1}{2} P_{11} - \sqrt{2} T_{2-1} \\ \frac{3}{2} P_{1-1} + \frac{1}{2} T_{21} & 1 - \frac{1}{2} P_{10} + \sqrt{3} T_{22} \end{pmatrix}.
\]

(36)

For unpolarized beam and target polarizations, parity conservation leads to the condition \( \rho_{\lambda\lambda'} = (-1)^{\lambda-\bar{\lambda}} \rho_{-\lambda-\bar{\lambda}} \). Along with the hermiticity property \( \rho_{\lambda\lambda'} = \rho_{\lambda\lambda}'^* \), Eq. (36) implies [58] \( P_z = P_x = 0, T_{20}, T_{21}, \) and \( T_{22} \) be real, \( T_{2-1} = -T_{21}, \) and \( T_{2-2} = T_{22} \), so that the most general form of the density matrix for unpolarized photoproduction is given as (following the sign
FIG. 18. (Color online) Comparison between the current CLAS (red triangles) and SAPHIR 2003 [25] (blue circles) results. The SAPHIR binning in $E_γ$ (GeV) is printed on each pad and the CLAS results are at the bin centers for each SAPHIR energy bin. The CLAS results are taken from the charged-mode topology. All error bars represent statistical uncertainties only.

Convictions in Ref. [59])

$$\rho^0 = \begin{pmatrix} \frac{1-\rho_{00}^0}{2} & \rho_{10}^0 & \rho_{1-1}^0 \\ \rho_{10}^0 & \rho_{00}^0 & -\rho_{10}^0 \\ \rho_{1-1}^0 & -\rho_{10}^0 & \frac{1-\rho_{00}^0}{2} \end{pmatrix}.$$  (37)

FIG. 19. (Color online) Comparison between the current CLAS (red triangles) and LEPS 2005 [26] (blue circles) results. The LEPS data had $E_γ = 200$ MeV wide bins (the bin center is printed on each pad). The present CLAS results are taken from the charged-mode topology. All error bars represent statistical uncertainties only.

FIG. 20. (Color online) Comparison between the current CLAS (red triangles) and 2000 CLAS [31] (blue circles) results at the energy bin center $E_γ = 3.6$ GeV. The CLAS 2000 energy binning was 600 MeV in $E_γ$, while the current CLAS binning is 10-MeV wide in $\sqrt{s}$.

Where $\rho_{00}^0$ and $\rho_{1-1}^0$ are purely real and only $\rho_{10}^0$ has both real and imaginary parts (the superscript denotes the unpolarized beam-target case). The physical interpretation of the SDME’s are [58]

$$P_y = -2\sqrt{2}\text{Im}\rho_{10}^0, \quad T_{20} = \frac{1}{2}(1 - 2\rho_{00}^0), \quad T_{21} = -\sqrt{6}\text{Re}\rho_{10}^0 \quad \text{and} \quad T_{22} = \sqrt{3}\rho_{1-1}^0.$$  

Even though the density matrix given by Eq. (37) consists of four real independent observables, for the vector meson decaying into pseudoscalar mesons ($\phi \rightarrow KK$, $\rho \rightarrow \pi\pi$, or $\omega \rightarrow \pi\pi\pi$), there are only three measurable quantities. For these decays, the intensity distribution is given by the Schilling’s equation [59]

$$I(\sqrt{s}, \cos \theta_{\phi\text{c.m.}}) \sim \frac{1}{2}(1 - \rho_{00}^0) + \frac{1}{2}(3\rho_{00}^0 - 1) \cos^2 \zeta - \sqrt{2}\text{Re}\rho_{10}^0 \sin 2\zeta \cos \psi - \rho_{1-1}^0 \cos 2\psi.$$  (38)

FIG. 21. (Color online) Comparison between the current CLAS (red triangles) and 1982 Daresbury [21] (blue circles) results at the bin center $E_γ = 3.3$ GeV. The Daresbury energy bins were 1-GeV wide in $E_γ$, while the CLAS binning is 10-MeV wide in $\sqrt{s}$.  

This text is accompanied by various figures and equations that illustrate the data analysis techniques and differential cross sections for various processes. The figures show comparisons between different experiments, such as CLAS and SAPHIR, and the physical interpretation of the SDME’s is discussed in detail.
FIG. 22. (Color online) SDME vs $\cos \theta^c_{\text{c.m.}}$: spin density matrix elements in the Adair frame for the charged-mode (with $\Lambda^*$ cuts) topology in the energy range $1.98 \text{ GeV} \leq \sqrt{s} < 2.28 \text{ GeV}$. The centroid of each 10-MeV-wide bin is printed on the plots. All error bars represent statistical uncertainties only.

where $\zeta$ and $\varphi$ are the polar and azimuthal angles of the vector meson decay into pseudoscalar mesons [see Eq. (39)], and we have explicitly retained the $(\sqrt{s}, \cos \theta^c_{\text{c.m.}})$ dependence. Since Equation (38) does not include $\text{Im} \rho_{01}^0$, $P_x$ is not measurable. Since $P_x$ and $P_z$ are also constrained to be 0 for unpolarized beam-target configurations, the vector polarization $\vec{P}$ is not measurable at all. Kloet et al. [58] have shown that the only way to measure the vector polarization is through leptonic decays of the vector mesons, with the additional requirement that one of the lepton spins also be measured.

**A. Helicity conservation and choice of reference frames**

The choice of the reference frame for the two decay angles in the intensity distribution of Eq. (38) can be made to emphasize various exchange mechanisms. The reaction is shown in the c.m. frame in Fig. 10. However, since the SDME’s are not Lorentz invariant quantities, an analyzing direction for the vector meson must be chosen. Three common choices exist in the literature, the Adair frame, the helicity frame, and the Gottfried-Jackson frame, as shown in Fig. 11. In the Adair (Ad) frame, the polarization axes for both the incoming and outgoing states are chosen as the $z$ axis (along the beam direction).

The Adair frame is convenient when the production mechanism conserves spin in the $s$-channel c.m. frame. For the helicity (Hel) frame, the vector meson direction in the c.m. system defines the quantization axis. This is preferred for $s$-channel helicity conservation (SCHC). Under the assumptions
of SCHC, $\rho_{00}^{\text{Hel}} = \rho_{10}^{\text{Hel}} = \rho_{1-1}^{\text{Hel}} = 0$ [35]. For the Gottfried-Jackson (GJ) frame, one makes a further boost to the vector meson rest frame from the overall c.m. frame. The quantization axis is along the direction of the incoming photon seen in the vector meson rest frame. For a $t$-channel exchange of $X$, the momentum of the incoming photon and $X$ is collinear in the GJ frame. Therefore the $\rho$ elements measure the degree of helicity flip due to the $t$-channel exchange of $X$ in the GJ frame. For example, if the $t$-channel exchange particle is a $J^P = 0^+$ state, then no helicity flip will occur (TCHC) and the vector meson will have the same helicity as the incoming photon. For this case $\rho_{00}^{\text{GJ}} = \rho_{10}^{\text{GJ}} = \rho_{1-1}^{\text{GJ}} = 0$ [35]. The quantization axes for these three frames are shown in Fig. 11.

It is clear that knowing the $\rho$ elements in one frame, one can immediately calculate them in any other frame by a Wigner rotation. The $y$ axis is always the normal to the vector meson production plane, $\hat{y} = \hat{k} \times \hat{q} / |\hat{k} \times \hat{q}|$, where $\hat{k}$ is the incoming photon direction and $\hat{q}$ is the outgoing vector meson ($\phi$) direction. The choice of the $z$ axis is frame dependent, as described above. For the Adair frame $\hat{z} = \hat{k}$, for the helicity frame, $\hat{z} = \hat{q}$, and for the GJ frame, $\hat{z} = \hat{k}'$, where $\hat{k}'$ points along the incoming photon direction in the vector meson rest frame.
FIG. 24. (Color online) SDME vs $\cos \theta_{\text{c.m.}}$: spin density matrix elements in the Adair frame for the charged-mode (with $\Lambda^*$ cuts) topology in the energy range $2.62 \text{ GeV} \leq \sqrt{s} < 2.84 \text{ GeV}$. The centroid of each 10-MeV-wide bin is printed on the plots. All error bars represent statistical uncertainties only.

The rotation angles (counter-clockwise is positive) are given by [59]

$$\alpha_{\text{Ad} \rightarrow \text{Hel}} = \theta_{\text{c.m.}},$$

$$\alpha_{\text{Hel} \rightarrow GJ} = -\cos^{-1} \left( \frac{\beta - \cos \theta_{\text{c.m.}}^\phi}{\beta \cos \theta_{\text{c.m.}}^\phi - 1} \right),$$

$$\alpha_{\text{Ad} \rightarrow GJ} = \alpha_{\text{Ad} \rightarrow \text{Hel}} + \alpha_{\text{Hel} \rightarrow GJ},$$

where $\beta = |\vec{p}_K|/E_K$ is the velocity of the daughter kaon in the $\phi$ rest frame (for the $\phi \rightarrow K\bar{K}$ decay).

B. “PWA” method and “Schilling’s” method of SDME extraction in the Adair frame

The rotation angles (counter-clockwise is positive) are given by [59]

$$\alpha_{\text{Ad} \rightarrow \text{Hel}} = \theta_{\text{c.m.}},$$

$$\alpha_{\text{Hel} \rightarrow GJ} = -\cos^{-1} \left( \frac{\beta - \cos \theta_{\text{c.m.}}^\phi}{\beta \cos \theta_{\text{c.m.}}^\phi - 1} \right),$$

$$\alpha_{\text{Ad} \rightarrow GJ} = \alpha_{\text{Ad} \rightarrow \text{Hel}} + \alpha_{\text{Hel} \rightarrow GJ},$$

where $\beta = |\vec{p}_K|/E_K$ is the velocity of the daughter kaon in the $\phi$ rest frame (for the $\phi \rightarrow K\bar{K}$ decay).

The expansion of the production amplitudes using partial wave analysis (PWA) techniques in Sec. VII allows for an elegant way of extracting the SDME’s. For this, we follow Schilling [59] and express the SDME’s in terms of the

To rotate the density matrix from reference frame $A$ to $B$, the transformation is

$$\rho^B = d^1(-\alpha_{A \rightarrow B})\rho^A d^1(\alpha_{A \rightarrow B}).$$

(41)
production amplitudes as
\[
\rho_{m_o m_p} = \frac{\sum_{m_o m_p m_i} M_{m_o m_p m_i m_v} M^*_{m_o m_p m_i m_v}}{\sqrt{\sum_{m_o m_p m_i m_v} |M_{m_o m_p m_i m_v}|^2}},
\]
(43)
where \(M_{m_o m_p m_i m_v}\) are the same amplitudes as in the PWA fit in Eq. (20), and \(m_o\), \(m_p\), and \(m_i\) are the spins of the incoming photon, target proton, outgoing proton, and the \(\phi\) vector meson, respectively. Note that the \(\phi \to KK\) decay portion of the full amplitude in Eq. (20) occurs as a constant factor that cancels between the numerator and the denominator in Eq. (43). The \(\phi\) decay portion of the full amplitude in Eq. (20) can therefore be suppressed for SDME extraction.

The above “PWA” method is completely equivalent to a direct application of the Schilling’s expression for the intensity given by Eq. (38) (“Schilling’s” method). Since the spin-quantization axis for our PWA amplitudes was along the beam direction, the PWA method of extraction yields results in the Adair frame. The PWA expansion was specifically tuned to represent distributions in all kinematic variables, in particular, the intensity distribution given by Eq. (38). The equivalence between the two methods were demonstrated previously [41,42]. The final results for the SDME’s we present in this analysis use the PWA method.

XI. RESULTS

A. Differential cross section results

From here on, by charged mode, we will denote only the charged-two-track topology; no final results are presented for the charged-three-track topology. Figures 12–14 show our differential cross section results in different energy bins for the charged mode. Unless otherwise mentioned, for all plots, we nominally include the \(/Lambda^1\) cuts as described in Sec. IV C. Figure 15 shows the differential cross sections for the neutral mode. The energy binning for the charged mode is uniformly 10-MeV wide, while the minimum bin width for the neutral

FIG. 25. (Color online) SDME vs \(\cos \theta_{c.m.}\): spin density matrix elements in the Adair frame for the neutral-mode topology. The minimum bin width is 30 MeV in \(\sqrt{s}\) and the centroid of each bin is printed on the plots. All error bars represent statistical uncertainties only.
FIG. 26. (Color online) The energy dependence of SDME’s (Adair frame) in the backward-angle bins for the charged-mode (with $\Lambda^*$ cuts) topology. All error bars represent statistical uncertainties only.

The diffractive nature of $\phi$ production means that most of the yields are concentrated in the forward-angle regime. Hence, we choose 0.1-unit-wide $\cos \theta_{c.m.}$ bins for $\cos \theta_{c.m.} \leq 0.35$ and finer 0.05-unit-wide $\cos \theta_{c.m.}$ bins in the $\cos \theta_{c.m.} > 0.35$ forward-angle regime, where more statistics are available.

Figures 16 and 17 show comparisons between the charged- and neutral-mode differential cross section results. Note that the angular bins are uniformly 0.1-unit- and 0.05-unit-wide in $\cos \theta_{c.m.}$ for Figs. 16 and 17, respectively. The two sets of results should not be taken as independent measurements, since the topology-wise analyses were not performed blind to each other. For any future theory fits to these data, we suggest that the charged- and neutral-mode results be taken together as a single set of measurements involving some degree of correlation. Any remnant difference between the two modes should be taken as an additional systematic uncertainty. With this caveat in mind, Figs. 16 and 17 show reasonable to good agreement between the two modes.

The forward-most angular bin shows a localized structure around $\sqrt{s} \approx 2.2$ GeV as already mentioned in Sec. I. This feature is discussed further in Sec. XII B. We note that the structure is present in both the modes.

B. Comparison with previous world data for differential cross sections

Previous world data for $\phi$ photoproduction cross sections are generally scarce and no world data exists for the neutral-mode topology at all. We therefore restrict our discussion in
this section to the charged-mode topology only, and unless otherwise mentioned, inclusive of the hard $\Lambda^+$ cuts. Most of the earlier results have very low statistics, wide energy bins and forward-angle coverage only. The current analysis incorporates substantial improvements on all of these factors along with sophisticated data analysis techniques. Therefore, we suggest that caution be taken while interpreting these comparisons. For low energy and forward-angle kinematics, there are two previous results from the SAPHIR [25] and LEPS [26] Collaborations. Both data sets have wide energy binnings, $E_\gamma \approx 200$-MeV-wide and 100-MeV-wide bins for SAPHIR and LEPS, respectively. However, the common feature in both results is that of a prominent enhancement around $E_\gamma \approx 2$ GeV ($\sqrt{s} \approx 2.2$ GeV) in the forward-angle $d\sigma/dt$, in agreement with our current results.

Since the SAPHIR and LEPS kinematics were mostly at forward angles, these results were presented as $d\sigma/dt$ vs $|t - t_0|$, where $t_0$ was the value of $t$ at $\cos \theta^\phi_{c.m.} = 0$. From the phenomenology of diffractive production, $d\sigma/dt$ was expected to show a simple exponential fall off with $|t - t_0|$. The conversion of $\cos \theta^\phi_{c.m.}$ to $t$ or $|t - t_0|$ depends on $\sqrt{s}$. With wide energy bins, it is not immediately clear which $\sqrt{s}$ should be chosen for this conversion. Therefore, we convert our results into the units chosen by SAPHIR and LEPS and make independent comparisons with both of them. Since our energy binning is much finer (10-MeV wide in $\sqrt{s}$), we overlay our results at the energy bin center of the SAPHIR or LEPS results. Figures 18 and 19 show the comparison between our results with SAPHIR and LEPS, respectively.

The only existing world data for large $|t|$ are the CLAS [31] results for a bin center at $E_\gamma = 3.6$ GeV (tagged photon energy range 3.3 to 3.9 GeV). The chief motivation of the previous CLAS experiment was to investigate whether $u$-channel processes (at small $u$ or large $t$) contribute to the $\phi$ channel. Assuming that the $\phi$ is almost pure $|s\bar{s}\rangle$ and the strangeness content in ordinary nucleons is small, the coupling constant $g_{\phi NN}$ is expected to be small and therefore nucleon exchanges in the $u$-channel are supposed to be suppressed. However, as shown in Fig. 20, both the CLAS 2000 and the current CLAS results show a small but distinct rise in the backward angles, suggestive of a non-negligible value for $g_{\phi NN}$.

Last, Fig. 21 compares our results with the $E_\gamma = 3.3$ GeV bin-center results from Daresbury [21]. The Daresbury binning was 1 GeV in $E_\gamma$, and away from the $t \to 0$ region, the error bars are large. Overall, within the limitations of statistical uncertainties, agreement between the two results is fair.

**C. Spin density matrix elements results**

Since polarization measurements are sensitive to interference between amplitudes and require enhanced statistics compared to cross sections which measure sum of the squared...
amplitudes, we retain a uniform 0.1-unit $\cos \theta_{\text{c.m.}}$ binning for the SDME results. Figures 22–24 show the SDME's for the charged-mode topology in the Adair frame. The most prominent feature is the large value of $\rho^{0}_{00}$, while $\rho^{0}_{10}$ and $\rho^{0}_{1-1}$ are small, but nonzero. There is a similarity with the corresponding results for the $\omega$ channel [42] in a “hump-like” structure, followed by a “dip”, for the $\rho^{0}_{00}$ element. At high $\sqrt{s}$, the $\omega$ results had a distinct “dip” for $\rho^{0}_{00}$ in the midforward angles. For the $\phi$, there are indications of a “dip” for $\rho^{0}_{00}$ in the mid- to midbackward angles, though the structure is much less well-defined due to statistical limitations at high $\sqrt{s}$ and $\cos \theta_{\text{c.m.}} < 0$. Figure 25 shows the SDME's for the neutral-mode topology in the Adair frame. The energy bins are at least 30-MeV wide in $\sqrt{s}$. Figures 26, 27 and 28, 29 show the energy dependence of the Adair frame SDME's in different angular bins for the charged and neutral mode, respectively.

For systematic uncertainties, we adopt the results from our previous $\omega$ analysis [42] where the maximal effect of incorrect acceptance on the extracted SDME's was studied by distorting the decay distributions in Eq. (38) by the uncertainties in our acceptance calculation. The SDME systematic uncertainties from this study were $\delta(\rho^{0}_{00}) = 0.0175$, $\delta(\rho^{0}_{1-1}) = 0.0125$ and $\delta(\rho^{0}_{10}) = 0.01$ and we quote these for the present $\phi$ analysis as well, since the underlying assumption is only the Schilling's equation for vector mesons.

### D. Comparison with previous world data for SDME

Previous (pre-2010) world data on the $\phi$ SDME's are extremely limited. Although many of the older papers did report a few results, the overall general conclusion was that the $\rho^{0}$ SDME’s in the helicity frame were all near zero. An important drawback in the SDME extraction method employed in these older data was that instead of fits to the full Schilling’s equation as given by Eq. (38), fits were performed to integrated intensity profiles. There are several problems that arose due to this. First, the SDME's are functions of both

---

**FIG. 28.** (Color online) The energy dependence of SDME's (Adair frame) in the backward-angle bins for the neutral-mode topology. All error bars represent statistical uncertainties only.
\( \sqrt{s} \) and the production angle \( \cos \theta^{c.m.}_{\phi} \). Second, the detector acceptance is a function of every independent kinematic variable \( \{\sqrt{s}, \cos \theta^{c.m.}_{\phi}, \zeta, \phi \} \) in Eq. (38) and therefore such integrated distributions are not properly acceptance corrected. Furthermore, it was claimed that the only way to obtain a good fit was to incorporate \( S-P \)-wave interference effects (see McCormick et al. [32]). As we have stressed earlier in Sec. VI, a certain amount of \( S-P \)-wave interference effect indeed must occur. However, claims to the degree of this effect based on such integrated intensity fits have to be considered with caution. In keeping with these facts, and the very limited physics conclusions from previous \( \phi \) SDME measurements, we choose not to compare our present results to any of the older data.

Recently, however, the LEPS Collaboration [36] has published \( \phi \) SDME’s by performing fits to the full Schilling’s expression and properly accounting for acceptance as well. Figure 30 shows the comparisons between the LEPS and the current CLAS results. The LEPS binning was 200 MeV in \( E_\gamma \), while our bins are much finer. Therefore, the CLAS results are shown at the approximate LEPS bin centers. Also, the LEPS results were quoted as functions of the variable \( |t - t_0| \). The conversion of \( |t - t_0| \) to \( \cos \theta^{c.m.}_{\phi} \) depends on the energy \( \sqrt{s} \).

Since the LEPS energy bins were wide, this conversion process brings an extra degree of uncertainty into the comparisons. Keeping in mind these approximations, the CLAS and LEPS results show good agreement.

**XII. PHYSICS DISCUSSION**

**A. Diffractive exchange parameters \( B_\phi \) and \( C_\phi \)**

As mentioned in the introductory section, the \( \phi \) photoproduction channel is ideally suited to study the phenomenology of Pomeron exchange in the diffractive limit of \( t \rightarrow t_0 \), where \( t_0 = |t|_{\text{min}} \) corresponds to \( \cos \theta^{c.m.}_{\phi} = 1 \) for a given \( \sqrt{s} \). The Pomeron Regge trajectory is approximately given by \( \alpha(t) \approx 1.08 + 0.25t \), where \( d\sigma/dt \) scales as \( \sim (\beta(t)\alpha(t))^2/s^2 \) and \( \beta(t) \) is the Regge residue that behaves like a form factor. Therefore, in the diffractive limit of small \( t \) and large \( s \), \( d\sigma/dt \) should show a very slow variation with \( s \).

Such diffractive Pomeron exchanges are expected to occur for all three vector mesons \( \rho \), \( \omega \) and \( \phi \). However, for the \( \rho \) and \( \omega \), additional meson exchanges occur as well. For the \( \omega \), \( t \)-channel \( \pi \) exchanges are thought to have a more dominant contribution than the Pomeron. Since the \( \phi \) is almost purely \( |s\bar{s}\rangle \), such light-quark \( \pi \) exchanges are suppressed and diffractive Pomeron exchange is the dominant contribution to the production amplitude. In the simplest VMD model [6], the...
photoproduction cross section can be related to the elastic $\phi p$ scattering cross section as
\begin{equation}
\frac{d\sigma}{dt}(\gamma p \rightarrow \phi p) \approx 4\pi\alpha \left(\frac{p_\phi}{E_\gamma}\right)^2 \frac{d\sigma}{dt}(\phi p \rightarrow \phi p), \tag{44}
\end{equation}
where $\gamma_\phi$ is the photon-$\phi$ coupling constant from Eq. (1). For Pomeron exchanges, the form-factor $\beta(t)$ is generally taken as $\exp(-B_\phi(|t-t_0|)/2)$ and Eq. (44) can be recast in the form
\begin{equation}
\frac{d\sigma}{dt}(\gamma p \rightarrow \phi p) = C_\phi \exp(-B_\phi(|t-t_0|)), \tag{45}
\end{equation}
with the parameters $B_\phi$ and $C_\phi$ as the slope and forward-angle cross sections, respectively. Figure 31 shows the variation of the extracted $B_\phi$ and $C_\phi$ from the charged mode for this analysis, in comparison with previous world data. It is important to note here that our fits to Eq. (45) included data points with $0.55 \leq \cos \theta_{\phi}^{c.m.} \leq 0.95$, since it is known that the slope shows a strong $t$ dependence as well [12]. The overall trend in Fig. 31 shows only a slow rise of both $B_\phi$ and $C_\phi$ with energy, the signature for diffractive phenomenology.

B. Forward-angle structure at $\sqrt{s} \approx 2.1$ GeV

As noted earlier in Sec. IV C, for $\sqrt{s}$ between 2 and 2.2 GeV, the $\phi p$ and $K^+\Lambda$(1520) channels can kinematically overlap in phase space if they have the same $K^+$, $K^-$, and proton final-state particle configuration. For the $\phi$ channel, this corresponds to the charged-mode topology. Therefore any effect of the $K^+\Lambda$(1520) channel on $\phi p$ photoproduction might be expected to be enhanced for the charged-mode. Figure 32 shows the extracted slope parameter $B_\phi$. Above $\sqrt{s} \approx 2.3$ GeV, pure diffraction sets in. However, below $\sqrt{s} \approx 2.2$ GeV, the production mechanism is no longer that of a simple diffractive Pomeron exchange.

FIG. 30. (Color online) Comparison of the charged-mode SDME’s (Gottfried-Jackson frame) between the current CLAS (red triangles) and forward angle LEPS [36] (blue squares) results. The CLAS results [$\Delta(\sqrt{s}) = 10$-MeV-wide bins] are shown at the approximate LEPS [$\Delta(E_\gamma) = 200$-MeV-wide bins] bin centers, printed on the top of each column. Note that the LEPS data points also involve an energy-dependent conversion from $|t-t_0|$ to $\cos \theta_{\phi}^{c.m.}$, which has an intrinsic approximation due to the wide energy bins. All error bars represent statistical uncertainties only.

FIG. 31. (Color online) The variation of the parameters (a) $B_\phi$ and (b) $C_\phi$ from a fit to $d\sigma/dt$ using Eq. (45) for the charged mode with $\Lambda^*$ cuts included, compared to previous world data. Only the forward-angle kinematic points satisfying $0.55 \leq \cos \theta_{\phi}^{c.m.} \leq 0.95$ were included in the fits for the present analysis. See text for details.

FIG. 32. (Color online) Comparison between the charged- and neutral-mode slope parameter $B_\phi$. Below $\sqrt{s} \approx 2.3$ GeV, the production mechanism is no longer that of a simple diffractive Pomeron exchange.
a simple diffractive Pomeron exchange. The slopes extracted from the two modes also show some slight difference here. Similarly, Fig. 33 shows a “structure” around $\sqrt{s} \approx 2.2$ GeV in $\rho_{00}^0$ (helicity frame). The “structure” is also noticeably enhanced for the charged mode. Figure 34 shows a comparison between results including or excluding the hard $K_{\Lambda}^{*}$ cuts (and neutral mode) as well. Second, there is an interference effect to kinematic overlap in phase space and this should affect the results are found in the $\sqrt{s} \approx 2.2$ GeV region.

It is therefore possible that there are two separate phenomena occurring here. First, the $\phi$-$\Lambda(1520)$ rescatters [27,28] due to kinematic overlap in phase space and this should affect the neutral mode as well. Second, there is an interference effect between the $K^+\Lambda(1520) (pK^-)$ mode and $\phi p$ (charged mode) when the final states are the same. Therefore, we explicitly distinguish between the terms “interference” and “overlap”, though it is possible that the two phenomena mix in some fashion. Figure 35 illustrates the effect of the $\Lambda(1520)$ in the two topologies. Consider the process $\gamma p \rightarrow X \rightarrow KK$, where the $KK$ refers to either $K^+K^-$ (charged mode) or $K^0\bar{K}^0$ (neutral mode), and $X$ refers to a generic intermediate state comprising of $\phi p$ and $K^+\Lambda(1520)$. If $\phi$-$\Lambda(1520)$ coupling is allowed, the charged-mode case has three “paths” (enumerated as 1, 2 and 3) to its final-state, while the neutral mode has two “paths” (enumerated as 4 and 5) to its final state.

A deeper understanding of any possible rescattering effects will require data on $K^+\Lambda(1520)$ photoproduction (both cross sections and polarizations), in both $pK$ and $\Sigma\pi$ decay modes of the $\Lambda(1520)$. Using the same data set as the present analysis, the CLAS Collaboration has recently published cross section results on the $\Sigma\pi$ [47,60], and data on the $pK^*$ mode are anticipated as well.

**C. Helicity nonconservation and $\rho_{00}^0$**

If we ignore the spin-indices of the target and outgoing protons (whose polarizations we do not measure) in Eq. (43), the definition of $\rho_{00}^0$ becomes

$$\rho_{00}^0 \propto \left|M_{\lambda\phi=0,\lambda_\gamma=1}\right|^2 + \left|M_{\lambda\phi=0,\lambda_\gamma=-1}\right|^2. \tag{46}$$

Therefore, a nonzero value of $\rho_{00}^0$ is a direct measure of helicity flips between the incoming and outgoing vector particles. Although we have presented most of our SDME results in the Adair frame in Sec. XI B, these can easily be converted into the helicity and Gottfried-Jackson frames by applying Wigner rotations, as described in Sec. X A. Doing so, one finds that $\rho_{00}^0$ is distinctly nonzero at all kinematics, in all the three reference frames. For a long time, it was believed that diffractive vector meson photoproduction proceeds via helicity conservation in the $s$ channel [6,35]. That is, the $\phi^0$ elements are very small in the helicity frame. It is indeed puzzling as to why a $t$-channel process (Pomeron exchange) should conserve helicity in the $s$ channel. In Ref. [35], Gilman et al. gave some phenomenological arguments for SCHC. The problem boils down to how the Pomeron ($tP$) couples (note that Regge theory only gives the overall energy behavior). In the Donnachie-Landshoff (DL) model, the Pomeron couples to partons via a $C=+1$ isoscalar-photon-like $\gamma^\mu$ coupling [6,61]. At very high energies where the parton masses can be neglected, the left- and right-handed sectors remain decoupled during a $\gamma^\mu$ coupling and no helicity flips occur in the $s$ channel, as shown in Fig. 36(a). However, the DL model is a phenomenological model after all, and there are no fundamental reasons to expect either SCHC or TCHC. In fact, naively, one would assign a 2$^{++}$ $t$-channel exchange-like behavior to the Pomeron (which can only exchange the quantum numbers of the vacuum), and this in turn would lead to TCHC, as Fig. 36(b). Others authors [62] have postulated a 2$^{++}$ tensor-like coupling as well.
We study of the signal-background separation procedure, use of carefully dealt with. In particular, this pertains to a detailed previous analyses due to statistical limitations, have been that systematic issues that were under very little control in one would expect TCHC to hold. The filled arrows in (a) and (b) depict the spins of the incoming and outgoing vector particles. The earlier CLAS ω results [42] already corroborated violation of SCHC for the ω channel and Fig. 36(c) shows that $ρ^0_0$ is non-zero in all three frames (Adair, Gottfried-Jackson, and helicity) for the $\phi$ even at forward angles where soft-diffractive processes are generally expected to be dominant. We hope that future partial wave analyses on these new data will shed light on the Pomeron amplitude.
