Strong Short-range Cooperativity in Hydrogen-Bond Chains

Nicholas Dominelli-Whiteley, James J. Brown, Kamila B. Muchowska, Ioulia K. Mati, Catherine Adam, Thomas A. Hubbard, Alex Elmi, Alisdair J. Brown, Ian A. W. Bell and Scott L. Cockroft

Abstract: Chains of hydrogen bonds such as those found in water and proteins are often presumed to be more stable than the sum of the individual H-bonds. However, the energetics of cooperativity are complicated by solvent effects and the dynamics of intermolecular interactions, meaning that such effects are typically derived from theory or indirect structural data. Here, we present direct measurements of energetic cooperativity in an experimental system in which the geometry and number of H-bonds in a chain were systematically controlled. Strikingly, we found that adding a second H-bond donor to form a chain can almost double the strength of the terminal H-bond, while further extension had little effect. The experimental observations add weight to computations which have suggested that strong, but short-range cooperative effects may occur in H-bond chains.

Hydrogen bond chains are prevalent structural motifs in supramolecular and biological systems. H-bonds are widely proposed to exhibit positive cooperativity,[1] which may be manifested by a combination of conformational[2-6] and electronic effects that may make a chain more stable than the sum of its parts.[13] Such cooperative effects have been shown to influence reactivity,[4] to contribute to the structure, interactions[5] and properties of biomolecules and materials,[6] and to facilitate the communication of chemical information.[7] H-bonded water clusters and chains have been isolated in the solid state[8] and studied experimentally in both liquid and gas phases.[9] Although many nanoscale and bulk properties may be influenced by the cooperativity of H-bonded networks, it is not possible to directly quantify interaction energies from structural or vibrational characteristics. In addition, discussion surrounding the relative contributions of electrostatics, polarization, and covalency in H-bond cooperativity[5b, 9] is further exacerbated by the challenge of considering the influence of the surrounding solvent.

Here, we have employed synthetic molecular balances[10] to directly measure the effect of H-bond chain length on the strength of H-bonding interactions in solution. At the outset of our investigation we identified the phenol, catechol, pyrogallol series (Figure 1B) as a pertinent model system for examining cooperativity in H-bond chains. Indeed, H-bond chains have previously been proposed to contribute to the supramolecular properties of catechol and pyrogallol derivatives.[8b, 11] We reasoned that the pre-organization and proximity of the intramolecular H-bond donors and acceptors in this series of compounds would minimize conformational entropic effects to allow examination of cooperative electronic influences. Initially we measured the experimental complexation free energies of phenol, catechol and pyrogallol with the strong H-bond acceptor, tri-n-butylphosphine oxide using 31P NMR. The binding energies became more favorable as the number of OH groups was increased (Figure 1A). Such a trend could be rationalized by cooperative effects arising from the formation of a linear intramolecular H-bond network between the OH groups (Figure 1B).[11b, 11c] However, the experimental energetic trend shown in Figure 1A was not reproduced in DFT energy calculations for the linear binding mode (Figure 1A cf. solid bars in Figure 3A). Furthermore, experimental evidence obtained in solution and the solid state indicates that catechol-derivatives may bind acceptors in alternative binding modes such as those shown in Figure 1C.[11c, 12] Thus, we side-stepped this conformational ambiguity by designing a constrained intramolecular system that enabled H-bond energies to be measured specifically at the end of a chain (Figure 2A).

The strength of intramolecular interactions can be assessed using conformational reporters that act as molecular balances.[10] The molecular balances employed in the present study were based on previous designs that enable the measurement of solvent and substituent effects on intramolecular interactions (Figure 2A).[14] The position of the conformational equilibrium in these new balances enables measurement of the energy of the H-bond at the end of a linear chain containing one, two or three H-bonds. These molecular balances were synthesized and found to exist in two conformational states on the NMR timescale at room temperature (see SI for NMR and minimized structures). Conformers were assigned using 2D NMR spectroscopy and the equilibrium constant K determined by integration of the 31P NMR peaks corresponding to each conformer. The difference in the free energy between the conformers was determined using ΔG = −RT lnK. Balance 1H was found to have a strong preference for the conformation in which the C=O – HO interaction was present in CDCl3 (Figure 2B). Strikingly, adding a second H-bond to form a chain (i.e. going from 1H to 2H) approximately doubled the measured ΔG from -4.2 to -8.1 kJ mol⁻¹. However, adding a further H-bond to the chain (2H to 3H) slightly decreased the preference for the H-bonded conformer. This unexpected trend was seen to persist in CD3CN solutions containing up to 10% (v/v) CD3CN (Figure 2B). At higher concentrations of CD3CN the conformational free energies tended to zero due to disruption of the intramolecular H-bonds (Table S3).

Figure 2. (A) Molecular balances and (B) conformational free energies (ΔG) measured in solution at 300 K. (C) Molecular balances used in the (D) Hammett analysis of substituent effects in H-bond chains in CDCl₃. Hammett constants were defined relative to the amide, with ortho-OH groups being approximated by σ (Table S6). Error bars omitted for clarity (Figure S16 shows error bars). ΔG₁ₓHB, ΔG₂ₓHB, ΔG₃ₓHB approximate the energies associated with chains containing one, two and three H-bonds, respectively.

The data are indicative of a large positive cooperative effect on forming a chain of two H-bonds compared to a single H-bond, while there is little additional change on further increasing the length of the chain. However, the conformational equilibrium shown in Figure 2A may be influenced by secondary substituent effects in addition to the C=O … HO interaction of interest. These secondary substituent effects were controlled for using the 0X and 1X series of compounds (Figure 2C) by plotting the sum of the Hammett constants of the X-substituents against the experimental free energies (Figure 2D). The 0X and 1X series formed separate correlations, with the offset approximating the free energy contribution of a single C=O … HO interaction. The steeper gradient of the 1X versus 0X data indicates the sensitivity of the C=O … HO interaction to the electronic effects of the substituents (the more electron-withdrawing the substituent, the stronger the H-bond). The free energies for compounds 2H and 3H (blue and purple circles) are vertically displaced from the 0X correlation in Figure 2D by similar amounts (ΔΔG₁ₓHB and ΔΔG₂ₓHB), confirming the minimal energetic effect of extending a H-bond chain beyond two H-bonds, even when background substituent effects are taken into account.

We originally envisaged extending the investigation to include 1,2,3,4-tetrahydroxybenzene derivatives capable of forming a four-membered H-bond chain. However, we found that 1,2,3,4-tetrahydroxybenzene possessed insufficient stability and solubility to facilitate NMR titrations, or the onward synthesis of molecular balances. Instead, we established that B3LYP/6-311G* calculated conformational energies (ΔE) correlated strongly with experimental ΔG values for all of the balances shown in Figure 2 (Figure S18, R² = 0.99). Thus, we confirmed that computations provided the opportunity to probe situations that could not be examined experimentally, offering insights into the physicochemical origins of the observed short-range cooperativity. Calculations performed on both the phosphine oxide complexes (Figure 3A) and balances (Figure 3B) exhibited a binary energetic pattern in which there was either one, or more than one, H-bond in the linear chain. The calculations also allowed H-bonds to be deliberately flipped to deliberately break the continuity of the H-bond chain (hashed bars in Figure 3). The dependence of the energies on the number of H-bonds in the chain, rather than the number of OH groups, confirmed that the observed cooperative effects originated from the formation of an intramolecular H-bond network, while also ruling out significant contributions from through-bond substituent effects. Furthermore, entropic and conformational differences across the compound series could not account for the observed binary trend observed in both the experiments and computations (Tables S4-5, Figures S13-15, S19-20). Additional calculations in which an external

Figure 3. (A) Calculated complexation energies of phenol derivatives with a phosphine oxide acceptor and (B) conformational energies in molecular balances as the length of the intramolecular OH chain was varied. Solid bars correspond to the linear H-bonded modes (states a, e, h, j), while the hashed bars correspond to calculated local minima in which the H-bond chains were deliberately disrupted by flipping the OH groups indicated in gray. Calculations were performed using B3LYP/6-311G* and all compound coordinates are provided as Supplementary Information.
phosphorus donor could bond in an ideal geometry to the back of the H-bond chains had similar energies (Figure 3C) to the intramolecular cases (Figure 3B). This result confirmed that intramolecular geometric constraints did not account for the lack of additional energetic cooperativity on adding a third or fourth H-bond to chain. A key finding from our experiments (Figure 2D) and computations (Figure 3) is that adding a second H-bond can, depending on context, almost double the strength of the terminal H-bond interaction. Such doubling of the energy cannot arise exclusively from additive electrostatic field effects since the H-bond interaction. Such doubling of the energy cannot arise exclusively from additive electrostatic field effects since the H-bond interaction.

In summary, we have investigated H-bonding cooperativity in an experimental system in which the geometry and number of H-bonds in a chain was strictly controlled. The strength of the terminal H-bond interaction almost doubled on going from one to two H-bonds, but further increasing the length of the chain had a negligible energetic effect. Experimental controls and computations confirmed that the observed binary energetic behavior depended entirely on whether a chain of (two or more) H-bonds was present, and ruled out significant through-bond substituent effects. Electrostatics alone do not account for the observed doubling of the interaction energy on forming an H-bond chain, thereby indicating substantial contributions from inductive polarization. Furthermore, the limited range of the cooperative effect was consistent with previous computations suggesting that polarization changes most rapidly at the ends of H-bond chains.86 Our findings have implications for the fundamental understanding, modelling and exploitation of H-bond chains particularly in regards to their roles in catalysis88 and in determining molecular structure and recognition properties.9a, 10c One might speculate that biology has already explored energetic cooperativity in phenolic H-bond chains, considering that catechol, and not pyrogallol (Figure 1B) moieties have been determined molecular structure and recognition properties.5a, 17c, 20
