A Ruthenium Racemisation Catalyst for Synthesis of Primary Amines from Secondary Amines

Dennis Pingen, a Cigdem Altintas, # Max Schaller, # Dieter Vogt. b*

A Ru-based half sandwich complex used in amine and alcohol racemization reactions was found to be active in the splitting of secondary amines to primary amines using NH3. Conversions up to 80% along with very high selectivities were achieved. However, after about 80% conversion the catalyst lost activity. Similar to Shvo’s catalyst, the complex might deactivate under the influence of ammonia. It was revealed that not NH3 but mainly the primary amine is responsible for the deactivation.

Introduction

Primary amines are valuable building blocks in industrial chemistry; they are the main building blocks for a large variety of polymers, surfactants, corrosion inhibitors and fine-chemicals. [1,2] For the production of primary amines waste-free, selective protocols are highly desired with special emphasis on renewable resources such as bio-alcohols. [3] However, current industrial (heterogeneously catalysed) syntheses of amines from alcohols inevitably give mixtures of primary, secondary, and tertiary amines. [4] Current homogeneously catalysed alcohol amination reactions were shown to be very selective towards primary amines, barely producing any secondary amines. Although the current homogeneous catalysts, developed by Milstein, [5] Beller [6] and Vogt [7] are very selective towards primary amines, anticipation on the industrial synthesis of primary amines also requires the development of catalysts for the splitting of secondary (and tertiary) amines. Reusing secondary amines in the synthesis of primary amines will reduce the waste stream in the total production. At the moment, only one example of a homogeneous catalyst has been reported that efficiently catalysed the splitting of secondary and tertiary amines. [8]

The splitting of secondary amines is expected to proceed via the ‘Hydrogen Shuttling’ concept; dehydrogenation of the secondary amine forming the dialkylimine. This subsequently undergoes nucleophilic attack from NH3 resulting in primary amine and primary imine. The primary imine will then be hydrogenated to produce another equivalent of primary amine (Scheme 1).

The system reported by Beller and coworkers uses Shvo’s catalyst in the splitting of secondary and tertiary amines. This catalyst has previously been used in various reactions, one of which is amine racemization. [9] As the racemization of amines by Shvo’s catalyst and related systems proceeds via initial dehydrogenation of the amine, [10] it is anticipated that similar systems will also be active in the splitting of amines.

Results and discussion

Ruthenium half sandwich complexes bearing a pentaphenylcyclopentadienyl (CpPh5) moiety (Figure 1) were investigated in the splitting of secondary amines with ammonia. Complexes 1-3 have been employed before in the racemization of alcohols. [9-12] In addition, complex 1 was also used in the racemization of amines. [9-10] Complex 2 did show activity as well, albeit a long induction period was noticed before activity was observed. [11] Complex 3 was developed as a more electron rich variant of complex 1 but was only active in alcohol racemization. [12]
Initial reactions with complexes 1 and dicyclohexylamine as model substrate were performed employing a catalyst loading of 2 mol% at 150°C (supporting information Table S5). Under these conditions only 40% conversion could be achieved (99% selectivity, see supporting information). Increasing the temperature to 170°C significantly improved the conversion without affecting the selectivity (Table 1). As it can be anticipated that the excess of NH₃ applied will have significant influence on the amine splitting, the amount of NH₃ was varied.

The results reported in Table 1 confirmed the expected strong influence on the amine splitting, the amount of NH₃ used varied.

Complex 1 (2 mol%), dicyclohexylamine (1.5 mmol), tert-amyl alcohol (3 mL), NH₃(l), 170°C. a) standard deviation over 3 experiments. b) 0.75 mL MTBE as co-solvent. c) 2 mol% KO'Bu added.

Complex 1 is the most active with 120 eq. of NH₃. Up to 80% conversion and a selectivity of 94% to the primary amine was achieved (entry 1). Complexes 2 and 3 both showed low activity under these conditions (entries 2-3). The situation was different at a 10-fold lower excess of NH₃ (12 eq., entries 5-7). Now complex 3 showed the highest conversion of 68% and complex 1 still gave reasonable conversion (54%). Complex 2 was the least active under both conditions (entries 2 and 6). The addition of base has been shown to be beneficial in activating complex 1 in the alcohol racemization. However, addition of KO'Bu with 120 eq. of NH₃ completely deactivated the catalyst (entry 4), while with 12 eq. of NH₃ still some conversion was achieved; though lower than without the addition of base (entry 8).

The results reported in Table 1 confirmed the expected strong effect of the excess amount of ammonia on the performance in catalysis. Complex 1 appeared to be the most active and therefore, the effect of the NH₃ excess was investigated in more detail for this complex (Table 2).

The data in Table 2 confirm that a large excess of NH₃ is required (60 - 120 eq.) in order to achieve good conversion. However, it is worth noting that the selectivity was very high (> 94%) in all cases, even at very low excess of NH₃. Under the optimised conditions complex 1 was now used for a range of substrates (Table 3).

For amines bearing bulky secondary alkyl substituents the conversion and selectivity was generally high (entries 1-3). Linear secondary amines resulted in lower conversion but also lower selectivity (entries 4-6). The lower selectivity can be in part attributed to the formation of nitriles as a side reaction. Surprisingly, diocylamine initially gave no primary amine, mainly secondary imine (entry 5). Increasing the excess of NH₃ resulted in lower conversion but gave primary amine in reasonable selectivity (entry 6). Dibenzyamine also resulted in low conversion, whereas a higher NH₃ loading also appeared to be beneficial for the selectivity (entries 7 and 8). In case of N-methylaniline, barely any conversion was observed. A larger excess of NH₃ brought no improvement (entry 9 and 10).

Reacting tertiary amines also leads to fairly low selectivity; the substrate has to undergo 2 steps before the final product can be formed. Moreover, it is likely that dehydrogenation of a tertiary amine is more difficult as it has to proceed either via the intermediate enamine or iminium species, which makes the formation of the secondary amine or imine more difficult.

Complex 1 (2 mol%, 0.03 mmol), substrate (1.5 mmol), t-amylalcohol (3 mL), NH₃ (2.5 mL for 60 eq., 5 mL for 120 eq.), 170°C, 23.5 h. a) standard deviation over 3 experiments. b) based on cyclohexylamine. c) based on aniline. d) single experiments, not in triplo.

As the results show, the maximum conversion reached was limited in all cases, which might be due to catalyst deactivation. In fact Beller and co-workers have shown earlier that the related Shvo’s catalyst was inhibited by the coordination of NH₃ as well as by primary amines. They showed that this inhibition became partially reversible at higher temperature. However, even at 150°C or higher, conversions were generally lower than 85%. In our case for complex 1 increasing the reaction temperature to 170°C did increase the conversion, though never reaching more than 80%. Hence we conclude that we are dealing with a different cause of deactivation and decided to study this in more detail. In order to see if we are dealing with product inhibition by primary amines, 20 mol% of cyclohexylamine were added at the start and the reaction was monitored in time (Graph 1). The reaction was significantly slower and gave approximately 15-20% lower conversion.

Graph 1: Catalyst inhibition by primary amine (A) compared to the reaction without additional primary amine (B). Conditions: Complex 1 (2 mol%, 0.09 mmol), diocylhexylamine (4.5 mmol), t-amylalcohol (9 mL), NH₃ (l) (2.5 mmol, 90 mmol, 60 eq.), 170°C. Cyclohexylamine (20 mol%, 0.9 mmol) added (A). ■ = cyclohexylamine, ▲ = cyclohexylamine. Data points for A have been normalized to the actually produced cyclohexylamine.

In order to reveal the inhibiting effect of the primary amine, the reaction of cyclohexylamine with complex 1 was monitored by ¹³C NMR. The Cp ring carbon atoms give a characteristic carbon shift and can probe a change at the Ru centre (106 ppm, Figure 2A). The resonance at about 197 ppm corresponds to the CO ligands, which can also be used as a probe for changes in the coordination sphere of Ru. The signals between 127 – 132 ppm belong to the phenyl groups on the Cp ring.
The addition of primary amine slowly led to an upfield shift of the Cp ring carbon atoms in the $^{13}$C NMR. After 18 h at r.t., the peak at 106 ppm had completely disappeared and a new peak at 101 ppm was observed (Figure 2B). There are now 2 carbonyl signals observed, one for the monocarbonyl complex 5 in which one CO of the original complex is replaced by the amine and the other one for the cationic dicarbonyl complex 4, in which the chloride has been replaced by the amine.

Investigating the reversibility of the amine coordination and substitution, the mixture consisting of complex 1 and cyclohexylamine was warmed to 60°C for 1 h. After this time, the peak at 106 ppm is observed again, indicating that cyclohexylamine coordination is indeed reversible (Scheme 2). The process of amine coordination is apparently reversible at already fairly low temperature, and is therefore unlikely to be the cause of catalyst deactivation. However, a small new peak emerges at 97 ppm (Figure 3A).

A similar treatment of complex 1 was repeated with ammonia instead of cyclohexylamine. A solution of complex 1 was placed in a 10 mL stainless steel autoclave, which was subsequently charged with NH$_3$. After stirring the solution for 1 h at 170°C the autoclave was opened and the excess of NH$_3$ was released. The solution was transferred to a Wilmad-Young NMR tube and a spectrum was recorded (Figure 3B).

Figure 3B reveals that a similar reaction occurred; again, a shift of the Cp carbons was observed, now from 106 to 102 ppm. When then 10 eq. of cyclohexylamine were added to the NH$_3$ adduct complex, the NH$_3$ was immediately replaced for the cyclohexylamine. If this type of coordination was indeed the cause of deactivation, one would expect this process to be irreversible.
To exclude deactivation by the starting material in catalysis, dicyclohexylamine, a reaction with 10 eq. of dicyclohexylamine was performed. Because conversion up to 80% is observed, it is not expected that this deactivates the catalyst. In addition, the bulkiness of the substrate might even hamper coordination to the complex if not under the exact reaction conditions. Figure S8 (supporting information) shows the complex after 18 h at room temperature in the presence of dicyclohexylamine. However, after addition of 10 eq. cyclohexylamine to this mixture and heating for 4 h at 60°C, the peaks at 101 and 97 ppm were observed again. In addition, a peak at 170 ppm was observed (Figure 4). The large downfield shift indicates that this originates from a carbonyl compound. However, the only carbonyl source in the mixture are the carbonyl ligands on the complex itself. It might be possible that one of the carbonyls undergoes nucleophilic attack by cyclohexylamine.\textsuperscript{[17,18]} This is in agreement with previous other carbonyl complexes, which were used in the carbonylation of amines.\textsuperscript{[19]} Moreover, complexes similar to those used in this study have been shown to be susceptible for nucleophilic attack by even less nucleophilic compounds.\textsuperscript{[20]}

Upon nucleophilic attack of the primary amine on one of the CO ligands, a carbamoyl complex is formed.\textsuperscript{[21]} The carbamoyl ligand neutralizes the cationic complex. The remaining proton in the amide bond can be removed by the excess of amines present in solution (Scheme 3). The carbamoyl complex appears to be very stable and does not react back (catalyst deactivation). The remaining Ru complex remains in solution though most likely in some dimeric form, which is typical for these types of ruthenium complexes.\textsuperscript{[22]}

In the $^{13}$C NMR spectra, distinct signals of the carbon in the CN bond of cyclohexyl groups were observed. Compared to free cyclohexylamine, this showed a downfield shift (see supporting information, Figure S11). In addition, the reaction was also monitored by \textit{in situ} IR. The carbonyl vibrations at 2010 and 2050 cm\textsuperscript{-1} seem to disappear equally. This indicates that there is no difference between the carbonyls in terms of reactivity for the nucleophilic attack of the amine, and that the original starting complex disappears. Upon heating the mixture to 40°C, upcoming peaks at 1710 and 1620 cm\textsuperscript{-1} are observed over longer reaction times. These regions are typical for amide/formamide vibrations. The increase of these peaks over time indicates the formation of carbamoyl and formamide derivatives from CO (Figure 5). The band at 1700 cm\textsuperscript{-1} increases fast in the beginning and remains strong, also indicating the formation of an amide that most likely remains coordinated to Ru. The band at 1620 cm\textsuperscript{-1} confirms this as well.
Another indication for the nucleophilic attack of the amine to the carbonyl is seen in the 2400 cm⁻¹ region. Here a strong band is seen almost from the start, which later becomes less intense. This region indicates the presence of ammonium ions. The decrease in intensity indicates that the ammonium is deprotonated, forming the inactive complex as stable species. The conversion of secondary n-alkylamines was found to be lower. It is likely that n-alkylamines react even more readily with the carbonyl moieties due to less steric hindrance. Performing the same reactions with n-hexylamine, revealed it was indeed fast, as the ¹³C-signal at 106 ppm was not observed at all (Figure S11 and S12 in SI). In addition, the resulting carbamoyl peak after heating has a slightly different shift (164.7 ppm), indicating that this is a product of a reaction of the amine with a carbonyl ligand. So far, the spectroscopic techniques used suggest a carbamoyl complex, though not certain in what form exactly. Therefore we performed mass spectrometry on the complex used in the in situ IR experiments. In this higher mass complexes (mass higher than the monometallic complex) were found, showing that indeed multimetallic, mostly bimetallic, species are formed upon degradation. Also, when complex 1 was refluxed in toluene in the presence of 40 eq. cyclohexylamine, the resulting complex displayed no carbonyl signals anymore, and only a single peak at 170 ppm was found (Figure 6).

In addition, complex 3 was also subjected to the deactivation experiments. Complex 3 showed initially less activity, though showed fairly good conversion at low NH₃ loading. As the reason of deactivation is clearer now, it might be that this complex just deactivates much faster. On the other hand, it might still be possible that the complex is just less active. In this case, also the PPh₃ can be monitored by means of ³¹P NMR. Again it was found that a reaction occurs upon addition of primary amine. However, it is also observed now that PPh₃ remains coordinated (free PPh₃ would show up at -5 ppm). The deactivation still occurs at a fairly low temperature relative to the reaction temperature, though it only starts at 90°C after longer reaction times compared to 60°C for complex 1. This suggests that the complex is more stable, though just less active (see supporting information for further details).

Conclusions

We have shown that a catalyst previously applied in amine and alcohol racemization is also an active catalyst in the splitting of secondary and tertiary amines with ammonia. However, full conversion could not be achieved, which is most likely due to deactivation of the catalyst. In this, it seems that deactivation is mainly caused by the primary amine product. One possibility is that the deactivation proceeds via nucleophilic attack of the primary amine to a carbonyl moiety on the metal complex. The resulting carbamoyl species has been identified by NMR, in situ FTIR and mass spectrometry.

Experimental

All work was carried out under standard Schlenk conditions under argon; all solvents were dried, degassed and purged with Ar prior to use. All used glassware was pre-dried at 120°C and heated with a heat gun while purged with Ar prior to use. Chemicals were purchased from Sigma-Aldrich and Strem and were used as received. All reactions were performed in a magnetically stirred home-made stainless steel autoclave equipped with manometer, temperature controller and sampling unit (50μL samples). ¹H, ¹³C, ³¹P NMR spectra were recorded on a Bruker Avance 400 MHz with broadband inverse detection probe and a Bruker Avance 500 MHz with dual channel cryo probe optimized for ¹³C/¹H (DCH). Chemical shifts are reported in ppm using TetraMethylSilane (TMS) as reference. All NMR experiments were performed under inert atmosphere in airtight Wilmad Young NMR quartz tubes. GC analyses were performed on a Shimadzu GC-2010 equipped with an Ultra-2 column. Ammonia of purity grade N4.7 was used and was introduced to the autoclaves using a Bronkhorst liquiFlow mass-flow controller (MFC). FT-IR spectra were recorded in situ on a Shimadzu 8300 equipped with a home-made autoclave with a built-in ZnS path length window. Complexes 1, ²¹⁰c and complex ³¹² were synthesized according to literature procedures.

General procedure for the splitting of secondary amines:
A 75 ml stainless-steel autoclave is charged with 2 mol% of the appropriate complex and purged with Ar. Secondary amine and t-amylalcohol were added via syringe. The autoclave is closed and liquid NH₃ was added via a mass flow controller (MFC). The mixture was heated to 170°C for the 23.5 h time.

Procedure for the NMR reactions:

Reaction of complex 1 with cyclohexylamine:
Into a Wilmad-Young NMR tube, complex 1 (0.073 mmol, 46.6 mg) was weighed and dissolved in CDCl₃. ¹H and ¹³C NMR spectra were recorded and after that, 10 eq. cyclohexylamine (0.73 mmol, 63 μL) were added. Again, both ¹H and ¹³C NMR were recorded and the mixture was left at room temperature for 18h. After this time, both ¹H and ¹³C were recorded. The mixture was heated to 60°C for 1 h.

Reaction of complex 1 with secondary amine and primary amine:
In a Wilmad-Young NMR tube, complex 1 (0.09 mmol, 32.7 mg) was weighed and dissolved in CDCl₃. ¹H and ¹³C NMR spectra were recorded and after that, 10 eq. dicyclohexylamine (0.5 mmol, 99.4 μL) were added. Again, both ¹H and ¹³C NMR were recorded and the mixture was heated to 60°C for 4h. Spectra were recorded again and the mixture was continued to heat at 60°C for 4 days. ¹H and ¹³C NMR revealed no change.

Reaction of complex 1 with ammonia and cyclohexylamine:
In a 15 mL stainless steel autoclave, complex 1 (0.09 mmol, 57 mg) was placed. CDCl₃ was added to dissolve the mixture and NH₃ (2.5 mL, 90 mmol) was subsequently added via a Mass Flow controller. The autoclave was closed and heated to 170°C for 1.45 h. After cooling to room temperature, the resulting mixture was transferred to a Wilmad-Young NMR tube and ¹H and ¹³C NMR were recorded. After that, 10 eq. cyclohexylamine (0.9 mmol, 89 mg, 0.1 mL) were added. Again, both ¹H and ¹³C NMR were recorded and the mixture was left at room temperature for 18h. After this time, both ¹H and ¹³C were recorded.

Reaction of complex 3 with cyclohexylamine:
In a Wilmad-Young NMR tube, complex 3 (0.05 mmol, 39.1 mg) was weighed and dissolved in CDCl₃. ¹H and ¹³C NMR spectra were recorded and after that, 11.4 eq. cyclohexylamine (65 μL, 0.57 mmol) were added. Both ¹H and ¹³C NMR were recorded and the mixture was left at room temperature for 18h. After this time, both ¹H and ¹³C NMR were recorded. The mixture was heated to 90°C for 6h. Again, both ¹H and ¹³C NMR were recorded. The mixture was heated again to 90°C for 2 days before recording the spectra again.

In situ FT-IR monitoring:
In a home-made stainless steel autoclave equipped with a ZnS path length cell, 6 mL CHCl₃ (dry degassed) was placed and a background was recorded for further use. At the same time, complex 1 (0.1 mmol, 63.8 mg) was weighed into a Schlenk tube and dissolved in dry degassed CHCl₃. The autoclave was emptied and dried before purging it with Ar again. The solution of complex 1 was transferred to the autoclave and a spectrum was recorded again. After this, cyclohexylamine (1 mmol, 115 μL) was added and the autoclave was sealed and heated to 40°C. Spectra were recorded with 15 minute time intervals.
