Soil erosion by water impacts soil organic carbon stocks and alters CO₂ fluxes exchanged with the atmosphere. The role of erosion as a net sink or source of atmospheric CO₂ remains highly debated, and little information is available at scales larger than small catchments or regions. This study attempts to quantify the lateral transport of soil carbon and consequent land–atmosphere CO₂ fluxes at the scale of China, where severe erosion has occurred for several decades. Based on the distribution of soil erosion rates derived from detailed national surveys and soil carbon inventories, here we show that water erosion in China displaced 180 ± 80 Mt cy⁻¹ of soil organic carbon during the last two decades, and this resulted in a net land sink for atmospheric CO₂ of 45 ± 25 Mt cy⁻¹, equivalent to 8–37% of the terrestrial carbon sink previously assessed in China. Interestingly, the “hotspots,” largely distributed in mountainous regions in the most intensive sink areas (>40 g C·m⁻²·y⁻¹), occupy only 1.5% of the total area suffering water erosion, but contribute 19.3% to the national erosion-induced CO₂ sink. The erosion-induced CO₂ sink underwent a remarkable reduction of about 16% from the middle 1990s to the early 2010s, due to diminishing erosion after the implementation of large-scale soil conservation programs. These findings demonstrate the necessity of including erosion-induced CO₂ in the terrestrial budget, hence reducing the level of uncertainty.

**Significance**

The role of soil erosion as a net sink or source of atmospheric CO₂ remains highly debated. This work quantifies national-scale land–atmosphere CO₂ fluxes induced by soil erosion. Severe water erosion in China has caused displacement of 180 ± 80 Mt cy⁻¹ of soil organic carbon during the last two decades, and the consequent land–atmosphere CO₂ flux from water erosion is a net CO₂ sink of 45 ± 25 Mt cy⁻¹, equivalent to 8–37% of the terrestrial carbon sink previously assessed in China. This closes an important gap concerning large-scale estimation of lateral and vertical CO₂ fluxes from water erosion and highlights the importance of reducing uncertainty in assessing terrestrial carbon balance.

**Significance**

The role of soil erosion as a net sink or source of atmospheric CO₂ remains highly debated. This work quantifies national-scale land–atmosphere CO₂ fluxes induced by soil erosion. Severe water erosion in China has caused displacement of 180 ± 80 Mt cy⁻¹ of soil organic carbon during the last two decades, and the consequent land–atmosphere CO₂ flux from water erosion is a net CO₂ sink of 45 ± 25 Mt cy⁻¹, equivalent to 8–37% of the terrestrial carbon sink previously assessed in China. This closes an important gap concerning large-scale estimation of lateral and vertical CO₂ fluxes from water erosion and highlights the importance of reducing uncertainty in assessing terrestrial carbon balance.
The carbon balance of soils in China is impacted by soil erosion in many regions (17, 18). The aim here is to quantify the horizontal carbon transport induced by water erosion and consequent land–atmosphere CO₂ fluxes in China during the last ~20 y. The case of China is an interesting “natural experiment” because of severe erosion in the 1980s, which was reduced substantially after implementation of national large-scale soil conservation programs in the 1990s (19).

Results

China occupies a large area of about 9.6 million square kilometers located within 73°33'E–135°05'E and 3°51'N–53°33'N. Its landforms range from deserts and plains to mountains, and its average land elevation varies from 3,000 m above sea level in Tibet to 10 m above sea level in the coastal region, roughly forming three steps from the west to the east. China covers several different climatic zones, and experiences annual precipitation varying from less than 400 mm in the dry area in the northwest to 2,000 mm in the southmost region. Consequently, China experiences very complicated soil erosion processes, of which the water-induced soil erosion is the most widely distributed. To estimate the carbon balance changes due to water erosion, we first give an overall picture of soil erosion and conservation based on the two national survey datasets of soil erosion in China from 1995–1996 and 2010–2012 (SI Appendix, National Survey on Soil Erosion and cese.pku.edu.cn/chinaerosion). Then, by combining erosion rates with soil carbon samples collected at 8,980 sampling locations for all soil types (20) (SI Appendix, Vertical Distribution of Soil Organic Carbon and globalchange.bnu.edu.cn/research/soil2), five erosion-related C flux components are quantified. As illustrated in Fig. 1, F1 is the removal of carbon from eroded soils, F2 is the deposition of eroded soil carbon, F3 is the dynamic replacement of atmospheric CO₂ in eroded soils, F4 is the carbon source to the atmosphere due to the decomposition of buried carbon, and F5 is the CO₂ source to the atmosphere from the decomposition of carbon during transport. F3 – (F4 + F5) constitutes the net land–atmosphere CO₂ flux from erosion; F1 and F2 represent components of the horizontal displacement of carbon.

Soil Erosion and Conservation in China. Fig. 2. Fig. 2 A and B shows the distributions over China of mean erosion rate and the change in erosion rate determined from the two national surveys (the second national survey was carried out in 1995–1996, and the fourth national survey was carried out in 2010–2012) that combined remote sensing land cover imaging with field data (recorded in 68,155 survey units covering 1% of the total area experiencing water erosion; for details of land cover, precipitation and soil distribution, see SI Appendix, Data). The most fragile soils in China are Mollisol, Calcic Inceptisols, and Ultisols based on the US Department of Agriculture (USDA) soil taxonomy [and Phaeozems, Calcic Cambisols, and Planosols based on Food and Agriculture Organization (FAO) soil classification]. As shown in Fig. 2A, the most intensively eroded regions are in the Loess Plateau region (mean rate of 3.0 ± 1.2 mm y⁻¹ and soil removal 1.59 ± 0.39 Gt y⁻¹), comprising 30.1% of the total) and in the upper Yangtze River Basin (mean rate 2.6 ± 1.0 mm y⁻¹ and total soil removal 1.37 ± 0.53 Gt y⁻¹, comprising 25.9% of the total), both of which have soils composed of readily eroded Inceptisols, based on USDA soil taxonomy (or Cambisols, based on FAO soil classification (21)).

Heavy rainfall events during the wet season (22), and intensive agriculture (23). Classified according to the water erosion grade, the histogram in Fig. 2A, Inset, shows that soil removal in Grade 3 areas (i.e., erosion rate = 1.90–3.70 mm y⁻¹) contributes the most to total soil loss (1.8 ± 0.6 Gt y⁻¹, taking 34 ± 11% of the total), whereas Grade 2 areas (erosion rate = 0.74–1.90 mm y⁻¹) comprise the largest proportion of the total erosional area (760,908 km², i.e., 50% of the total). After 1990, a huge national-scale program of “returning farmland to forests and grassland” for soil conservation and restoration was implemented in China, especially in the Loess plateau regions. About 22% of the total eroded area was put into restoration, mainly through soil conservation and afforestation projects. Hydraulic engineering works such as terracing, check dams, and shelterbelts affected an area of about 1 million square kilometers during 2002–2012. Restrictions on forest litter raking and grazing in mountainous regions were further implemented over 0.75 million square kilometers during the same period (24) in North China (including the Loess Plateau) and Southwest China (including the upper Yangtze River). The histogram in Fig. 2B, Inset, shows that the combined area of Grades 2, 3, and 4 erosion (erosion rates = 0.74–0.90 mm y⁻¹, 1.90–3.70 mm y⁻¹, and 3.70–5.90 mm y⁻¹, respectively) was reduced by 461,000 km² (i.e., reduction of 1.3 ± 0.6 Gt y⁻¹ in soil removal). However, the combined area of Grades 5 and 6 erosion (erosion rate = 5.90–11.10 mm y⁻¹, and erosion rate > 11.10 mm y⁻¹, respectively) increased by 25,000 km² (i.e., increase of 0.3 ± 0.1 Gt y⁻¹ in soil removal). The largest reduction of soil erosion in between the time periods covered by the two national surveys occurred in the Loess Plateau, where the erosion rate was reduced by 0.5 ± 0.2 mm y⁻¹, and the total removal of soil was reduced by 1.1 ± 0.4 Gt y⁻¹.

Conversely, the rates of erosion continued to increase in 345 out of 378 counties in Northeastern and Southern China by 0.6 Gt y⁻¹, with a 43.6% increase in erosional area in these two regions.

Flux of Soil Carbon Removal. The flux component associated with removal of soil carbon by erosion (F1; SI Appendix, Table S1),
obtained by multiplying soil organic carbon (SOC) content from inventories by erosion rate, amounts to a total of 180 ± 80 Mt C y⁻¹ over the last two decades. This removal flux is higher in regions with intensive erosion and high initial SOC densities (see Fig. 3A). The upper Yangtze River region, with an average F1 of 140 ± 63 g C m⁻² y⁻¹ for an eroded area of 367,525 km², contributes 29% to the total removal carbon, whereas North China has a smaller removal rate of 75 ± 35 g C m⁻² y⁻¹ despite very severe erosion since the early 1950s (25). This decoupling between carbon removal and erosion rate is explained by the relatively low initial soil carbon content of North China (26). The histogram in Fig. 3A, Inset, shows that F1 in the erosional area of Grade 3 (erosion rate = 1.90–3.70 mm y⁻¹) has the largest value (79 ± 25 Mt C y⁻¹). However, the SOC removal is most intensive (469 ± 156 g C m⁻² y⁻¹) in areas that are Grade 6 (erosion rate > 11.10 mm y⁻¹).

Between the two national surveys, F1 decreased by 44% (64 ± 28 g C m⁻² y⁻¹) due to the reduction of eroded areas. The histogram in Fig. 3B, Inset, shows that F1 reduced by 80 ± 36 g C m⁻² y⁻¹ in the combined area occupied by Inner Mongolia, North China, Northwest China, Southwest China, and where erosion slowed down (the total erosional area of the four regions reached 1,100,000 km²), whereas F1 increased by 35 ± 16 g C m⁻² y⁻¹ in Northeast and South China, where erosion intensified. The histogram in Fig. 3B, Inset, shows that F1 decreased by 127 ± 50 Mt C y⁻¹ in the regions of water erosion Grades 2, 3, and 4 (erosion rates = 0.74–0.90 mm y⁻¹, 1.90–3.70 mm y⁻¹, and 3.70–5.90 mm y⁻¹, respectively) but increased by 34 ± 11 Mt C y⁻¹ in Grades 5 and 6 regions (erosion rate = 5.90–11.10 mm y⁻¹, and erosion rate > 11.10 mm y⁻¹, respectively), mainly due to the corresponding changes in areas of each erosion grade.

Flux of Soil Carbon Deposition. The flux component representing deposition of eroded soil carbon (F2; SI Appendix, Table S1) was estimated from sediment delivery ratio (SDR) data. SDR is defined as the sediment yield at the outlet of a given small catchment and indicates the efficiency by which soil eroded in the catchment hillslopes is exported from the catchment. According to field data (22), SDR in the range 0.1–1 is positively correlated with erosion severity. Hence, typical nationwide SDR enables grading according to the five classes of erosion severity and is applied to each of the 30,670 minimum polygons generated by the upscaling approach (SI Appendix, Scale-up approach based on minimum polygons). We derive F2 for the whole of China by summation over all polygons, giving a total F2 of 98 ± 58 Mt C y⁻¹ averaged over the period between the two national surveys. The largest deposition rates are found for the Tibet Plateau, where the area affected by water erosion is only a small fraction of the total area (190 ± 118 g C m⁻² y⁻¹), followed by Northeast China (90 ± 53 g C m⁻² y⁻¹).

Erosion-Induced CO₂ Flux in the Erosional Area. Now we examine the effects of erosion on land–atmosphere CO₂ fluxes. The dynamic replacement flux component F3 is calculated using a modified method based on Van Oost et al. (11) that estimates the erosion-induced CO₂ flux in an area of interest by comparing the modeled SOC content of a soil profile (SI Appendix, Identifying the erosion-induced CO₂ fluxes). The calculated rate of CO₂ uptake (SI Appendix, Table S1) is 32 ± 16 g C m⁻² y⁻¹ nationwide, and the total dynamic replacement integrated across all eroded areas is 47 ± 24 Mt C y⁻¹. Fig. 3C shows that the spatial distribution of F3 is rather uniform across China, except for a few areas in Northeast, Northwest, and Southwest China that are CO₂ sources. Severely eroded areas in Southwest and North China (Fig. 2D) make the greatest contributions to the recovery CO₂ sink (17.6 ± 5.3 Mt C y⁻¹ and 9.5 ± 6.6 Mt C y⁻¹, respectively).

Spatial distributions of decadal changes in the recovery CO₂ sink during the period between the two national surveys (Fig. 3D) and of the removal flux (Fig. 3B) are similar. This demonstrates that the acceleration or slowdown of horizontal carbon removal has changed the dynamic replacement in the same direction. For example, the dynamic replacement increased by 17 ± 10 g C m⁻² y⁻¹ and 23 ± 16 g C m⁻² y⁻¹ in Northeast and South China, where soil erosion accelerated during the period between the two national surveys. Meanwhile, the dynamic replacement weakened by 10 ± 5 g C m⁻² y⁻¹ in the Loess Plateau due to sustained soil conservation over the past ~20 y. Fig. 3D, Inset, also highlights a linear relationship between soil removal and F3 (R² = 0.87). Overall, the recovery CO₂ sink at

![Image](A) Spatial distributions of water erosion in China from national surveys in 1995–1996 and 2010–2012. (A) Averaged erosion rate of the two surveys, where red lines demark boundaries of Loess Plateau and Upper Yangtze River Basin that suffer the most intensive water erosion. (B) Change in erosion rate during period between the two surveys, where red lines demark boundaries of regions in Northeast and South China that experience fastest increase in erosional area. Insets consist of histograms of (A) average and (B) change in total soil removal with superimposed black dots indicating water erosion area, classified according to water erosion grade.
the country scale decreased from 52 ± 28 Mt C yr⁻¹ in 1995–1996 to 42 ± 21 Mt C yr⁻¹ in 2010–2012, being primarily driven by effective soil conservation measures in China. Interestingly, the plot of accumulated F3 as a function of accumulated erosion area (defined as an area with water erosion rate larger than 0.74 mm yr⁻¹) in Fig. 3C, inset, shows that the most intensive sink area (>40 g C m⁻² yr⁻¹) contributes 19.5% (0.9 Mt C⁻¹) to the national erosion-induced carbon sink while taking up only 1.3% of the total area undergoing water erosion. By contrast, the weakest sink area (<10 g C m⁻² yr⁻¹) contributes only 26% (12.2 Mt C⁻¹) of the total sink although it covers 79.3% of the erosional area. The largest rates of recovery CO₂ uptake are located in North and Southwest regions where erosion is still severe. This finding agrees with saturation theory that the most efficient uptake of CO₂ by a soil carbon pool occurs when it is farthest from carbon saturation (27).

It should be noted that the modified method based on Van Oost et al. (11) ignores dissolved losses of C from topsoil through leaching, which could contribute another source of vertical loss. As suggested by Li et al. (28), Long et al. (29), and Gou et al. (30), the dissolved organic carbon (DOC) leaching potential ranges from 3.8 to 8.7 kg ha⁻¹ yr⁻¹, corresponding to a DOC leaching potential of 0.55–0.96 Mt C⁻¹. Li et al. (28) assumed that DOC leaching is linearly proportional to precipitation, and thus derived an empirical formula for leaching of hillslope croplands in a subtropical forest catchment of the Yangtze River basin. Using this alternative approach, the DOC leaching potential throughout China is estimated to be 0.94 Mt C⁻¹ using yearly averaged precipitation data for the period 1995–2012. These two sets of results show that the potential DOC leaching flux in China is negligible compared with F3.

Erosion-Induced CO₂ Flux in the Depositional Area. It is commonly accepted that deposition of carbon induces a CO₂ source in the depositional area (13, 31). As the eroded soil is deposited, part of the previous topsoil carbon enters into and enriches the first layer of subsoil (31). Decomposition of the newly buried carbon-rich soil brings about an extra CO₂ source. This flux component F4 was calculated as the product of deposited SOC (F2) by the decomposition rate of carbon in the subsoil layer, assuming an exponentially decreasing law of turnover rate with depth (SI Appendix, Erosion-Induced CO₂ Source), which yields an estimate of F4 in the range 0.6 ± 0.4 g C m⁻² yr⁻¹, equivalent to a net CO₂ source to the atmosphere of 0.9 ± 0.5 Mt C⁻¹. Beres et al. (32) found that the rate of decay of the most active soil C pool in a depositional landform located in naturally eroding grassland is far from exponentially declining. At or near steady state (for soil and C accumulation), the assumption of exponential decay should nevertheless be acceptable. However, at the timescales under consideration (decades), the buried SOC can effectively be preserved (e.g., refs. 11, 33, and 34), because the decay rates in burial zones are substantially lower than in topsoils for both steady and dynamic profiles. Thus, the physical environment is the key control, rather than the chemical nature of the SOC, and the approximation of an exponential law of decay is acceptable.

Erosion-Induced CO₂ Flux During Sediment Transport. By breaking down the soil aggregates and transporting soil material, erosion promotes carbon emission. Although Jacinthe et al. (35) found, in an incubation experiment, that a substantial fraction of SOC (20–50%) degraded into CO₂ after 100 d, other studies [e.g., Wang et al. (34) and Van Hemelryck (36)] reported that the additional release was hardly induced by erosion compared with the baseline condition of noneroding soil. Following Guenet et al. (37), who measured the enhanced emission when SOC enters the aquatic environment, we assumed that the rate of decomposition is \(\sim\)63% higher during transport. As a result, we further derived the erosion-induced flux component during transport F5 to be a CO₂ source of 1 ± 0.5 Mt C yr⁻¹, which is relatively small compared with F3. The present approach is therefore consistent with the understanding of the impact of erosion on soil C decomposition rates on land.

Discussion
Importance and Comparison. F1 represents 0.16% of the total 100–120 Gt C (38, 39) of SOC storage in China. Lal (7) derived the amount of soil erosion from sediment transport data collected from different basins worldwide. By assuming the SOC content to be 2–3%, Lal estimated that SOC removals in Europe and Oceania, each of which have a similar area to China, are 200–400 Mt C⁻¹ and 100–200 Mt C⁻¹, respectively; these values are comparable with F1 in China, where SOC content is 3.4%. However, Zhang et al. (40) calculated a much higher SOC erosion of 640–1,040 Mt C yr⁻¹ based on a much higher assessment of soil erosion (11.3–18.2 Gt yr⁻¹) than in the present study (3.2–7.4 Gt yr⁻¹). SOC deposition represents 55% of SOC removal flux in the same source catchment. Ratios of F2 to F1 averaged over Yangtze River Basin, Pearl River Basin, Huai River, and Yongding River Basin agree well with values obtained in a previous study (41), whereas those of the Yellow River Basin and Liao River Basin are higher. An important sink of carbon is SOC exported from the source watersheds that enters into the aquatic environment (42, 43), and that can be determined from subtracting the terrestrial deposition from the SOC removal (F1 – F2). It can be seen that total SOC exported from source catchments is 82 ± 49 Mt C⁻¹ (SI Appendix, Table S1), which represents roughly half of the total SOC eroded inland. This implies that the potential aquatic carbon sink in China can be significant. Of all the regions, the Southwest contributes most to total SOC exported from source watersheds (28 ± 16 Mt C⁻¹). In particular, SOC that is finally delivered to the ocean comprises a more permanent sink. The particulate organic carbon (POC) fluxes at the outlets of seven major river basins in China, whose combined drainage area is \(\sim\)76% of the total external drainage area of China, imply that the burial of carbon with sediment from these rivers sums up to 5.4 Mt C yr⁻¹ (SI Appendix, Table S2).

Averaged over the total area suffering water erosion, F3 is 33 g C m⁻² yr⁻¹, roughly within the range of 0.7–60 g C m⁻² yr⁻¹ obtained from field estimates for small watersheds in Europe and North America (11, 13, 44–46). It is important to note that the recovery CO₂ sink is smaller than the horizontal removal of carbon (F1). The average ratio of vertical F3 to F1 (vertical to lateral carbon ratio, VLC) in eroding areas is \(\sim\)0.25, approximately comparable with Van Oost et al.’s (11) value of 0.26 estimated for representative small watersheds in Europe and extrapolated to global scale. In China, lower VLC ratios occur in the Tibetan Plateau (\(\sim\)0.05), Northwest China (\(\sim\)0.12), and Inner Mongolia (\(\sim\)0.17), where the water erosion area is limited. Conversely, higher VLC ratios are found in North China (\(\sim\)0.51) and Southwest regions (\(\sim\)0.34) subject to intensive water erosion. This also implies an increasing trend of erosion-induced recovery CO₂ sink in the Northeast and the Southeast regions, noting their relatively high VLC ratios and increasing trend of SOC removal during the past 20 y. The average ratio of dynamic replacement to SOC removal obtained in the present study for China is 0.25; hence, we estimate the magnitude of the global recovery CO₂ sink to be on the order of 0.1–0.4 Gt C yr⁻¹ (the global SOC flux having previously been estimated to be 0.4–1.6 Gt C yr⁻¹) (11, 47, 48). In other words, erosion-induced CO₂ sequestration could contribute 5–20% to the global land sink.

Compared with the erosion-induced CO₂ sink in the erosional area, the enhanced CO₂ emissions in the depositional area or during sediment transport are relatively small, together representing ~4% of F3. Therefore, the total vertical C flux obtained by summing up F3, F4, and F5 equates to a CO₂ sink of 45 ± 25 Mt C yr⁻¹ (SI Appendix, Table S1), taking up 8–37% of the total terrestrial CO₂ sink of China (0.19–0.26 Gt C yr⁻¹) (3).

Control of Carbon Flux. A sharp decrease in SOC removal occurred over the past \(\sim\)20 y, which may be mainly attributed to the large reduction in soil erosion resulting from conservation activities and climate change. Miao et al. (49) suggested that climate change
contributed 17% and 48% to the decrease of sediment yield in the upper and middle reaches, respectively, of Yellow River Basin, whereas conservation activities contributed 83% and 52% from 1958 to 2008. This implies that China’s conservation policy has proved very efficient in controlling soil loss. The reduced soil erosion also caused the erosion-induced CO$_2$ sink to diminish in the erosional area (F3). A sensitivity analysis carried out by altering each parameter by $\pm$20% (SI Appendix, Uncertainty and Sensitivity Analysis) shows that carbon input ($\pm$29%) is the primary factor determining the CO$_2$ sink, followed by erosion rate ($\pm$23%) and carbon turnover rate ($\pm$13%). To further diagnose the influences of various drivers that have not been included in the model calculation, we performed multiple linear regression of F3 over all land polygons as a function of vegetation type, annual precipitation, and average temperature. The results show that the spatial variation of F3 is primarily driven by the average temperature (18.8%), which controls the key parameter of net primary production (NPP) through affecting the enzyme kinetics during the processes of photosynthesis and autotrophic respiration (50, 51), and is secondarily driven by precipitation and vegetation types. The most sensitive regions, which are small in area but contribute a great amount to both lateral and vertical C fluxes, are hotspots on which conservation policies should be focused.

Conclusions
In summary, our results show that water erosion removed 180 $\pm$ 80 Mt C y$^{-1}$ of soil carbon in China over the last two decades, which caused a redistribution of land–atmosphere CO$_2$ fluxes. The erosion-induced CO$_2$ sequestration is about 8–37% of the terrestrial carbon sink at country scale. According to the average ratio of dynamic replacement to SOC removal obtained in this study for China (0.25), we extrapolate that erosion-induced CO$_2$ sequestration could contribute 5–20% of the global land sink. These results confirm the significance of lateral soil carbon transport by erosion processes in the global carbon cycle, and
highlight the importance of reducing uncertainty in assessing the terrestrial carbon balance due to soil erosion.

Methods

The lateral and vertical carbon fluxes induced by water erosion of soils are calculated using a variety of sources such as soil carbon budgets (compiled in 1995–1996 and 2010–2012) on erosion rates and a national soil database containing 9,980 profiles, together with NPP and carbon pool turnover rate data derived from 10 global carbon cycle models. Furthermore, multiple regression analysis is undertaken based on long series data on distributions of vegetation cover and climatic information (1995–2012) obtained from 675 gauging stations located throughout China.

Estimates of lateral SOC fluxes of erosion (F1), deposition (F2), and the carbon balance at the erosional area (F3) were determined based on minimum polygon areas generated by overlaying the data layers of erosion rate, soil carbon content, NPP, and carbon pool turnover rate in ArcGIS. F1 was given by the product of erosion rate and SOC content in the eroded soil (SI Appendix, SOC erosion). F2 was determined by introducing the concept of sediment delivery ratio (SI Appendix, SOC deposition). F3 was assessed using a modified model based on Van Oost et al.’s method (11) (SI Appendix, Carbon Recovery at the Eroded Area). These three fluxes were calculated and their values added up for each polygon, and the total flux at country scale was obtained by summation over all polygons (SI Appendix, Scale-up approach based on minimum polygon). Erosion-induced CO₂ flux at the depositional area (F4) was estimated as the CO₂ emission from the newly buried carbon-rich topsoil (SI Appendix, Erosion-Induced CO₂ Source). Erosion-induced CO₂ flux during sediment transport (F5) was determined as the difference between CO₂ emissions before and after erosion (SI Appendix, Enhanced Decomposition of SOC).
