ABSTRACT

Background

Fatigue is a common and disabling symptom in people with a primary brain tumour (PBT). The effectiveness of interventions for treating clinically significant levels of fatigue in this population is unclear.

Objectives

To assess the effectiveness and safety of pharmacological and non-pharmacological interventions for adults with PBT and high levels of fatigue.

Search methods

In March 2016, we searched the Cochrane Register of Controlled Trials (CENTRAL), MEDLINE, PsycINFO and CINAHL and checked the reference lists of included studies. We also searched relevant conference proceedings, searched for ongoing trials via ClinicalTrials.gov and contacted major co-operative groups with trials in this area.

Selection criteria

We included randomised controlled trials (RCTs) that investigated any pharmacological or non-pharmacological intervention in adults with PBT and fatigue, where fatigue was the primary outcome measure. We restricted inclusion specifically to studies that enrolled only participants with clinically significant levels of fatigue.

Data collection and analysis

Three review authors (JD, SYK, DC) independently evaluated search results, extracted data from selected studies and carried out a bias risk assessment. We extracted data on fatigue, cognition, mood, quality of life and adverse events outcomes.
Main results

We identified nine studies. We excluded eight of these as they did not restrict participation to people with high fatigue. The single eligible trial investigated the use of modafinil compared to placebo. Although this study found a significant improvement over time in the primary outcome of fatigue, the improvement occurred after both modafinil and placebo with no significant difference in response between the two groups. The included trial did not reach its planned recruitment target and therefore may not, in practice, have been adequately powered to detect a difference. The trial was at a low risk of bias across most areas. There was an unclear risk of bias related to the use of mean imputation because the investigators did not analyse the impact of imputation on the results.

Authors’ conclusions

There was insufficient evidence to draw reliable and generalisable conclusions regarding potential effectiveness or harm of any pharmacological or non-pharmacological treatments for fatigue in people with PBT. More research is needed on how best to treat people with brain tumours with high fatigue.

**PLAIN LANGUAGE SUMMARY**

**Interventions for the management of fatigue in adults with a primary brain tumour**

**Background**

A primary brain tumour (PBT) is a cancer that began in the brain rather than spread from other parts of the body. Fatigue (tiredness) is common in people with a PBT. This may be due to the tumour, its treatment or to the use of other medicines such as antiepileptic drugs (which are used to treat epilepsy seizures). It may also occur with other symptoms such as sleep disturbance, thinking problems and emotional distress. Treatments to help manage fatigue may improve a person’s quality of life, their ability to tolerate cancer treatment (which themselves are associated with fatigue), and their ability to carry out social and day-to-day activities.

**Study characteristics**

In March 2016, we searched five medical databases. We found one clinical trial that was eligible for inclusion; the trial investigated the medicine modafinil in 37 adults with PBT and high levels of fatigue. People in the study received six weeks of modafinil followed by a one-week washout period and six further weeks of placebo, or vice versa. The washout period aims to allow time for any effects of the first treatment to wear off before the new one gets started.

**Key findings**

The one included trial found no evidence of a difference between modafinil and placebo in treating fatigue. It is possible that this could be due to the trial not reaching its planned number of participants. Several other studies investigated the management of fatigue too, but in these studies high fatigue was not essential for participation. We do not currently know whether any treatments are effective in the management of people with PBT and high fatigue.

**Quality of the evidence**

With only one included trial, the overall quality of evidence was low. More high-quality studies are needed that enrol adults with BPT and high fatigue.
### Summary of Findings for the Main Comparison

**Modafinil compared with placebo for fatigue in people with a primary brain tumour**

**Patient or population:** people with a primary brain tumour  
**Settings:** hospital, outpatient  
**Intervention:** modafinil  
**Comparison:** placebo

*Illustrative comparative risks are hypothetical values used for illustrative purposes.*
| Fatigue - fatigue severity | The mean fatigue severity score ranged across control groups from 34.06 to 36.22 points. | The mean fatigue severity score in the intervention groups was **0.22 lower** (-0.79 to 0.35 lower) | - | 37 (1) | ⚫⚫⚫⚫ low | High scores indicate a high level of fatigue |
| Adverse events (follow-up: 6 weeks) | Low-risk population | RR 2.79, 95% CI 0.59 to 13.16 (1 to 180) | - | 37 (1) | ⚫⚫⚫⚫ low | |

* The basis for the **assumed risk** (e.g. the median control group risk across studies) is provided in footnotes. The **corresponding risk** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

CI: confidence interval; RR: risk ratio.

**GRADE Working Group grades of evidence**
- **High quality**: Further research is very unlikely to change our confidence in the estimate of effect.
- **Moderate quality**: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
- **Low quality**: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
- **Very low quality**: We are very uncertain about the estimate.
BACKGROUND

Description of the condition
Fatigue is one of the most common symptoms experienced by people with cancer. The reported prevalence rates for cancer-related fatigue in the clinical trial setting is in the range of 70% to 80% (Lawrence 2004; Lovely 1999). Cancer-related fatigue is "a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer that is not proportional to recent activity and interferes with usual functioning" (NCCN 2014). Fatigue is also a common adverse effect of cancer treatment (Roscoe 2002), occurs across various cancer types (Stone 2000), and persists in disease-free survivors (Serraes 2007). As the scientific knowledge about cancer-related fatigue expands, there is increasing recognition on the importance of its effective management (Goedendorp 2009).

Prevalence of fatigue in primary brain tumours
Prevalence estimates suggest that as in other cancer populations, fatigue is an extremely common problem in people with a primary brain tumour (PBT). In one study, 96% of people with high-grade glioma reported moderate or severe fatigue (Fox 2007). Studies enrolling mixed high-grade and low-grade tumour populations estimated that up to 42% of people with PBT had fatigue (Pelletier 2002). Fatigue remains troublesome throughout the course of survivorship, from the 12 months following PBT diagnosis (Molassiotis 2010), to more than eight years after diagnosis (Struik 2009). Fatigue in PBT has been studied both as a primary outcome (Armstrong 2010; Lovely 1999), and as a secondary outcome related to symptoms such as depression (Rooney 2011), poor quality of life (Kvale 2009), and sleep-wake disturbances (Miaskowski 2011).

Associated clinical variables
Fatigue in the setting of PBT has multiple potential causes including primary treatments of the tumour, secondary symptomatic treatments, and the physical and emotional consequences of the diagnosis (Armstrong 2012). Up to 80% of people undertaking cranial radiotherapy report fatigue (Lovely 1999). Although it is rarely the only possible cause, radiotherapy in particular may exacerbate fatigue by endocrine (hormone) dysfunction when the irradiated area encroaches upon the hypothalamus or pituitary gland. The hypothalamic-pituitary-adrenal axis feedback system is responsible for controlling the secretion of many hormones that regulate many body processes, including sleep (Arlt 1997; Taphoorn 1995).

Fatigue is also a recognised adverse effect of many medications that may be taken by people with PBT, including chemotherapy, anticonvulsant drugs (Lu 2009; Maschio 2008; Struik 2009), and corticosteroids (Drappatz 2007; Hinds 2007). Fatigue is further associated with sleep disturbance, cognitive complaints, depression and anxiety (Armstrong 2010; Fox 2007; Pelletier 2002), and this cluster of symptoms may significantly influence people’s quality of life (Fox 2007). Symptom clustering can make the presence of fatigue difficult to distinguish from other symptoms such as depression (Rooney 2011).

The relationship between histological tumour grade and fatigue remains unclear. Some authors find fatigue to be more common in high-grade than in low-grade tumours (Salo 2002), whereas other authors do not (Armstrong 2010; Pelletier 2002). Regardless, the wide range of possible causes suggest that fatigue is best investigated as a multifactorial symptom alongside these other associated issues (Armstrong 2010).

Methods of measuring fatigue
Many tools have been developed to measure fatigue in people with cancer (Jean-Pierre 2007); each instrument relies on subjective patient report. The Brief Fatigue Inventory (Mendoza 1999) has been used in several studies including brain tumour correlation studies (Kim 2012), and clinical trials (Gehring 2012). Other measurement tools validated for use in cancer include the Functional Assessment of Cancer Therapy - Fatigue (Yellen 1997), the Cancer-Related Fatigue Distress Scale (Holley 2000), the Fatigue Assessment Questionnaire (Glaus 1998), the Revised Piper Fatigue Scale (Piper 1998), and the Multidimensional Fatigue Symptom Inventory (Stein 2004). Several general and brain tumour-specific quality of life measures also assess fatigue, such as the Functional Assessment of Cancer Therapy - Brain (FACT-Br) (Cella 1993), the MD Anderson Symptom Inventory Brain Tumour Module (MDASI-BT) (Armstrong 2006), the European Organization of Research and Treatment Quality of Life Questionnaire-C30 (EORTC QLQ-C30) (Ringdal 1993), and the World Health Organization Quality of Life assessment (WHOQOL) (WHOQOL Group 1995). With many different tools available caution is needed when synthesising data in a systematic review or meta-analysis.

Description of the intervention
In this review, we included pharmacological and non-pharmacological interventions for fatigue in PBT. We defined pharmacological interventions as a drug, given by any route at any therapeutic dose, with the primary intention of treating fatigue. Such drugs could include psychostimulants and antidepressants. We defined non-pharmacological interventions and general strategies as any psychological or behavioural treatment with the primary aim of improving fatigue in PBT. These interventions could, for example, include physical activity, cognitive or behavioural therapies and psychosocial interventions.
How the intervention might work

Studies have started to explore interventions aimed at improving and alleviating symptoms of fatigue (e.g. Cramp 2012; Goedendorp 2009; Minton 2013).

Pharmacological interventions

Pharmacological treatments might reduce fatigue by acting on critical neurotransmitter pathways. For example, the central nervous system stimulant, methylphenidate, could enhance neural signal processing by increasing concentrations of dopamine and norepinephrine (norepinephrine) (Volkow 2002). Similarly, the central nervous system stimulant, modafinil, may enhance the effect of dopamine, associated with wakefulness and motivation (Young 2010).

Non-pharmacological interventions

Psychological interventions may improve fatigue by introducing and reinforcing adaptive coping strategies (Armstrong 2012). This approach can be effective through the use of cognitive therapy, which identifies negative or maladaptive thoughts/beliefs, challenges them and replaces them with more helpful and realistic alternatives (Beck 1979). These strategies could be used alongside behavioural interventions such as exercise. Exercise may improve fatigue in people with PBT by increasing mental and physical stamina. A reduction in fatigue could be achieved through a balance between activity and rest (Winningham 1992). Excessive rest could promote muscle wasting and decreasing cardiorespiratory fitness, adding to the perception of fatigue (Dimeo 2001). By increasing functional capacity, exercise could reduce fatigue (NCCN 2014), while alleviating anxiety and improving mood (Dimeo 2001).

Why it is important to do this review

Fatigue is consistently the single most frequently reported symptom in studies of people with PBT. Therefore, there is a pressing need to search for trials in this area systematically to generate a high-quality review of interventions for fatigue in people with PBT. With survival times for low-grade PBT typically measured in years, and survival times for certain subgroups of people with high-grade PBT gradually increasing, there is great potential benefit in establishing which interventions are effective for fatigue. Effective interventions could improve quality of life, yet the multifactorial nature of fatigue (potentially including neuroendocrine, neuroimmune and psychosocial causes) makes it a symptom that can be particularly difficult to treat (Bowe 2012).

A clear synthesis of the evidence for the effectiveness of managing fatigue in PBT is currently lacking. This review will answer a clinically useful research question: what are the effective interventions for managing fatigue in adults with a PBT?
Non-pharmacological interventions
For psychological interventions, we aimed to study any cognitive treatment given with the aim of improving fatigue in PBT. For behavioural interventions, we aimed to investigate the effectiveness of any behavioural or social treatment given for the improvement of fatigue in PBT; this may have included exercise and energy management techniques. We included RCTs in which the control group was allocated to treatment as usual or to a waiting list.

Types of outcome measures

Primary outcomes
- Fatigue at study endpoint.

Due to potential differences in effectiveness endpoints between the different interventions, we aimed to analyse both short-term and long-term effects of these interventions, where the data were available.

High fatigue may be summarised categorically as ‘present’ or ‘absent’ (e.g. in response to a clinical interview), or else quantified ordinarily on a rating scale assessing fatigue using cut-offs defined by the measure used. Such rating scales can be specific to fatigue, or may assess fatigue as part of a wider symptom screen (e.g. as part of quality of life). We included studies in which fatigue was self-reported using any validated method. Due to the subjective nature of fatigue, we did not include studies using clinician-reported or relative- or carer-reported measures, because these may not be a true reflection of the person's symptoms.

If fatigue was measured by a rating scale, we aimed to quantify its improvement with respect to the recommended scale threshold for ‘caseness’. If possible, we also aimed to record the total number of people reaching ‘non-fatigued’ status.

Secondary outcomes
- General functioning, including quality of life measurements (e.g. Health Related Quality of Life questionnaire), and depression (e.g. Hospital Anxiety and Depression Scale) and cognitive outcomes (e.g. Addenbrooke’s Cognitive Examination - Revised) according to validated measures.
- Overall survival (OS) and progression-free survival (PFS).
- Adverse events as described by Katz 2012. Adverse event occurrence: clinical adverse events; any serious adverse event as defined by any medical occurrence in any participant that resulted in a dose reduction or treatment discontinuation, which did not necessarily have causal relationship with the treatment. The International Conference on Harmonisation Guidelines defines serious adverse events as any event that may jeopardise the person or require an intervention to prevent it (ICH-GCP 1997). This includes any important medical event that: was life-threatening, led to death, resulted in significant or persistent disability or congenital anomaly/birth defect, or required inpatient hospitalisation or prolongation of existing hospitalisation, which may have jeopardised the person or required intervention to prevent it.

If possible and appropriate, we aimed to combine outcomes in a meta-analysis. The secondary outcomes were not criteria for eligibility for this review, but were outcomes that we noted and reviewed.

Search methods for identification of studies

Electronic searches
We searched the Cochrane Central Register of Controlled Trials (CENTRAL) (Issue 2, 2016), MEDLINE (1950 to March 2016), EMBASE (1980 to March 2016), PsycINFO (1974 to March 2016) and CINAHL (1982 to March 2016), (Appendix 1, Appendix 2; Appendix 3; Appendix 4). We did not apply language or date restrictions in any of the searches.

Searching other resources

Unpublished and grey literature
We searched online databases of registered clinical trials to identify ongoing trials. We also approached the major co-operative trial groups active in this area.

Handsearching
We handsearched the reference lists of included studies and previous systematic reviews. We handsearched the latest journal and conference materials in 2014 and 2015 from the following sources:
- Annual Meeting of the European Society of Medical Oncology (ESMO);
- Annual meeting of the European Association of Neuro-Oncology (EANO);
- Annual meeting of the World Federation of Neuro-Oncology (WFNO);
- Annual Meeting of the American Society of Clinical Oncology (ASCO);
- Annual Meeting of the Society for Neuro-Oncology (SNO);
- Annual Meeting of the Society for Behavioral Medicine (SBM);
- Annual Meeting of the American Psychosocial Oncology Society (APOS);
- Annual Meeting of the International Psycho-Oncology Society (IPOS);
- Annual Meeting of the Multinational Association of Supportive Care in Cancer (MASCC).
Data collection and analysis

Selection of studies
We downloaded all titles and abstracts retrieved by electronic searches to the reference management database EndNote. We removed duplicates and three review authors (JD, SYK, DC) independently examined the remaining references. The review authors were not blinded to the authors or affiliations of the studies. We excluded those studies that clearly did not meet the inclusion criteria and we obtained copies of the full text of potentially relevant references. Three review authors (JD, SYK, DC) independently assessed the eligibility of retrieved papers. We resolved disagreements by discussion and documented the reasons for exclusion.

Data extraction and management

Data extraction
For included trials, we extracted data as recommended in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011). Three review authors (JD, SYK, DC) independently extracted data onto a data extraction form specially designed for the review.
We extracted data on the following:
• article details (author, year of publication, journal citation, country and language);
• intervention (characteristics, e.g. drug name, dose and duration);
• study design and methodology (including inclusion and exclusion criteria, assignment process and timing of measurements);
• population demographics (e.g. age, gender and marital status) and total number involved;
• details of participants’ health status (including tumour pathology and treatment details).
• dichotomous and continuous outcome measures (fatigue, cognitive functioning, quality of life, depression and adverse events);
• risk of bias.

Where possible, we extracted all data relevant to an intention-to-treat analysis, in which participants are analysed in groups to which they are assigned.

Data management
We collated and entered data into Review Manager 5 (RevMan 2014).

Continuous data
For continuous outcomes (e.g. fatigue scales, cognitive tests and measures, depression measures, quality of life measures), we expressed the treatment effect as a mean difference (MD) with 95% confidence interval (CI). We extracted post-intervention data to calculate the MD, the final value and standard deviation (SD) of the outcome of interest, and the number of participants assessed in each treatment arm at the end of follow-up. If more than one trial was eligible, and trials measured outcomes on the same scale, we aimed to express treatment effect as an MD, with 95% CIs. If trials measured outcomes on different scales, we aimed to express treatment effect as standardised mean differences (SMDs) between treatment arms, with 95% CIs.

Dichotomous data
For dichotomous outcomes (e.g. high or low fatigue), we extracted the number of participants in each treatment arm who experienced the outcome of interest, at baseline and at study endpoint. We aimed to dichotomise fatigue using validated thresholds. We noted the time points at which outcomes were collected and reported.

Assessment of risk of bias in included studies
We assessed the risk of bias in included studies using Cochrane’s ‘Risk of bias’ tool (Higgins 2011). This included assessment of:
• selection bias: random sequence generation and allocation concealment;
• performance bias: blinding of participants and personnel (participants and treatment providers);
• detection bias: blinding of outcome assessment;
• performance bias: participants received similar care out with the intervention they received;
• attrition bias: incomplete outcome data;
• reporting bias: selective reporting of outcomes
• other possible sources of bias.

See Appendix 5 for full description of each risk of bias area. Three review authors (JD, SYK, DC) applied the ‘Risk of bias’ tool independently and resolved differences by discussion. We summarised results in a ‘Risk of bias’ summary table. We aimed to interpret the results of any meta-analyses in light of the findings with respect to risk of bias. We judged and reported all bias criteria in terms of ‘low’, ‘high’ or ‘unclear’ risk of bias. We classified criteria as having an ‘unclear’ risk of bias where insufficient information was provided, or when there was uncertainty over the potential for bias. We contacted authors to clarify uncertainties, if possible. It was noted that blinding may not have been possible for all treatment comparisons, particularly with respect to any non-pharmacological interventions such as exercise.
Measures of treatment effect
For continuous data, we used MDs or SMDs as appropriate. For dichotomous data, we calculated the risk ratio (RR).

Dealing with missing data
We did not impute missing outcome data for the primary outcome. For the primary outcome, if data were missing, or only imputed data were reported, we contacted trial authors to request data on the outcomes among participants who were assessed. We included details of missing data in the narrative summary and ‘Risk of bias’ table, and stated whether authors examined the extent to which the missing data could have altered the results of the review.

Assessment of heterogeneity
Assessment of heterogeneity was not possible because only one trial was eligible for inclusion in the review. We planned to assess heterogeneity between studies by visual inspection of forest plots (including the presence of outliers and a poor overlap of CIs), and by a formal statistical test of the significance of the heterogeneity (Deeks 2001). We planned to investigate and report heterogeneity according to Higgins 2011.

Assessment of reporting biases
Three review authors (JD, SYK, DC) reviewed and recorded reporting biases. We aimed to examine funnel plots to assess the potential for small-study effects, such as publication bias, if the meta-analysis included more than 10 trials.

Data synthesis
We planned to pool data for meta-analysis using Review Manager 5 if studies were comparable with respect to participants, interventions and outcomes (RevMan 2014). We intended to combine studies at the level of the intervention itself (e.g. psychostimulant, cognitive behavioural therapy, exercise) rather than broad categories (e.g. pharmacological, psychological, behavioural). Had a meta-analysis been possible, we planned to carry it out as follows.
- We intended to use random-effects models with inverse variance weighting for all meta-analyses, with 95% CIs (DerSimonian 1986).
- For dichotomous data for adverse events, we planned to pool RRs.
- We intended to note the time points at which outcomes were collected and reported.

However, data synthesis was not possible as only one trial was eligible for inclusion in the review.

Subgroup analysis and investigation of heterogeneity
We planned to conduct subgroup analyses comparing changes in scale score studies using identical scales, where appropriate. We also intended to perform subgroup analyses according to World Health Organization (WHO) tumour grade (low grade/high grade) and interventions delivered only during treatment/only during follow-up. However, subgroup analysis and investigation of heterogeneity was not possible because only one trial was eligible for inclusion in the review.

Sensitivity analysis
We planned to involve all review authors in determining whether sensitivity analysis would be required, under the guidance of Higgins 2011. We intended to consider the following factors as possible sources of heterogeneity across studies.
- Differing study quality (high or low levels of risk of bias).
- Different classes of drugs.
- Dosage or scheduling differences.

We planned to identify additional possible types of sensitivity analyses during the conduct of the review. However, sensitivity analysis was not carried out as only one trial was eligible for inclusion in the review.

RESULTS

Description of studies
See: Characteristics of included studies; Characteristics of excluded studies; Characteristics of ongoing studies tables.

Results of the search
Figure 1 shows details of the search.
Figure 1. Study flow diagram.

5595 records identified through database searching

0 additional records identified through other sources

4941 records after duplicates removed

4941 records screened

4932 records excluded

9 full-text articles assessed for eligibility

8 full-text articles excluded, with reasons

1 studies included in qualitative synthesis

0 studies included in quantitative synthesis (meta-analysis)
We found 4941 citations when searching electronic databases and following de-duplication of the results. The results were narrowed to nine articles upon screening of the titles and abstracts. One trial was eligible for inclusion in the review (Boele 2013). Eight studies did not meet our inclusion criteria for analysis due to the lack of high self-reported fatigue as a necessary inclusion criterion (Butler 2007; Gehring 2009; Gehring 2012; Kaleita 2006; Lee 2014; Locke 2008; Shaw 2006; Shaw 2015). We identified no additional studies when searching conference proceedings and the reference list of the single included trial. We identified no additional studies when contacting experts in the field. There was one ongoing trial (Umphrey 2013).

Included studies
For detailed information see Characteristics of included studies table.
We found one eligible trial. Boele 2013 investigated the use of modafinil in treating fatigue in people with PBT compared with a placebo intervention.

Participant demographics
The study recruited 37 of the estimated 64 required participants from three neuro-oncology centres in The Netherlands. Their mean age was 48.16 years (SD 12.02). Participants had a meningioma (32.4%), low-grade glioma (37.8%) or high-grade glioma (29.7%), with the majority having had surgery (94.6%), without further radiotherapy (56.8%) or chemotherapy (78.4%). There were more women (62.2%) than men (37.8%). All participants were required to have experienced high fatigue, determined using a cut-off above 27 on the Checklist Individual Strength (CIS). The authors obtained ethical approval and registered the trial with a clinical trials database. All participants gave informed consent. The study recorded adverse events.

Intervention characteristics
Modafinil (2-benzhydrylsulfinylethanamide) is a wakefulness-promoting drug that targets fatigue, cognitive functioning and mood. The study used a dose escalation, washout and cross-over method for both arms and participants received either modafinil then placebo or placebo then modafinil. It included a dose reduction and withdrawal technique if participants experienced adverse events.

Primary and secondary outcomes
The study assessed the primary outcome measure of fatigue using the CIS. It included secondary subjective measures of depression, health-related quality of life and everyday cognitive functioning. Cognitive functioning was assessed using a neuropsychological test battery to assess verbal memory, working memory, attention, executive function and psychomotor speed. Assessments were carried out at baseline, six weeks and 12 weeks.

Data collection
The study used a cross-over trial design, therefore they collected data for each participant on completion of the modafinil and placebo treatment schedules. Of 155 eligible participants, 39 participants met the inclusion criteria and agreed to participate. Two participants dropped out prior to randomisation leaving 37 participants in the trial, of whom 25 completed both treatment schedules and had all outcomes measured. Imputation was carried out for missing values for those who completed questionnaires and neuropsychological assessments.

Statistical analyses
The trial used a within-participants design to determine differences between modafinil and placebo test scores. It used a Wilcoxon signed-rank tests as no data were normally distributed. No corrections were carried out to account for multiple statistical testing.

Excluded studies
For detailed information see Characteristics of excluded studies table.
We found eight studies that included fatigue as a primary or secondary outcome measure, but we excluded them as high fatigue was not a necessary inclusion criterion for participation. Three studies investigated an intervention in people with brain tumours undergoing radiotherapy (Butler 2007; Lee 2014; Shaw 2015). Five studies evaluated an intervention in people with brain tumours not on active treatment (Gehring 2009; Gehring 2012; Kaleita 2006; Locke 2008; Shaw 2006).

Studies of people undergoing radiotherapy
Butler and co-authors evaluated the use of d-threo-methylphenidate hydrochloride in a double-blind randomised placebo-controlled clinical trial in people with primary metastatic brain tumours receiving radiotherapy. Participation was not limited to people with fatigue. The study enrolled 68 participants. Using the Functional Assessment of Cancer Therapy - Fatigue sub scale (FACT-F), there were no differences between groups in measures of fatigue eight weeks after the completion of radiotherapy (P value = 0.64) (Butler 2007).
Lee and co-authors presented an update of their randomised, placebo-controlled pilot trial of armodafinil at the 2014 ASCO annual conference, which included 77 people undergoing radiotherapy. Participation was not limited to people with fatigue. This ongoing study included measures of fatigue, mood and quality of life. There were significant improvements in fatigue at 42 days using the Brief Fatigue Inventory (Wilcoxon P value = 0.008) (Lee 2014).

Shaw and co-authors conducted a double-blind placebo-controlled study of armodafinil on fatigue in people undergoing cranial irradiation. Fatigue was not a necessary inclusion criterion. The study enrolled 54 participants, and measured fatigue and daytime sleepiness. There were no significant differences in outcome measures between groups at the end of radiotherapy or at a four-week follow-up compared to baseline. However, in a post-hoc analysis, there was an improvement in fatigue in participants with higher baseline fatigue, as measured by the FACIT-F (Shaw 2015).

Studies of people not on active tumour treatment

Gehring and co-authors investigated the use of a cognitive rehabilitation programme in people with glioma in a randomised wait-list controlled trial. Participation was restricted to people with subjective and objective cognitive deficits, rather than fatigue. The study enrolled 140 adults, and measured cognition, fatigue, quality of life and community integration. Using the Multidimensional Fatigue Inventory, people in the intervention arm reported lower mental fatigue at six months (P value = 0.026), compared to baseline, but not activity (P value = 0.82) or motivation (P value = 0.063) (Gehring 2009).

Gehring and co-authors enrolled 24 people with brain tumours in an open-label randomised pilot trial comparing methylphenidate and modafinil. Participation was not limited to people with fatigue. The primary outcome measure was cognitive function. Other outcome measures included fatigue, sleep disturbance, mood and quality of life. In a post-hoc analysis that combined the treatment groups, there was a beneficial effect on fatigue at four weeks (P value = 0.04) compared to baseline, as measured using the Brief Fatigue Inventory (Gehring 2012). Kaleita and co-authors conducted a double-blind randomised dose-controlled trial of modafinil on cognition, mood and fatigue in people with brain tumours. The study did not restrict participation to people with fatigue. There were 30 participants in the study. There were improvements in fatigue, using the Fatigue Severity Scale, at eight (P value = <0.0001) and 12 weeks (P value = 0.0003) after modafinil initiation compared to baseline (Kaleita 2006).

Locke and co-authors reported the feasibility of a cognitive rehabilitation and problem-solving programme in 19 people with PBT. Participation was not restricted to people with fatigue. The study included measures of fatigue, cognition, mood and quality of life. The study used the Brief Fatigue Inventory to assess fatigue. There were no statistical analyses, but most participants in both groups had only mild fatigue (Locke 2008).

Shaw and co-authors evaluated 24 people with a brain tumour enrolled to a single-arm open-label study of donepezil. Participation was not limited to people with fatigue. The study recorded cognition, mood, fatigue and quality of life. There was an improvement in fatigue at 24 weeks using the Profile of Mood States Fatigue Subscale (P value = 0.03) (Shaw 2006).

Risk of bias in included studies

Three review authors (JD, SYK, DC) independently assessed the included trial using the Cochrane ‘Risk of bias’ tool (Higgins 2011). Where risk of bias was unclear, we contacted the author for clarification. Following discussion, we reached agreement on ‘Risk of bias’ scores. Figure 2 shows the risk of bias summary.
**Allocation**

The trial was at a low risk of bias, using a pharmacy randomisation system to allocate participants to each treatment arm. This was confirmed via correspondence to be through the use of a computer randomisation system.

**Blinding**

The trial was at a low risk of bias. Participants, treating physicians and researchers were blind to treatment allocation.

**Incomplete outcome data**

The trial was at an unclear risk of bias. The study reported that 12 participants dropped out; a similar number of participants dropped out between time-point 1 and 2 (Modafinil arm; n = 4, placebo arm; n = 3); more participants dropped out of the placebo arm (n = 4) than the modafinil arm (n = 1) between time-point 2 and 3. It was unclear why participants dropped out of each group, therefore we contacted the author for correspondence to request clarification. Five participants dropped out of the trial due to adverse events while receiving modafinil; three participants received modafinil first, two participants received modafinil second. Two participants dropped out of the trial due to adverse events while receiving placebo. The study used mean imputation where missing values were present in attempted questionnaires or neuropsychological assessments. They did not carry out an analysis to determine whether imputation or missing data could have altered the results of the study.
Selective reporting
The trial was at a low risk of bias; all outcomes appear to have been reported.

Other potential sources of bias
We did not identify any additional sources of bias.

Effects of interventions
See: Summary of findings for the main comparison Modafinil compared with placebo for fatigue in people with a primary brain tumour
We found one eligible trial that investigated the use of modafinil in treating fatigue in people with PBT compared with a placebo intervention (Boele 2013).

Primary outcome

Fatigue at study endpoint
There was no significant difference in fatigue measures between modafinil and placebo score for concentration problems (MD -1.06, 95% CI -3.18 to 1.06), reduced motivation (MD -0.48, 95% CI -2.93 to 1.97), reduced activity (MD -1.01, 95% CI -5.64 to 3.62) or fatigue severity (MD -0.22, 95% CI -0.79 to 0.35) (Analysis 1.1).

Secondary outcomes

Cognitive functioning
A significant difference was found between modafinil and placebo scores in attentional functioning (MD -0.03, 95% CI -0.05 to -0.01). There were no significant differences in objective cognitive functioning (verbal memory, MD 0.26, 95% CI 0.05 to 0.57; working memory, MD 0.07, 95% CI -0.04 to 0.18; information processing, MD 0.17, 95% CI 1.19 to 1.53; executive function, MD 0.14, 95% CI -0.33 to 0.61; psychomotor speed, MD 0.10, 95% CI -0.26 to 0.46) (Analysis 1.2), subjective cognitive functioning (MD 1.62, 95% CI 0.74 to 3.98) (Analysis 1.3), depression (MD 0.19, 95% CI 1.33 to 1.71) (Analysis 1.4) or quality of life (physical, MD 1.34, 95% CI -0.20 to 2.27; mental, MD -1.40, 95% CI -4.84 to 2.04) (Analysis 1.5).

Adverse events
Reported adverse events included tingling sensations, depressive feelings or behaviours, nervousness, dizziness, vertigo, headaches, loss of appetite and seizures. Five participants dropped out of the trial due to adverse events while receiving modafinil; two participants dropped out of the trial due to adverse events while receiving placebo. There was no difference in adverse events reported between groups (RR 2.79, 95% CI 0.59 to 13.16) (Analysis 1.6).

DISCUSSION
The aim of this review was to determine the effectiveness of interventions to treat high fatigue in people with PBT. We included one randomised controlled cross-over trial comparing the effect of modafinil to placebo (Boele 2013).

Summary of main results
Boele 2013 recruited 37 participants and used a cross-over design to compare modafinil and placebo across three centres in The Netherlands. The washout period between treatments was one week. Since the half-life of modafinil is 10 to 12 hours, the washout period was likely adequate. There was no significant difference in fatigue between modafinil and placebo groups. This finding was difficult to interpret because the trial failed to reach its recruitment target and may have lacked power to exclude a false-negative result. There were improvements in fatigue severity and motivation in both modafinil and placebo conditions compared with baseline.

Overall completeness and applicability of evidence
We could only include one RCT examining the effectiveness of an intervention to treat fatigue in adults with PBT. The trial included people with glioma and meningioma tumours and, therefore, may be representative across these brain tumour types. All participants were fatigued at baseline and, therefore, results could potentially generalise to people with fatigue. However, since this trial had low accrual and high attrition, and restricted follow-up to 12 weeks, overall the applicability of the evidence was limited. We excluded eight studies that reported fatigue outcomes, but which enrolled a general population of people with brain tumours rather than restricting eligibility to people who were highly fatigued. We excluded these studies in order that our conclusions could be readily applied to a clinically relevant problem. However, we recognised that the excluded studies contained valuable data. More research is needed into whether the interventions investigated specifically benefit highly fatigued people with PBT, who are the ones most likely to require treatment in clinic.

Quality of the evidence
See Figure 2.
This review summarised the current evidence for the effect of pharmacological and non-pharmacological interventions for the treatment of fatigue in adults with PBT. There was only one trial eligible for inclusion in the review. The included trial was at a low risk of bias across most areas, with an unclear risk of bias with respect to incomplete outcome data. Low accrual and high attrition limited the generalisability of this trial and taken together, the overall quality of evidence is currently low.

Potential biases in the review process
We searched five databases extensively, which included published studies and the most recent conference proceedings. We also searched the reference list of the included trial. Though we thoroughly handsearched the literature and searched online databases for unpublished and grey literature, and contacted known experts in the field to determine any further unpublished studies that may be eligible, we may have nevertheless failed to identify all eligible studies, specifically those that have not been published.

Agreements and disagreements with other studies or reviews
Authors of two narrative reviews on this topic also highlighted the lack of high-quality evidence for treatment, noting favourable effectiveness of interventions in the general cancer population (Armstrong 2012; Schiff 2014).

We found one ongoing Phase III double-blind placebo-controlled RCT using armodafinil for the treatment of fatigue in people with high-grade gliomas that aims to include only people with fatigue (Umphrey 2013). This study will hopefully offer more evidence for inclusion in a future update.

AUTHORS’ CONCLUSIONS
Implications for practice
At present, the effectiveness of any treatment for high fatigue in people with primary brain tumours is unclear. As detailed above only one trial met our pre-defined inclusion criteria with 37 participants. This limits the conclusions that can be drawn. Other trials enrolling a general population of people with brain tumour suggest a potential benefit of certain treatments, but these data are difficult to generalise to clinical practice and require further study.

In the wider cancer field, one Cochrane review about drug therapy for the management of cancer-related fatigue estimated the effect of several drugs including psychostimulants, hematopoietic growth factors, antidepressants and progestational steroids. Psychostimulants showed a small but significant improvement in fatigue over placebo (Z = 2.83; P value < 0.01). The conclusions were based on small samples (Minton 2010). The differences in the results from this review may be due to the inclusion of only people with PBT, that only one study met our pre-defined inclusion criteria and that modafinil was not one of the drugs included in the cancer-related review. The widely used National Comprehensive Cancer Network (NCCN) guidelines recommend identifying treatable contributory factors including sleep disturbance, anaemia, pain, emotional distress, nutritional deficiencies, poor functional status, medication and co-morbidities (NCCN 2014). Given the relative lack of solid evidence, if a person with PBT and fatigue starts pharmacological treatment for fatigue, it may be advisable to use close follow-up to help detect and manage adverse effects.

Implications for research
Randomised controlled trials are necessary to address the benefits and risks of using pharmacological and non-pharmacological interventions. These should be appropriately powered. Important research questions may include whether any intervention focusing on decreasing fatigue in people with primary brain tumours:

• is effective in treating high fatigue;
• has clinically significant effects on depression and cognition;
• has clinically significant pharmacokinetic interactions with tumour-related treatment (antinepileptic drugs, chemotherapy);
• has a clinically significant effect on survival.

ACKNOWLEDGEMENTS
With thanks to the Cochrane Neuro-Oncology Group for their contribution and continued support and feedback throughout the editorial process.

Inclusion criteria: aged ≥ 18 years; glioblastoma multiforme, anaplastic astrocytoma, gliosarcoma or anaplastic oligodendroglioma; clinically stable (stable/improved Karnofsky Performance Status compared to the prior month); completed radiotherapy > 21 days and ≤ 24 months prior to enrolment; ≥ 6 score on the worst fatigue question of the Brief Fatigue Inventory; previous surgery (gross total or sub-total resection) or biopsy; negative serum pregnancy test done ≤ 7 days prior to registration; ability to complete questionnaire(s) by themselves or with assistance, Eastern Cooperative Oncology Group Performance Status 0, 1, 2 or 3; provide
informed written consent; willing to return to enrolling institution for follow-up (during the active monitoring phase of the study); stable dose of corticosteroid ≤ 28 days prior to registration

**Exclusion criteria:** history of hypersensitivity to other psychostimulants; history of steroid psychosis; history of/currently taking medications for attention deficit hyperactivity disorder, severe anxiety disorder, schizophrenia or substance abuse by patient record or self report, or both; currently taking medications to treat fatigue including psychostimulants, antidepressants, acupuncture (antidepressants used to treat items other than fatigue (such as hot flushes or depression) were allowed if the person had been on a stable dose for ≥ 30 days and planned to continue for the duration of the trial); anticipating surgery; laboratory evidence of hypothyroidism with an elevated thyroid-stimulating hormone concentration in the blood > 5.0 mIU/L; profound anaemia (haemoglobin < 10 g/dL) ≤ 28 days prior to registration; clinical depression per physician discretion; active/ history of Tourette's syndrome or tic disorder, glaucoma, intractable epilepsy or uncontrolled seizure disorder; history of myocardial infarction, unstable angina, left ventricular hypertrophy or mitral valve prolapse syndrome; use of strong or moderate inhibitors of cytochrome P450 3A4 ≤ 7 days prior to registration; use of medications or substances that are inducers of cytochrome P450 3A4 ≤ 7 days prior to registration

**Follow-up:** 8 weeks

**Setting:** 92 centres in the USA

Differences between protocol and review

For clarification, we changed the following sentence “We include details of missing data in the narrative summary and 'Risk of bias' table, alongside an assessment of the extent to which the missing data could have altered the results of the review” in the protocol, to “We included details of missing data in the narrative summary and 'Risk of bias' table, and stated whether authors examined the extent to which the missing data could have altered the results of the review” in the full review. This was to clarify that we had not planned to carry out any formal analyses but to assess the extent to which the missing data could have altered the results by reviewing any assessments carried out by the included studies.
