Abstract

The observations collected during the BORTAS campaign in summer 2011 over Canada are analysed to study the impact of forest fire emissions on the formation of ozone (O₃) and total peroxy nitrates (ΣPNs, ΣROONO₂). The suite of measurements on board the BAe-146 aircraft, deployed in this campaign, allows us to calculate the production of O₃ and of ΣPNs, a long lived O₃ reservoir whose concentration is supposed to be impacted by biomass burning emissions. In fire plumes, profiles of carbon monoxide (CO), which is a well-established tracer of pyrogenic emission, show concentration enhancements that are in strong correspondence with a significant increase of ΣPNs concentrations, whereas minimal increase of the concentrations of O₃ and NO₂ are observed. In those fire plumes the average ΣPNs production is 12 times greater than in the background plumes, by contrast the average O₃ production is only 5 times greater. These results suggest that, at least for boreal forest fires and for the measurements recorded during the BORTAS campaign, fire emissions impact both the oxidized NOₓ and O₃, but: (1) ΣPNs production is affected significantly respect to the O₃ production and (2) in the forest fire plumes the ratio between the ΣPNs production and the O₃ production is lower than the ratio evaluated in the background air masses, thus confirming that the role played by the ΣPNs produced during biomass burning is significant in the O₃ budget. These observations are consistent with elevated production of PAN and concurrent low production (or sometimes loss) of O₃ observed in some another campaigns (i.e. ARCTAS-B) focused on forest fire emissions. Moreover our observations extend ARCTAS-B results since PAN is one of the compounds included in the ΣPNs family detected during BORTAS. The implication of these observations is that fire emissions in some cases, for example Boreal forest fires and in the conditions reported here, may influence more long lived precursors of O₃ than short lived pollutants, which in turn can be transported and eventually diluted in a wide area. These observations provide additional indirect evidence that O₃ production may be enhanced as plumes from forest fires age.
1 Introduction

Biomass burning emissions are an important atmospheric source of fine carbonaceous particles, trace gases and aerosols that significantly affect the chemical composition of the atmosphere and the radiation balance of the Earth–atmosphere system (Crutzen et al., 1979; Crutzen and Andreae, 1990; Andreae and Merlet, 2001; Bond et al., 2004; Langmann et al., 2009; Bowman et al., 2009). Biomass burning generates large quantities of carbon monoxide (CO), nitrogen oxides (NO$_x$ = NO + NO$_2$) and non-methane hydrocarbons (NMHCs), which are the major precursors involved in the photochemical production of tropospheric ozone (O$_3$) (Goode et al., 2000; Chan et al., 2003). Moreover, biomass burning emissions include some greenhouse gases (CO$_2$, CH$_4$, N$_2$O) that alter the climate and air quality (Langmann et al., 2009; Lapina et al., 2006; Simpson et al., 2006). Quantification of the influence of boreal forest fires on the Earth–atmosphere system and on the climate has become one of the key topics for the scientific community.

Forest fires in the boreal regions of Siberia, Canada and Alaska peak during the period from May to October (Lavoue et al., 2000). Some studies highlight the increase in the number of boreal forest fires and the total forested area burned over Canada during the past three decades, corresponding to an increase in temperature and reduction in moisture of the area of interest (Gillett et al., 2004; Rinsland, 2007; Marlon, 2008). Wotton et al. (2010) estimate an increase of 30% in boreal forest fire occurrence by 2030, causing a possible growth of 30% in the emission of CO$_2$ and other greenhouse gases (Amiro et al., 2009). The effects of boreal biomass burning emissions on the O$_3$ concentration has been investigated by several authors with some studies showing situations where O$_3$ concentrations increase and others where it was unaffected (e.g., Wofsy et al., 1992; Jacob et al., 1992; Mauzerall et al., 1996; Wotawa and Trainer, 2000; Val Martin et al., 2006; Real et al., 2007; Leung et al., 2007; Jaffe and Wigder, 2012; Parrington et al., 2012). The analysis of the ARCTAS-B (NASA Arctic Research of the Composition of the Troposphere from Aircraft and Satellites) aircraft measurements of...
biomass burning plumes in central Canada in the spring and summer of 2008 showed consistent production of peroxyacetyl nitrate (PAN), with little evidence for O₃ formation and, in some plumes, the O₃ mixing ratios measured within boreal biomass burning plumes were indistinguishable from measurements outside of the plumes (Alvarado et al., 2010). The production measured in boreal fire plumes has been reported to be a function of the plume age (Parrington et al., 2013), but with mixed, non-conclusive results. For example, boreal fire plumes transported over the Azores and measured between 1 and 2 weeks after emission showed an O₃ increase between 40 and 90% (Val Martin et al., 2006; Pfister et al., 2006). On the other hand, observations over Siberia in 2006 of aged boreal fire plumes (up to a week) showed some plumes with O₃ enhanced and others with O₃ depletion On average the O₃ in the fire plumes was not significantly different from that in the background atmosphere (Verma et al., 2009). Mixed results were also observed in previous observations of boreal forest fire emissions, in these cases in relatively non-aged plumes (1–2 days), O₃ was reported to be enhanced in one third of the boreal fire plumes with concentrations in the remaining plumes being unaffected (Wofsy et al., 1992; Mauzerall et al., 1996).

In the atmosphere, volatile organic compounds (VOCs) are oxidized by OH, NO₃ or O₃ producing an alkyl radical R that rapidly reacts with molecular oxygen O₂ to form peroxy radicals (HO₂, RO₂) (Reaction R1). The RO₂, then, can proceed in different ways: (1) reacting with NO and producing a molecule of alkyl nitrate (ΣANs, ΣRONO₂) (R2) or an alkoxy radical RO (R4) or (2) reacting with NO₂ and producing peroxy nitrates (ΣPNs, ΣROONO₂) (R3). Therefore, the Reactions (R3) and (R4)–(R8) have the same starting Reaction (R1); but Reactions (R3) and (R4) have opposite effects on the O₃ budget. The Reaction (R3) is, in fact in competition with the O₃ production resulting from Reactions (R5)–(R8). The reaction cycles that are of interest when considering
NO\textsubscript{x} and HO\textsubscript{x} (R1–R8) are illustrated schematically in Fig. 1 and listed below:

\begin{align*}
    \text{OH} + \text{RH} + \text{O}_2 + \text{M} & \rightarrow \text{RO}_2 + \text{H}_2\text{O} + \text{M} \quad \text{(R1)} \\
    \text{RO}_2 + \text{NO} + \text{M} & \rightarrow \text{RONO}_2 + \text{M} \quad \text{(R2)} \\
    \text{RO}_2 + \text{NO}_2 + \text{M} & \rightarrow \text{RO}_2\text{NO}_2 + \text{M} \quad \text{(R3)} \\
    \text{RO}_2 + \text{NO} & \rightarrow \text{RO} + \text{NO}_2 \quad \text{(R4)} \\
    \text{RO} + \text{O}_2 & \rightarrow \text{R'C}(\text{O}) + \text{HO}_2 \quad \text{(R5)} \\
    \text{HO}_2 + \text{NO} & \rightarrow \text{OH} + \text{NO}_2 \quad \text{(R6)} \\
    2\text{NO}_2 + 2h\nu & \rightarrow 2\text{NO} + 2\text{O}_2 \quad \text{(R7)} \\
    2\text{O} + 2\text{O}_2 + 2\text{M} & \rightarrow 2\text{O}_3 + 2\text{M} \quad \text{(R8)}
\end{align*}

In July and August 2011 the BOReal forest fires on Tropospheric oxidants over the Atlantic using Aircraft and Satellites (BORTAS) measurement campaign was carried out in order to quantify the impact of boreal biomass burning on the composition and distribution of tropospheric oxidants. The BORTAS project involved several international institutions with the support of the UK Facility for Airborne Atmospheric Measurements (FAAM). The instruments were installed on board the FAAM BAe146 research aircraft and the campaign was based at Halifax airport (Nova Scotia, Canada). During the campaign, fifteen flights were carried out (nominally referenced as flights B618 to B632) in Eastern Canada that were planned to maximize the probability of sampling air masses produced from forest fires in Canada (Ontario) or the USA. More detailed information about the BORTAS campaign objectives and preliminary results are presented by Palmer et al. (2013). The primary aim of this paper is to evaluate and to understand the impact of the boreal fire emissions during the BORTAS campaign on the formation of O\textsubscript{3} and \Sigma PN\textsubscript{s} within biomass burning plumes and, in particular, to estimate the balance between the production of ozone \( P(\text{O}_3) \) and the production of total peroxy nitrates \( P(\Sigma \text{PNs}) \) in this specific environment. This paper is organized as follows. Subsequent to this introduction, the second Sect. presents the instruments and measurement sites
from which data are used in the analysis. In the third Sect., the data analysis is presented. In the fourth Sect. the results of this study are discussed.

2 Instrumental

A comprehensive description of the BORTAS experiment and of the overall instruments involved can be found in Palmer et al. (2013). In this paper only the instruments whose data are included in this analysis are summarized in Table 1. NO$_2$, ΣPNs and ΣANs were measured using the TD-LIF (Thermal Dissociation – Laser Induced Fluorescence) instrument developed at the University of L’Aquila (Italy) (Dari-Salisburgo et al., 2009; Di Carlo et al., 2013). Briefly, this technique permits direct measurement of NO$_2$ molecules excited by laser radiation. The ΣPNs and ΣANs are measured after thermal-dissociation into NO$_2$ by heating the air sample at 200 and 400°C, respectively (Day et al., 2002; Di Carlo et al., 2013). The measurements of O$_3$ were carried out with an UV absorption system Model 49C (Thermo environmental Corp.) (Wilson and Birks, 2006). CO was measured using a VUV resonance/fluorescence system (Gerbig et al., 1999). A chemiluminescence instrument was also used to measure NO$_x$ (Lee et al., 2009; Reidmiller et al., 2010). VOC concentrations were measured by the University of York using a WAS (Whole Air Sampling) system coupled to a GC-FID (Gas Chromatography with Flame Ionization Detector) (Hopkins et al., 2003; Purvis et al., 2013).

3 Data analysis

3.1 Geographical location and meteorological situation

Figure 2 shows the geographic coverage of the five flights selected for our analysis. The flights were carried out between 12 Jul and 3 Aug 2011 over Canada and, in particular, above the North Atlantic Ocean, Nova Scotia, Maine and Québec. The altitude during
the flights exceeded a typical planetary boundary layer depth of 2000 m a.s.l. so that local emissions do not affect the measurements, especially those carried out in the fire plumes. Table 2 summarizes some specific features of each flight BORTAS selected in this analysis and provides a brief description of the meteorology associated with them. Other details about the BORTAS flights can be found in Palmer et al. (2013). From these descriptions, it can be seen that the synoptic situation of the fire plume flights are similar to those of background flights.

3.2 Identification of the plumes: vertical profiles and back trajectories

Several studies have identified CO as a very important pyrogenic species (Crutzen et al., 1979; Andreae and Merlet, 2001; Lewis et al., 2013), therefore it is one of the tracers used to identify the plumes emitted by boreal fires. However, it is necessary to discriminate between anthropogenic and biomass burning CO emissions; for this purpose, following Lewis et al. (2013), we defined a CO threshold of 200 ppbv and we verified at the same time the presence of other pyrogenics such as furfural or camphor to confirm the fire origin of the plume. In conclusion, we classify the air masses in three classes: (1) those sampled within boreal biomass burning plumes (CO ≥ 200 ppbv with significant presence of other pyrogenics species such as furfural or camphor (Andreae and Merlet, 2001), (2) those impacted by anthropogenic emissions (CO ≥ 200 ppb without the presence of furfural or camphor) and (3) those sampled in background conditions (CO < 200 ppb). Using the above criteria to distinguish between flights where we sampled fire plumes and those when we sampled background air we analysed the vertical profiles of species known to have a significant biomass burning source, such as NO₂, ΣPNs, ΣANs, CO, O₃ and some VOCs (i.e., methacrolein, acetylene, benzene, ethyl-benzene, toluene, o-xylene, benzaldehyde, furfural and camphor). The CO and pyrogenic species analysis allows us to select five flights in which we distinguish between those where we sampled boreal fire emissions (B622, B623 and B624 – labelled henceforth “plume” flights) and those in which we measured background air (B619, B622 and B630 – labelled henceforth “background” flights). Flight B622 is a partic-
ular case in which both conditions are met, and we split this flight into two different parts: plume and background. Figure 3 shows profiles of the species indicated above as a function of the altitude for the plume flights (upper panels) and for the background flights (lower panels). It is possible to observe in Fig. 3 that the vertical structures are different in the two conditions. In the upper panels (plume flights) the concentrations of some species, especially CO, ΣPNs, Acetylene and Benzene, show significant and concomitant increases at 3500 and 6000 m a.s.l. Moreover, in the plume measurements at 2000 m a.s.l. a large increase in the CO levels is measured concurrent with an increase in the ΣPNs smaller than at the other altitudes. This suggests that the conditions of the air masses at 2000 m a.s.l. are more complex and that it potentially has various origins, i.e., impacted both by anthropogenic and boreal biomass burning emissions. The ΣANs concentrations are lower than the ΣPNs and do not show significant structures. The O₃ profile shows little variability between 1000 and 7000 m of altitude with no concentration changes that coincide with variations in CO. In the background flights, as expected, the concentrations of the species analysed are quite constant with the altitude.

To facilitate the determination of the sources of the biomass burning plumes (Tereszchuk et al., 2011; Parrington et al., 2012), we calculated Lagrangian back trajectories using the Hysplit model (Draxler et al., 2003) to verify the origin of the air masses. The Fire Locating And Monitoring of Burning Emissions (FLAMBE) archive provides fires emissions data from 2000 to the present worldwide (Reid et al., 2009) incorporating active fire detection data from geostationary and polar-orbiting satellites. To locate the sources of the boreal biomass burning plumes measured during the BORTAS campaign the FLAMBE inventory data have been used in conjunction with the Hysplit back trajectories. In Figs. 4 and 8 day back-trajectories are evaluated starting from points along the flight track and the corresponding fires (red asterisks) from the FLAMBE archive are shown for the plume flight B619 (upper panel) and for the background flight B623 (lower panel). The same analysis has been done for all the flights of the campaign, although here we report only the results of flights B619 and B623 since they
are representative of all the other flights. Parrington et al. (2013) evaluated the photochemical age of the air masses for each flight using the ratio of \( \log(\text{n-butane/ethane}) \) and assuming an OH concentration of \( 2 \times 10^6 \text{ molecules cm}^{-3} \). They found that the age calculated for the air masses sampled within the boreal biomass burning emissions ranges between 1 and 5 days and the background air is older than 6 days.

Their results are in agreement with the back-trajectories analysis, confirming that the air masses sampled during the plume flights crossed biomass fires during the previous 8 days and, conversely, the background air masses do not overlap fires up to 8 days before. In addition Griffin et al. (2013), investigates boreal fire plumes during the BORTAS campaign using back trajectories calculated by the Canadian Meteorological Centre (CMC) and shows that the boreal fire plume originated from forest fires is approximately 1.5 days old, which is in agreement with the age calculated for the air masses sampled within the boreal biomass burning emissions. In Fig. 5 the time series of NO\(_2\), \( \Sigma \)PNs, \( \Sigma \)ANs, \( O_3 \), CO and furfural (when measured) for the B619 flight (top panel) and the B630 flight (bottom panel) are shown. During these background flights (B619 and B630) the concentrations of all the species measured remain quite stable, the \( \Sigma \)PNs concentrations are significantly greater than the \( \Sigma \)ANs but lower compared to those measured in the plume flights (less than 0.5 ppb). Moreover, \( \Sigma \)PNs do not show the significant structure that is shown in the \( O_3 \) measurements. CO is substantially lower than the 200 ppb threshold with the exception of one peak measured during B619 during a period spent in the airport for refuelling (at ground level) where the CO level is affected by anthropogenic emissions and increases, reaching a maximum of about 300 ppb during take off. The B622 flight shows two regimes, as indicated by the CO concentrations and by the furfural measurements. In the first part of the flight (between 2000 and 4000 m.a.s.l., highlighted by a grey box in Fig. 5b) the CO levels (cyan line) exceed 150 ppb and the furfural (yellow line) shows three big plumes (up to 1.2 ppb) in which the \( \Sigma \)PNs also increase (reaching the maximum value of 3.5 ppb). On the other hand, in the second part of the flight the CO and \( \Sigma \)PNs decrease and the furfural is below the detection limit indicating that the air sampled is not produced by
biomass burning. It is interesting to observe that the $O_3$ and the NO$_2$ concentrations are quite stable flying within or outside of the fire plume even if we expect that the biomass burning emissions may affect directly these species.

Flight B623 represents a case in which the air masses sampled for most of the flight were impacted by biomass burning emissions and the remaining air masses show influence from human activities. In fact, CO levels are also always greater than 200 ppb and the furfural is below the detection limit during the whole flight, indicating an anthropogenic origin of the air masses. The fire plumes (highlighted by grey boxes) are characterized by sharp increases in the CO concentrations (maximum value of 552 ppb) and in the $\Sigma$PNs concentrations (maximum value of 1.5 ppb) measured while flying at constant altitude of about 4000 m.a.s.l. In the final part of the flight (between 00:26 and 01:00 UTC) a vertical spiral was carried out flying from 2000 m.a.s.l. up to 8000 m.a.s.l. In this leg, plumes originating from different fires (identified analyzing the Hysplit back trajectories) were sampled. At about 4000 m.a.s.l. back trajectories showed that the air masses sampled had the same origin of the fires plumes sampled at the same altitude in the first part of the flight. Both plumes were characterized by high levels of $\Sigma$PNs (up to 1.7 ppb). At the top of the spiral, according to the back-trajectories, air masses originated from fires in the Western States of the USA (Oregon, Montana, Washington, Idaho, California, Nevada) with the concentration of $\Sigma$PNs low and $O_3$ concentrations quite high (about 60 ppb). This high $O_3$ concentration represents the highest value measured during the whole flight (blue line).

### 3.3 $\Sigma$PNs and Ozone production

The connection between $O_3$ and peroxy nitrates can be highlighted studying the trend between $O_x$ ($O_x = O_3 + NO_2$) and $\Sigma$PNs; as show in Fig. 6. Two different dependences can be identified distinguishing the air masses that are representative of the background environment (flights B619, part of the B622 and B630) and those emitted or influenced by emissions from biomass burning (flights B623, B624 and part of B622). The linear fit of the data influenced by biomass burning emissions has a slope of $\sim 1.87$.
compared to ∼ 203.5 for the slope of the linear fit of background data which indicates the important role played by the ΣPNs in the ozone \( \text{O}_3 \) budget in the air masses influenced by fire emissions. This can be quantified by calculating the productions of \( \text{O}_3 \) and ΣPNs, following the ΣANs production schemes introduced by Atkinsons (1985) and applied in other studies (Perring et al., 2010). Here we applied the same technique for the calculation of the PNs production defining the branching ratio for the peroxy nitrates as \( \alpha = k_{R3}/(k_{R3} + k_{R4}) \). Therefore, the net ΣPNs production is given by \( \alpha(\text{OH} + \text{RH} + \text{O}_2 + \text{NO}_2 \rightarrow \text{H}_2\text{O} + \text{RO}_2\text{NO}_2) \) and the net \( \text{O}_3 \) production is described as \( (1 - \alpha)(\text{RH} + 4\text{O}_2 + h\nu \rightarrow \text{H}_2\text{O} + \text{R’C(Î}) + 2\text{O}_3) \).

The production terms can be written as:

\[
P(\sum \text{PNs}) = \sum_{i} \alpha_i k_{\text{OH+RH}_i} \text{[OH][VOCs]} \tag{1}
\]

\[
P(\text{O}_3) = \sum_{i} 2(1 - \alpha_i) k_{\text{OH+RH}_i} \text{[OH][VOCs]} + k_{\text{OH+CO}[OH][CO]} \tag{2}
\]

where we considered the weighted sum of the contribution of each VOC to the ΣPNs and to the \( \text{O}_3 \) production. For the \( \text{O}_3 \) we take into account also the CO contribution on the \( P(\text{O}_3) \) because of the significant emissions associated with biomass burning.

In our analysis, using the Master Chemical Mechanism (Jenkin et al., 2003; Saunders et al., 2003), we identified the VOC species that contribute to the production of peroxy nitrates and then selected those measured during the BORTAS campaign to be used for the ΣPNs production calculation. The mechanism of ΣPNs production is similar for all the VOC, therefore we illustrate as an example the production mechanism of the perbenzoyl nitrate (C\(_7\)H\(_5\)NO\(_5\)), derived directly from the oxidation of benzaldehyde (C\(_7\)H\(_6\)O) and the indirect production of the PN (C\(_6\)H\(_5\)NO\(_7\)), generated by the oxidation of the benzene. In the first case, the aldehyde’s reaction with OH allows the abstraction of a hydrogen atom and generates an acyl radical and H\(_2\)O. Then, the benzaldehyde reacts with OH producing an R\(^{\cdot}\)CO radical that rapidly reacts with \( \text{O}_2 \) forming an acyl peroxy radical (C\(_7\)H\(_5\)O\(_3\)); the acyl peroxy radical, afterwards, can react either with NO\(_2\)
forming the perbenzoyl nitrate or with NO producing C$_6$H$_5$O$_2$ and NO$_2$, and from their photo dissociation a molecule of O$_3$ is generated. The example of indirect production of PNs starts with benzene oxidation by OH forming three different products: 11.8 % of these reactions generate benzene-1,3,5-triol (C$_6$H$_6$O$_3$) and HO$_2$. The benzene-1,3,5-triol oxidation by OH, in turn, produces a molecule of C$_6$H$_5$O$_5$ in 31 % of cases, that finally, reacts with NO$_2$ to form the peroxy nitrate C$_6$H$_5$NO$_7$ or with NO generating (C$_5$H$_5$O$_4$) and NO$_2$ (and, as consequence, O$_3$). For the branch of benzene oxidation that produces PN it is necessary to weight the contribution of the VOC oxidation to the PN formation by applying a branching ratio of 0.118 to the reaction constant for the initial benzene oxidation by OH and of 0.31 for the following benzene-1,3,5-triol oxidation. The same procedure has been applied also to the other VOCs that do not directly produce peroxy nitrates. Table 3 summarizes all the species involved in the evaluation of the ΣPNs and O$_3$ production during all the flights, indicating for each of them the OH reaction constants and the branching ratio calculated as $\alpha = k_{R3}/(k_{R3} + k_{R4})$.

The reaction constants were evaluated using the MCM model data or the references therein, and from this, the branching ratios ($\alpha = k_{R3}/(k_{R3} + k_{R4})$) were calculated. For the branching ratio of Methacrolein, the value of the $k_{R4}$ is $(8.70 \times 10^{-12}) \exp(290/T)$, where $T$ is the temperature, and $k_{R3}$ was evaluated following the MCM model procedure that takes into account the ambient pressure. For the other species, the $k_{R4}$ reaction constant is $(7.50 \times 10^{-12}) \exp(290/T)$, where $T$ is the ambient temperature, and $k_{R3}$ was evaluated for Methacrolein. Table 4 summarizes the concentrations of each species involved in the ΣPNs and O$_3$ production (ppt), the production terms $P(O_3)$ and $P(\Sigma PNs)$ (expressed in ppt s$^{-1}$), their ratios $P(O_3)/P(\Sigma PNs)$ and the concentrations of other significant species for the O$_3$ budget. The data was identified for all flights where fire plumes were detected and for those when air masses did not show the influence of fire emissions. The $P(O_3)/P(\Sigma PNs)$ ratio is indicative of the balance existing between the two possible terminations of the NO$_x$-HO$_x$ cycle and gives information about the number of O$_3$ molecules produced per molecules of ΣPNs: as the...
ratio increases so the $O_3$ production (R5)–(R8) becomes the dominant process in the reactions cycle (R1)–(R8) respect to the $\Sigma$PNs production (R3).

Figure 7 shows graphically the results summarized in Table 4. It is evident that during the background flights both the VOC (in green) and CO (in red) concentrations are significantly lower with respect to those measured during the plume flights, as expected. At the same time, however, the $O_3$ does not show significantly different concentrations in the biomass burning plumes. Conversely $\Sigma$PNs concentrations in the fire plumes increase to a level three times higher than the measurements in background air masses and the alkyl nitrates double. Analysing the measured concentrations of $O_3$ and $\Sigma$PNs, we deduced that the boreal biomass burning emissions affect the $\Sigma$PNs production more (on average 12% higher in the fire plume compared with the background air) than the ozone production, which increase by only 5% in the fire plume. Therefore in the fire plumes sampled during the BORTAS campaign we observed more production of NO$_x$ reservoir species, which can be transported and potentially impact the $O_3$ concentrations in other locations. Alvarado et al. (2010), using GEO-CHEM model, estimate that 40% of the initial NO$_x$ emission from boreal forest fires were converted into PAN. Since PAN is one of the compounds included in $\Sigma$PNs family, our results show that a consistent production of $\Sigma$PNs in fire plumes compared with background air is plausible. Moreover, calculating the ozone and peroxy nitrate production ratio (Fig. 6), we found that it is lower in the fires plumes than in the background samples. This suggests that the production of peroxy nitrates during the boreal biomass burning becomes a significant process and that it suppresses the ozone production to only 5%, at least in cold air when the thermal dissociation of $\Sigma$PNs is not efficient. In order to understand the impact of a specific category of VOCs, we calculated the contribution of each VOC species and CO on the $\Sigma$PNs and $O_3$ production for the fire plume flights (B619, B622, B623 and B624). We find that the ozone production, as expected, is dominated by CO (with percentages exceeding 93% for all the flights). Moreover, the production of peroxy nitrates is dominated by methacrolein (with percentages ranging between 38 and 86%), followed by benaldehyde (47–7%) and o-xylene (19–3%).
An unusual case, in terms of the peroxy nitrates production, is the background flight (B630) during which 75% of $P(\Sigma$PNs) is derived from o-xylene and only 13% from methacrolein, which dominates on all the other flights analysed in this study. At first look this is strange because methacrolein is one of the major products of isoprene oxidation and it is expected that air masses coming from boreal forests (burning or not) would be characterized by high concentrations of biogenic VOCs rather than o-xylene which is an anthropogenic VOC. Lai et al. (2013) found that at the Taipei International Airport (Taiwan) the most abundant VOCs produced by the aircraft exhaust emissions is o-xylene. During the B630 flight the altitude was of about 7000 m.a.s.l. (ranging between 7500–6000 m.a.s.l.), higher than the other flights (1700–6000 m.a.s.l.), and the flight track was around the eastern coast of Canada: Nova Scotia and Newfoundland Island. At the flight altitude of B630 it is possible to sample air masses affected by aircraft emissions and, so it is likely that the o-xylene dominance on the $\Sigma$PNs production can be explained due to emissions from aircraft traffic.

Finally, the analysis of the $O_3$ and $\Sigma$PNs production in different environments (background and boreal biomass burning plumes) indicates the impact on the tropospheric $O_3$ budget of the fire emissions. In fact, the air masses influenced by biomass burning emissions show a lower (about 90) $P(O_3)/P(\Sigma$PNs) ratio with respect to that for the background air masses (about 180) suggesting that the ozone production in the fire plumes is suppressed and peroxy nitrate formation dominates. Moreover, the higher VOCs and $\Sigma$PNs concentrations measured during the fire plume flights, associated with stable $O_3$ levels in the two environments, are indicative of processed air masses (produced 4–5 days before) and suggest that NO$_2$ reservoir species are produced in these plumes and transported to other regions.

4 Conclusions

In July and August 2011 the BORTAS aircraft campaign was carried out in Canada investigating the impact of the emissions of boreal biomass burning on tropospheric
chemistry. We analysed the ΣPNs and O₃ production in two different environments: air masses affected by fire emissions and those representative of background air. Comparing the production of ΣPNs and O₃ in plumes impacted by fire emissions with that in background air, we found that, on average, ΣPNs production is more strongly enhanced than O₃ production: 12% vs. 5%. This result supports previous analyses of boreal fire emission (i.e. Parrington et al., 2013) that reported an increase in O₃ production with the age of the plume. Boreal biomass burning plumes observed during BORTAS campaign show minimal enhancement of the O₃ and NO₂ concentrations and slight enhancement of the O₃ production. However, they show significant enhancement in both concentration and production of ΣPNs, which can act as a reservoir and enhance ozone production downwind of the plume.

Acknowledgements. The BORTAS project was supported by the Natural Environment Research Council (NERC) under grant number NE/F017391/1. M. Parrington was supported by the NERC grant. P. I. Palmer acknowledges support from his Philip Leverhulme Prize.

Figure 1. A schematic of the atmospheric chemical system (Atkinson and Arey, 2003; Palmer et al., 2013).
**Figure 2.** FAAM146 flight tracks during July 2011. The different colours are the tracks of each different flight: during the B623 and B624 fire plumes were observed, during B619 and B630 background air was measured, whereas in the B622 flight fire plume and background air were detected. See Table 2 for details of individual flights.
Figure 3. Vertical profiles of Benzene, Toluene, Acetylene, Methacrolein O-Xylene (panels on the left) and $\Sigma$ANs, $\Sigma$PNs, NO$_2$, CO and O$_3$ (panels on the right) concentrations averaged for the plume flights (upper panels: B622, B623, B624 flights) and the background flights (lower panels: B619, B622, B630 flights).
Figure 4. Location of the boreal biomass burning activity during the BORTAS campaign recorded by the FLAMBE inventory (red asterisks) and air mass backward trajectory analysis starting from location along the flight trajectories. The flight B623 (lower panel) was crossing fire plumes, whereas the flight B619 (upper panel) plumes not impacted by fires.
Figure 5. Time series of the $\Sigma$PNs, $\Sigma$ANs, NO$_2$, O$_3$, CO, Furfural (ppbv) measured during the flights in this analysis: the flights B619 (panel a) and B630 (panel d) were background plumes, the flight B622 was in part impacted by fire plume and part by no-fire (panel b), the flight B623 (panel c) was affected by fire plume. The time is reported in Coordinated Universal Time (UTC).
Figure 6. Scatter plot between measured O$_3$ and measured ΣPNs. Straight line is best fit linear regression.
**Figure 7.** Average concentrations of the species involved in the $\text{O}_3$ and $\sum \text{PNs}$ production. VOCs are in green, CO in red, $\text{NO}_2$ in blue, $\text{O}_3$ in magenta, $\sum \text{PNs}$ in cyan and $\sum \text{ANs}$ in yellow. In grey is reported the ratio between the $P(\text{O}_3)$ and $P(\sum \text{PNs})$. The left side shows data measured during background flights; the right side shows data from fire plume flights.
