Abstract

In this paper, we investigate different approaches for dialect identification in Arabic broadcast speech. These methods are based on phonetic and lexical features obtained from a speech recognition system, and bottleneck features using the i-vector framework. We studied both generative and discriminative classifiers, and we combined these features using a multi-class Support Vector Machine (SVM). We validated our results on an Arabic/English language identification task, with an accuracy of 100%. We evaluated these features in a binary classifier to discriminate between Modern Standard Arabic (MSA) and Dialectal Arabic, with an accuracy of 100%. We further reported results using the proposed methods to discriminate between the five most widely used dialects of Arabic: namely Egyptian, Gulf, Levantine, North African, and MSA, with an accuracy of 59.2%. We discuss dialect identification errors in the context of dialect code-switching between Dialectal Arabic and MSA, and compare the error pattern between manually labeled data, and the output from our classifier. All the data used on our experiments have been released to the public as a language identification corpus.

Index Terms: Dialect Identification, Vector Space Modelling

1. Introduction

The task of Dialect Identification (DID) is a special case of the more general problem of Language Identification (LID). LID refers to the process of automatically identifying the language class for given speech segment or text document. DID is arguably a more challenging problem than LID, since it consists of identifying the different dialects within the same language class. The importance of addressing DID can be gauged from its growing interest in the Automatic Speech Recognition (ASR) community [1]. A good DID system can facilitate the identification of dialectal segments from an untranscribed mixed-speech dataset. This process can help reduce the ASR word error rate (WER) for dialectal data by training ASR systems for each dialect, or by adapting the ASR models to a particular dialect.

The natural language processing (NLP) community has aggregated dialectal Arabic into five regional language groups: Egyptian (EGY), North African or Maghrebi (NOR), Gulf or Arabian Peninsula (GLF), Levantine (LAV), and Modern Standard Arabic (MSA). An objective comparison of the varieties of Arabic dialects could potentially lead to the conclusion that Arabic dialects are historically related, but not synchronically, and are mutually unintelligible languages like English and Dutch. Normal vernacular can be difficult to understand across different Arabic dialects [2]. Arabic dialects are thus sufficiently distinctive, and it is reasonable to regard the DID task in Arabic as similar to the LID task in other languages. Table 1 shows two phrases across the different dialects, it is clear from this example that there are lexical variations across the different dialects which motivates us to consider it.

Two broad LID approaches have been investigated in the literature: low-level acoustic features, and high-level phonetic and lexical features. In the lexical area, words, roots, morphology, and grammars [3, 4] have been studied. Acoustic features such as shifted delta cepstral coefficients [5] and prosodic features [6] using Gaussian mixture models (GMMs), i-vector representations and support vector machine (SVM) classifiers [5] have been shown to be effective for LID. More recent work explored the use of frame-by-frame phone posteriors (PLLRs) [7] as new features for LID. New subspace approaches based on non-negative factor analysis (NFA) for GMM weight decomposition and adaptation [8] were also applied to both LID and DID tasks. GMM weight adaptation subspaces seem to provide complementary information to the classical i-vector framework. Finally, phoneme sequence modeling and its n-gram subspace have been studied for both Arabic DID [9] and LID [10].

In this paper we investigate three Vector Subspace Models (VSMs) for Arabic DID based on 1) lexical, 2) phonetic, and 3) i-vectors. We conduct a thorough feature selection study of these models to better understand their interaction. A further contribution of this work is the release of an Arabic DID system so others can extend and improve DID performance on this task.\(^5\)

2. Vector Space Models

2.1. Senone based Utterance VSM

Senone refers to an n-gram phone sequence. In our case \(n \leq 4\). VSM construction takes place in two steps: first, a phoneme recognizer is used to extract the senone [11] sequence for a given

\(^5\)https://github.com/Qatar-Computing-Research-Institute/dialectID
speech utterance. The phoneme sequence is obtained by automatic
vowelization of the training text, followed by vowelization to
phonetization (V2P). The 36 chosen phonemes cover all
the dialectal Arabic sounds. Further details about the speech
recognition pipeline, training data, and phoneme set is given
in [12]. For the phoneme sequence, we process the phoneme
lattice, and obtain the one-best transcription, ignoring silences
as well as noisy silences. Each speech utterance (u) is then
represented as a high dimensional sparse vector (\( \mathbf{u} \)):

\[
\mathbf{u} = \{ A(f(u, s_1)), A(f(u, s_2)), \ldots, A(f(u, s_d)) \},
\]

where \( f(u, s_i) \) is the number of times a senone \( s_i \) occurs in
the speech utterance \( u \), and \( A \) is the scaling function. We experi-
ment with both an identity scaling function and \( tf.idf \) scaling
function, commonly used in the field of Natural Language Pro-
cessing [13] to downweight the contribution of the words (in
our case senones) that occur in almost all documents (in our
case utterances), as these words (senones) do not provide any
discriminative information about the speech utterances.

The vector space is then represented by the matrix, \( \mathbf{U} \in \mathbb{R}^{d \times N} \) (see Fig 1). This approach and the notation used to define a
VSM is directly inspired by the seminal works in the area of
VSM of Natural Language in [14, 15, 16] and in LID [17].

\[
\mathbf{U} = \begin{bmatrix}
A(f(s_1, u_1)) & A(f(s_1, u_2)) & \cdots & A(f(s_1, u_N)) \\
A(f(s_2, u_1)) & A(f(s_2, u_2)) & \cdots & A(f(s_2, u_N)) \\
\vdots & \vdots & \ddots & \vdots \\
A(f(s_d, u_1)) & A(f(s_d, u_2)) & \cdots & A(f(s_d, u_N))
\end{bmatrix}
\]

Figure 1: Senone-based utterance VSM. Column vectors of the
matrix correspond to the speech utterance vector representation
formed using equation 1. \( d \) is the size of the senone dictionary,
and \( N \) is the total number of speech utterances in the dialectal
speech database.

2.2. Word based Utterance VSM

The word-based utterance VSM \( \mathbf{U}_w \) is constructed in two
steps in a manner similar to the senone features: An ASR sys-
tem is used to extract the word sequence for each utterance
in the speech database. Details about the ASR system can be
found in [12]. Each speech utterance (u) is then represented as
a high-dimensional sparse vector (\( \mathbf{u} \)):

\[
\mathbf{u} = \{ A(f(u, w_1)), A(f(u, w_2)), \ldots, A(f(u, w_d)) \},
\]

where \( f(u, w_i) \) is the number of times a word \( w_i \) occurs in
the speech utterance \( u \) and \( A \) is the scaling function which has
the same interpretation as for \( \mathbf{U}_s \) (above). Vocabulary size was
55k. The tri-gram dictionary size was 580k which we used to
construct the word based VSM

2.3. i-vector based Utterance VSM

2.3.1. Bottleneck Features (BN)

Recently, bottleneck features extracted from an ASR DNN-
based model were applied successfully to language identifica-
tion [18, 19, 20]. In this paper, we used a similar bottleneck
features configurations as in our previous ASR-DNN system
for MSA speech recognition [21]. This system is based on two
successive DNN models. Both DNNs use the same setup of
5 hidden sigmoid layers and 1 linear BN layer, and they were
both based on tied-states as target outputs. The senone labels
of dimension 3040 are generated by a forced alignment from
an HMM-GMM baseline trained on 60 hours of manually tran-
scribed Al-Jazeera MSA news recordings [12]. The input to the
first DNN consists of 23 critical-band energies that are obtained
from Mel filter-bank. Pitch and voicing probability are then
added. 11 consecutive frames are then stacked together. The
second DNN is used for correcting the posterior outputs of the
first DNN. In this architecture, the input features of the second
DNN are the outputs of the BN layer from the first DNN. Con-
text expansion is achieved by concatenating frames with time
offsets of -10, -5, 0, 5, and 10. Thus, the overall time context
seen by the second DNN is 31 frames.

2.3.2. Modeling

An effective and well-studied method in language and dialect
recognition is the i-vector approach [8, 22, 5]. The i-vector
involves modeling speech using a universal background model
(UBM) – typically a large GMM – trained on a large amount
of data to represent general feature characteristics, which plays
a role of a priori on how all dialects look like. The i-vector ap-
proach is a powerful technique that summarizes all the updates
happening during the adaptation of the UBM mean components
to a given utterance. All this information is modeled in a low
dimensional subspace referred to as the total variability space.
In the i-vector framework, each speech utterance can be rep-
resented by a GMM supervector, which is assumed to be gener-
ated as follows:

\[ M = u + Tv \]

Where \( u \) is the channel and dialect independent supervector
(which can be taken to be the UBM supervector), \( T \) spans a
low-dimensional subspace and \( v \) are the factors that best de-
scribe the utterance-dependent mean offset. The vector \( v \) is
treated as a latent variable with the i-vector being its maximum-
a-posteriori (MAP) point estimate. The subspace matrix \( T \) is
estimated using maximum likelihood on large training dataset.
An efficient procedure for training and for MAP adaptation of i-
vector can be found in [23]. In this approach, the i-vector is the
low-dimensional representation of an audio recording that can
be used for classification and estimation purposes. In our ex-
periments, the UBM was a GMM with 2048 components, BN
features were used, and the i-vectors were 400-dimensional.

In order to maximize the discrimination between the dif-
ferent dialect classes in the i-vector space, we combine Lin-
ear Discriminant Analysis (LDA) and Within Class Co-variance
Normalization [5]. This intersession compensation method has
been used with both SVM [5] and cosine scoring [8].

3. Dataset

3.1. Train Data

The training corpus was collected from the Broadcast News do-
main in four Arabic dialects (EGY, LA V, GLF, and NOR) as
well as MSA. Data recordings were carried out at 16KHz. The
recordings were segmented to avoid speaker overlap, remov-
ing any non-speech parts such as music and background noise.
More details about the training data can be found in [8]. Al-
though the test database came from the same broadcast domain,
the recording setup is different. The test data was downloaded
directly from the high quality video server for Aljazeera (bright-
cove) over the period of July 2104 until January 2015, as part of QCRI Advanced Transcription Service (QATS) [24].

3.2. Test Data

The test set was labeled using the crowdsourced platform Crowd-Flower, with the criteria to have a minimum of three judges per file and up to nine judges, or 75% inter-annotator agreement (whichever comes first). More details about the test set and crowdsourcing experiment can be found in [25]. The test set used in this paper differs from that used in [8] for two reasons: First, the crowdsourced data is available to reproduce the results, and thus can be used as a standard test set for Arabic DIDs; second, the new test set has been collected using different channels, and recording setup compared to the training data, which makes our experiments less sensitive to channel/speaker characteristics.

The train and test data can be found on the QCRI web portal. Table 2 and Table 3 present some statistics about the train and the test data.

4. Experiments

4.1. Choosing the Best Classifier

We first studied the best classification approach for the DID task from a set of two generative models: n-gram language model [26] and Naive Bayes [27], and two discriminative classifiers: linear SVM [28] and Maximum Entropy [29]. We measured the performance of each model on the DID task, in the word or lexical-based utterance vector space, which is constructed using the approach mentioned in section 2, using identity scaling function, and performing no dimensionality reduction. Hence, the dimensionality of an utterance vector, \( d_{\text{Ut}} \), is the same as the size of the lexicon, which in our case was 55k. Results can be seen in table 4. As the linear SVM performs the best, it is our choice of classifier for the rest of the experiments.

4.2. Feature Selection Study

Here we examine the dialect information captured by the three utterance VSMs explained in section 2. We also explore the concatenation of the utterance vector representations, and report the results in Tables 5 and 6. Details about the terms in the results table are given below:

- \( U_{w}^{i} \): Refers to the utterance VSM in which each utterance is represented by a vector given by equation 2, where \( A \) is chosen to be the identity function. The bases of the vectors are the words in the lexicon. SVD is used to reduce the dimensionality of the utterance Vector Space from 55k originally, to 300, 600, 1200, 1600 at which point increase the gain in the classification performance tends to saturate.

- \( U_{w}^{i, idf} \): Same as the previous Utterance VSM, except that \( A \) is chosen via \( t.f.idf \) [13] instead of identity function, which gives us significant improvement in accuracy over the previous vector space.

- \( U_{s}^{i} \): Refers to the utterance VSM in which each utterance is represented by a vector given by equation 1, where \( A \) is chosen to be the identity function. Utterance vector bases corresponds to senones. Just as with the word-based utterance VSM, we use SVD on the vector space and experiment with different dimensions. The utterance Vector Space constructed using senone features is more discriminative than word-based Vector space.

- \( U_{s}^{i, idf} \): Refers to the same vector space as the previous one, except that \( A \) is chosen to be the \( t.f.idf \) function. \( t.f.idf \), does not help in the case of senone features.

- **Feature Combination:** Combining the best senone-based utterance VSM, \( U_{s}^{i} \), and the best lexical-based utterance VSM, \( U_{w}^{i, idf} \), to form a concatenated feature vector representation. SVD is performed to reduce the dimensions of the feature space. Feature combination does not help and hence we conclude that the two vector spaces are capturing similar information.

- \( U_{\text{Vec}}^{i} \): Refers to the utterance VSM, where each utterance is represented by a compact 400d i-vector (section 2.3). We use the bottleneck features to train the UBM, which is then used to extract the i-vector. We do not experiment with different i-vector dimensions and take the best dimension reported in [5] for the LID task. The i-vector feature space is significantly more discriminative than previously defined feature spaces.

- \( U_{\text{Vec} + LDA + WCNN} \): Reducing the dimensionality of the i-vector space using LDA and performing WCNN has been reported to do well in LID tasks [5] and we use the same technique and see a significant improvement in the DID results.

- \( U_{\text{Vec} + LDA + WCNN} + U_{s}^{i} \): Finally we concatenate the best senone-based VSM with the best i-vector-based VSM, to form a concatenated vector representation for each utterance and see slight improvements in the results. As the lexical and senone-based representations encode the same information about the dialect, we do not experiment with concatenated lexical and i-vector representations.

</tr>
</tbody>
</table>

Table 4: Performance of different classifiers using lexical features, with lexicon size of 55k. ACC, PRC and RCL correspond to accuracy, precision and recall on the test set.
4.4. System Output Combination

We fused the scores of the best senone system and the SVM-based i-vector system. In the fusion steps, the original scores of each system were normalized and combined using the same fusion weights for both systems. This approach yielded a final accuracy of 60.2%, which is the best performance we achieved.

4.5. Discussion

We infer from the confusion matrix in Table 7 that GLF and LAV are the most confusable dialect pair. We believe that this is related to the greater lexical similarity between these two dialects (see Table 1). Note, the confusion matrix is from the best DID system. We borrowed Table 8 from previous work [25] on the test set, which shows the amount of time the same speakers switch between dialect and another (mainly MSA, and their own native dialect). For example, in the second row of Table 8, there are 200 samples from potential Gulf speakers. After manually labeling, there were 106 (53%) segments labeled as MSA, 82 (41%) validated as GLF, 8 (4%) as LAV, and 4 segments were not identified with enough confidence to be considered. This means more than 50% of the random GLF speakers data is in fact MSA speech segments. This is strong evidence for the amount of code-switching between one dialect and MSA from the same speaker.

6. Conclusions

This paper presents our efforts on automatic dialect identification for Arabic broadcast speech. We have demonstrated a dialect classifier with an accuracy of 60.2% using system combination. We also achieved 100% accuracy on two binary classification tasks; MSA vs Dialectal Arabic and English vs Arabic. We studied the potential code-switching pattern in our classifier and its correlation with the manual annotation. Further work for this research is to study the code-switch between MSA and dialectal Arabic without considering speaker diarization or silence between speech segments in what can be called dialectalization. We shall also study deep neural network approaches of classification to learn a more complex non-linear decision boundary.
