Abstract

Speed of access is a very important property for phrase tables in phrase based statistical machine translation as they are queried many times per sentence. In this paper we present a new standalone phrase table, optimized for query speed and memory locality. The phrase table is cache free and can optionally incorporate a reordering table within. We are able to achieve two times faster decoding by using our phrase table in the Moses decoder in place of the current state-of-the-art phrase table solution without sacrificing translation quality. Using a new, experimental version of Moses we are able to achieve 10 times faster decoding using our novel phrase table.

1 Introduction

Phrase tables are the most basic component of a statistical machine translation decoder, containing the parallel phrases necessary to perform phrase-based machine translation. Due to the noisy nature of phrase extraction and the large phrase vocabulary, phrase tables’ size can reach hundreds of gigabytes in size. Lopez (2008) describes phrase tables of size of half of terabyte. A decade ago it was prohibitively expensive for a phrase table of this size to reside in memory, even if hardware supported it: a gigabyte of RAM back in 2006 costed about a 100 USD, compared to 5 USD in 2016. Because of that for a long time Machine Translation was considered a big data problem and the engineering efforts were focused on reducing the model size. This lead to the creation of several binary phrase table implementations that tackled the memory usage problem: Zens and Ney (2007) and Junczys-Dowmunt (2012b) developed memory mapped phrase tables which also reduce memory usage using specific datastructures. The former uses a trie (Fredkin, 1960) and the latter uses specific for the purpose phrasal rank encoding. Lopez (2007) and Germann (2015) developed suffix array based phrase tables, which work directly with the parallel corpora in order to enable easier addition of new data, avoid long binarization times and keep memory usage low, but traditional precomputed phrase tables offer better performance. RAM prices have dropped 20 times over the past 10 years and high performance server machines have hundreds of gigabytes of memory. For those machines it is no longer needed to sacrifice query performance in favour of compression techniques such as the one in Junczys-Dowmunt (2012a). Furthermore the machines nowadays are highly parallel and locking caches which didn’t hurt performance in the past now prevent implementations from scaling. We have designed a new phrase table called ProbingPT based on linear probing hash (Heafield, 2011) for storage and lock-free querying, in order to deliver the best possible performance in modern use cases where memory is not an issue.

2 Implementation

First, we will give a brief overview of Junczys-Dowmunt’s (2012b) CompactPT which is currently the state of the art phrase table in terms of both speed and space usage. It uses phrasal rank compression (Junczys-Dowmunt, 2012a) which can be viewed as a form of byte pair encoding (Gage, 1994). The method recursively encodes bigger strings as a composition of several smaller ones until only small units remain. Minimum perfect hashing (Nick Cercone, 1983) is used to hash phrases to their expansions and on top of that bit aligned Huffman encoding is used to fur-
other compress the phrases. This approach achieves the smallest model size but it has several drawbacks when it comes to lookup. First, minimum perfect hashing requires a secondary hash function called fingerprinting in order to avoid false positives which results in increased CPU usage. Second, while phrasal rank encoding is extremely space efficient, it is quite slow to compute, because of the multitude of random memory accesses necessary to reconstruct a single phrase. The reason is that when a request to read a portion of memory is submitted what is actually fetched is not only the bytes that were requested but also the surrounding bytes. This is because usually when one byte of memory is accessed, the surrounding bytes would also be necessary so memory has been designed to fetch things in small burst, called DRAM bursts. As such peak memory performance can only be achieved by accessing consecutive memory and random memory accesses reduce the total memory bandwidth, because some of fetched bytes are not used.

In order to speed up querying in CompactPT, extensive caching is used but it is not thread local and causes a lot of locking for higher thread count. In our experiments we found that more than 8 threads actually hurt CompactPT’s performance. The phrase table also has a mode which disables phrasal rank encoding and caching. In this mode performance at higher thread count doesn’t decrease but instead flattens out, however it is unable to achieve better performance than the phrase rank encoding version no matter the thread count. Even if caches don’t cause lock contention at higher thread count, they carry additional overhead during runtime. Our goal in design was to eliminate the necessity for cache by using high performance datastructures and eliminate random memory accesses to maximize the memory bandwidth.

2.1 ProbingPT

Our phrase table is based on an existing linear probing hash table implementation (Heafield, 2011). Linear probing hash provides $O(1)$ search time, has a very small overhead per entry stored and is shown to be very fast in practice (Heafield, 2011). The phrase table consists of two byte arrays: The first contains the probing hash table and the second one contains the payloads (phrase probabilities, word alignments and optionally lexically reordering scores) associated with each entry in the hash table. Hashes of the source phrases are used as keys. When the phrase table is queried, the source phrase is hashed and we try to find it in the probing hash table. If it is found inside the hash table we are given a start and end index corresponding to the location of the target phrases associated with the source phrase queried inside the payloads byte array. The payloads byte array stores consecutively in binary format each target phrase together with its scores and word alignment information. We have also provided the option to store lexical reordering information and sparse features. Unlike previous phrase tables implementations, this phrase table doesn’t employ any compression method which allows for all target phrases associated with a single source phrase to be fetched in a single memory operation. In contrast, both Junczys-Dowmunt’s (2012b) and Zens and Ney (2007) employ pointer chasing during querying in order to extract and reassemble the results. Their approaches are more space-efficient but incur higher memory cost due to increased number of random memory accesses. Furthermore our implementation doesn’t require any scratch memory to decompress queries: they can be read directly from the payloads byte array which contributes to its speed and avoids extra memory operations (allocations/deallocations) or the need for caching. Storing lexical reordering information inside the phrase table reduces the memory usage, because we no longer need to store a key for every lexical reordering score, as we reuse the phrase table key. Extracting lexical reordering scores no longer carries an extra performance penalty as querying is tied to the phrase table query and all related scores would be fetched with the same DRAM burst, because they are stored consecutively in memory. To our knowledge, this is the first phrase table implementation that incorporates lexical reordering table.

The phrase table is part of upstream Moses but it can also be used standalone.

3 Experimental setup

For our performance evaluation we used French-English model trained on 2 million EUROPARL sentences. We used a KenLM (Heafield, 2011)
language model and cube pruning algorithm (Chiang, 2007) with a pop-limit of 400. We time the end to end translation of 200,000 sentences from the training set. All experiments were performed on a machine with two Xeon E5-2680 processors clocked at 2.7 Ghz with total of 16 cores and 16 hyperthreads and 290 GB of RAM. In all of our figures “32 cores” means 16 cores and 16 hyperthreads. Note that hyperthread do not provide additional computational power but merely permit better resource utilization by allowing more work to be scheduled for the CPU by the OS. This allows the CPU to already have scheduled work to do while a scheduled process is waiting for IO. Using hyperthreads will not necessarily increase performance and in cases with high lock contention it can be detrimental for performance.

3.1 Decoders

We use two different decoders for our experiments: The widely used moses machine translation decoder, available publically and Moses2, an experimental faster version of Moses.4 We perform some benchmarks using Moses to show the speedup our implementation offers as a drop-in replacement to existing phrase tables in the widely used decoder. Unfortunately Moses has known multi-threading issues that come from the usage of several functions which call std::locale as part of their initiations, which carries a global lock.1 As such it is not entirely adequate to use it to measure the performance of the phrase tables because it serves as a bottleneck that might hide performance issues. Thus we used the highly optimized Moses2 to show the speed our phrase table can achieve when it is running on a fast decoder, optimized for multi-threading. Furthermore because of their intrusive nature, integrated lexical reordering tables are only implemented in Moses2. It is expected that when Moses2 matures it will be merged back into Moses master.

3.2 PhraseTables

In our experiments we focus on comparing ProbingPT against CompactPT. There are currently two other phrase tables: PhraseDictionaryOnDisk, a multithreading enabled implementation of the Zens and Ney (2007) phrase table and PhraseDictionaryMemory, an in-memory phrase table which reads in the raw phrase table and puts it inside a hash map. Junczys-Dowmunt (2012b) has shown that CompactPT is faster than PhraseDictionaryOnDisk under any condition, so we do not run experiments against it. PhraseDictionaryMemory comes with the downside that it needs to parse in the phrase table first, before decoding can commence, which leads to long loading times and huge memory usage. In our experimental setup, the in-memory phrase table took 20 minutes to load and consumed 86 GBs of memory, more than ten times more memory than any other phrase table. Even when disregarding loading time, we found out that it is consistently 1-5% slower than ProbingPT in various thread configurations. We decided not to include those results, as they do not show anything interesting and because of the aforementioned shortcomings, PhraseDictionaryMemory is seldom used in practice, unless the dataset involved is really tiny.

ProbingPT and CompactPT produced identical translations under the same decoder. In our tests 3 out of 200,000 sentences slightly differ in their translation. This is expected according to Junczys-Dowmunt (2012b) because CompactPT’s fingerprinting leads to collisions and extracting the wrong phrase in few rare cases. We conclude that our implementation is correct and can be used as drop-in replacement for CompactPT. We have provided the complete set of conducted experiments on Figure 5 in the appendix. Those are useful if the reader wishes to compare system/user time usage between different configurations.

3.3 Model sizes

<table>
<thead>

</tr>
<tr>
<td>CompactPT RO</td>
<td>0.6 GB</td>
</tr>
</tbody>
</table>

Table 1: Phrase table sizes

CompactPT which is designed to minimize model size has naturally lower model size compared to ProbingPT. However the extra RAM used is only 2% of the available on our test system which is insignificant. Using the extra memory is justified by the increased performance.
4 Evaluation

Figure 1 shows performance comparison of two systems with CompactPT based reordering tables that differ in the phrase table used. The best performing ProbingPT system here delivers about 30% better performance compared to the corresponding CompactPT system. We see that the CompactPT system doesn’t improve its performance when using more than 8 threads, but the ProbingPT one continues to scale further until it starts using hyperthreads.

We find it likely that the performance of the ProbingPT system on Figure 1 is hampered by the inclusion of CompactPT based reordering. Moses doesn’t support ProbingPT based reordering and in order to measure the head-to-head performance of the two phrase tables we conducted the same test using two systems that do not use reordering tables and only differ by the phrase table, as shown on Figure 2. We can see that ProbingPT consistently outperforms CompactPT by 10-20% at lower thread count but the difference grows as much as 5 times in favour of ProbingPT at the maximum available thread count on the system. If we compare the best performance achieved from both system, ProbingPT is capable of delivering twice the performance of CompactPT. It is important to note that ProbingPT’s performance always increases with the increase of the thread count, whereas CompactPT’s performance doesn’t improve past 8 threads. We can also see that the ProbingPT based system can even take advantage of hyperthreads, which is not possible with any system that uses CompactPT based table (Figure 1). On Table 2 we can observe that removing the reordering table from the CompactPT system has a much smaller effect than removing it from the ProbingPT system. This hints that lexicalized reordering only slows down the decoder because it is implemented in an inefficient manner. We can
conclude that Moses can achieve faster translation times on highly parallel systems by using ProbingPT.

4.1 Why is CompactPT slower?

In the single-threaded case it likely that CompactPT’s many random memory accesses cause it to be slower than ProbingPT, because consecutive memory accesses are much faster due to the DRAM burst effect. When the thread count grows, the performance gap between CompactPT and ProbingPT widens, because of the locking that goes on in the former’s cache. This can be seen from Figure 3 which shows the system time used during the execution of the phrase table only test. System time shows how much time a process has spent inside kernel routines, which includes but is not limited to locking and memory allocation. The ProbingPT system uses orders of magnitude less system time compared to the CompactPT one. The system time used in the CompactPT system grows linearly until 8 threads and then the growth rate starts increasing at a faster rate widening the gap with ProbingPT. This is also the reason why CompactPT’s performance severely degrades when using hyperthreads. The ProbingPT system on the other hand (Figure 3) increases its usage of system time at a linear rate even when using hyperthreads. We can conclude that the simpler design of ProbingPT scales very well with the increase of number of threads and is suitable for use in modern translation systems running on contemporary hardware.

4.2 Integrated reordering table

As integrated lexical reordering is only available in Moses2 we conducted an experiment where we compare systems using CompactPT based reordering and ProbingPT integrated reordering (Figure 4). The best ProbingPT based system is able to translate all sentences in our test set in only 4 minutes, whereas the best CompactPT reordering system took 39 minutes (Table 3). We also observed limited scaling when using CompactPT based reordering: the best performance was achieved at 8 threads. For contrast with Moses (Table 2) we can see that lexicalized reordering has negligible impact on performance if it is used within ProbingPT (We believe the reason we are getting slightly worse results when not using a reordering table are due to a bug in our implementation). We are not entirely certain which factor contributed more to the increased performance: having a reordering table based on the faster ProbingPT or the reduced IO and computational resources that the integrated reordering table requires. As we do not currently have a standalone ProbingPT based reordering table we can not say for sure. Nevertheless we achieve 10x speedup by using our novel reordering table within Moses2.

4.3 Profiling the code

We were very surprised of the speedup our phrase table offered, particularly in Moses2, because in phrase based decoding, the number of phrase table queries increases linearly with the length of the sentence. They constitute a tiny fraction of the number of language model queries, which are about 1 million per sentence (Heafield, 2013). We decided to investigate our results using Google’s profiler. We profiled the pair of systems, displayed on Figure 4, because they showed the highest relative difference between each other. In the system which has ProbingPT based reordering, the language model is responsible for about 40% of the decoding runtime, compared with only 1% in the Moses2 system with CompactPT based reordering. In the latter system the runtime is dominated by CompactPT search and std::locale locking due to the phrase table using string operations during its search.

In Moses the difference between using ProbingPT and CompactPT is not so apparent, before we go to higher thread count, because the decoder itself is very slow and hides the phrase table inefficiencies. It is clear that even though the phrase table queries are a small part of the full decoding process, they are enough to slow it down 10 times if no other bottlenecks exist. Using ProbingPT for both the phrase table and the reordering model makes for a compelling combination.

5 Future work

In the future we will add support for hierarchical phrase tables inside ProbingPT. In hierarchical machine translation the burden on the phrase table is a lot higher so the improved performance would be even more noticeable. Given the difference between the systems with and without ProbingPT based reordering in Table 3 we believe that adding that feature to Moses will allow us to get performance similar to that in the final column of

6 Conclusion

As hardware evolves extremely fast, it may prove useful to revisit old problems which are considered solved. The new available technology compels us to reconsider our priorities and decisions we took in the past.

We designed a faster phrase table that is able to take full advantage of the modern highly parallel CPUs. It shows better performance than related work and also scales better with higher thread count and it helped us expose performance issues in Moses. We believe ProbingPT is useful to industry and researchers who use modern server machines with many cores and a lot of main memory. Enthusiast machine translation users would probably prefer to use CompactPT as it is most suitable when memory is limited and the thread count is low.
