Contributors statement

Ms. H.A. van Zanten was the executive researcher of the study. She performed literature search, data collection, data analysis, data interpretation, writing and submitting of the manuscript.

Mr. S.C. Pauws was involved in data analysis, critically reviewed the manuscript and approved the final version.

Mr. B.J. Stenson was involved in interpretation of the data, critically reviewed the manuscript and approved the final version.

Mr. E. Lopriore critically reviewed the manuscript and approved the final version.

Mr. F.J. Walther critically reviewed the manuscript and approved the final version.

Mr. A.B. te Pas was the project leader and performed literature search, designed the study, and coordinated data analysis, data interpretation, writing, editing, and submitting of the manuscript.

Abstract

Background

Following recent recommendations, the oxygen saturation (SpO₂) target range for preterm infants in our nursery was narrowed towards the higher end from 85-95% to 90-95%.

We determined the effect of narrowing the SpO₂ target range on the compliance in target range and distribution of SpO₂ in preterm infants.

Methods:

Before and after changing the target range from 85-95% to 90-95%, infants <30 weeks of gestation receiving oxygen were compared during their admission on the NICU. For each infant distribution of SpO₂ was noted by collecting SpO₂ samples each minute, and the percentage of time spent with SpO₂ within 90-95% was calculated. Oxygen was manually adjusted. Hypoxaemic events (SpO₂<80%) where oxygen was titrated were analysed.

Results:

Data were analysed for 104 infants (57 before and 47 after the range was narrowed). The narrower range was associated with an increase in the median (IQR) SpO₂ (93 (91–96)% vs 94 (92-97)%; p 0.01), but no increase in median time SpO₂ within 90-95% (49.2 (39.6-59.7)% vs (46.9 (27.1-57.9)%; p 0.72).

The distribution of SpO₂ shifted to the right with a significant decrease in SpO₂ <90%, but not <80%.

The count of minute values for SpO₂ <80% decreased while the frequency and duration of hypoxaemic events and oxygen titration was not different.

Conclusion:

Narrowing the target range from 85-95% to 90-95% in preterm infants was associated with an increase in median SpO₂ and a rightward shift in the distribution, but no change in time spent between 90-95%.
What is already known

1. Titrating oxygen manually to maintain $\text{SpO}_2$ within intended target range can be challenging.

2. A higher $\text{SpO}_2$ target range (91-95%) leads to a lower mortality, but more retinopathy of prematurity (ROP) when compared to a lower $\text{SpO}_2$ target range (85-89%).

What this study adds

1. Implementing a narrower TR from 85-95% to 90-95% was not associated with a change in duration of a $\text{SpO}_2$ level between 90-95%.

2. The distribution of $\text{SpO}_2$ shifted to the right, with a decrease in $\text{SpO}_2 < 95\%$, but no effect on hypoxaemia (i.e. $\text{SpO}_2 < 80\%$).
Introduction:

Oxygen therapy in preterm infants is routinely monitored by pulse oximetry during their admission in a neonatal intensive care unit (NICU). In order to prevent the risk for hypoxaemia and hyperoxaemia, neonatal caregivers in most units titrate fraction of inspired oxygen (FiO₂) manually in order to stay within the set oxygen saturation (SpO₂) target range (TR). Recent randomized trials in evaluating lower SpO₂ TR (85%-89%) versus higher SpO₂ TR (91%-95%) in preterm infants¹-³ have shown that using a higher SpO₂ TR led to a reduced mortality but increased the rate of retinopathy of prematurity (ROP) when compared to a lower SpO₂ TR.¹³ Although the groups in the studies¹-³ had a substantial overlap in SpO₂ levels and the optimal TR remains undefined, European and Dutch guidelines now recommend a SpO₂ TR of 90–95% for preterm infants.⁴

Maintaining SpO₂ within TR during oxygen therapy requires compliance with alarm limit settings, prompt responses and careful oxygen titration of caregivers which can be a difficult task to perform.⁵-⁷ Hyperoxaemia can easily occur, especially when extra oxygen is given after hypoxaemic events.⁸ The workload of caregivers, education and awareness about the hazards of hypoxaemia and hyperoxaemia, and appropriate alarm settings, can also influence the caregivers compliance in SpO₂ targeting.⁵⁹¹⁰

Following the recommendation of European and Dutch guidelines our TR for SpO₂ was recently changed from 85-95% to 90-95%. This could lead to more intrinsic stability in infants¹¹ but we also recognized that complying with this smaller range could be challenging for the NICU-nurses.⁵¹¹¹¹² We studied the effect of narrowing TR towards the higher end on the distribution of SpO₂ and compliance in SpO₂ targeting during oxygen therapy.

Methods:
A prospective designed pre-post implementation study was performed in the NICU of the Leiden University Medical Center (LUMC), which is a tertiary level perinatal center with a traditional open-bay NICU architecture and an average of 550 intensive care admissions per year. In the Netherlands, no ethical approval is required for anonymised studies with medical charts and patient data that were collected and noted for standard care. The LUMC Medical Ethics Committee provided a statement of no objection for obtaining and publishing the anonymised data. All preterm infants <30 weeks of gestation (GA) admitted to the NICU in LUMC between February 2014 and October 2014 (SpO₂ TR 85-95%) and November 2014 and March 2015 (SpO₂ TR 90-95%) receiving respiratory support (endotracheal and non-invasive ventilation) were included. Data was collected until infants were transferred out of the intensive care area in our unit or to a regional hospital. Preterm infants with major congenital heart disease were excluded. All infants received caffeine therapy and doxapram was added in case of refractory apnoeas.

The characteristics of each infant as well as clinical parameters and ventilator settings (including FiO₂ and SpO₂) were sampled every minute and routinely collected in the patient data management system (PDMS) (Metavision; IMDsoft, Tel Aviv, Israel). During both periods the heart rate and SpO₂ were collected using a Masimo pulse oximeter (Masimo Radical, Masimo Corporation, Irvine CA, USA) integrated in a Philips bedside Intellivue monitor (Philips Healthcare Nederland, Eindhoven, The Netherlands) with an averaging time set at eight seconds. During both periods caregivers titrated the supplemental oxygen manually following local guidelines (Figure 1). In our NICU the average nurse:patient ratio was 1:2. During both periods the alarm was activated when SpO₂ was directly below or above the set TR, when FiO₂ >0.21. When no supplemental oxygen was required, no upper alarm limit was activated. We considered a washout period around changing TR setting not necessary. Before the TR was changed, all caregivers were fully informed. In addition, before the start of each shift the TR and alarm settings were checked by the nurse if they were set appropriate, which is standard care in our NICU.
We were interested in the extent to which nurses were able to comply with the narrower TR, and
compared the percentage of time spent with SpO$_2$ was between 90-95% when FiO$_2$ >0.21.
Additionally, the percentage of time spent with SpO$_2$ 90-95%, >95%, >98%, <90%, <85% and <80%
were calculated. To evaluate whether the SpO$_2$ distribution changed when no oxygen therapy was
given to the infant, the percentage of time that SpO$_2$ was <90%, <85% and <80% when infants were
breathing air was also calculated.

In addition, all hypoxaemic events during non-invasive ventilation were identified in PDMS and
analysed from the occurrence of SpO$_2$ <80% accompanied with bradycardia (<80 beats per minutes
(bpm)), until the administered oxygen returned to the baseline oxygen before the hypoxaemic event
occurred. As data is sampled every minute, every hypoxaemic event (ABC) where extra oxygen was
titrated was evaluated by documenting the following characteristics: lowest stored minute value
(depth) and count in low minute values (duration) of HR <80 bpm, lowest stored minute value
(depth) and the count in low minute values (duration) of SpO$_2$ <80%, ΔFiO$_2$ (maximum additional FiO$_2$
minus baseline FiO$_2$), the count in minute values with additional oxygen, occurrence and count in
minute values with SpO$_2$ >95%. Hypoxaemia was defined as SpO$_2$ <80% and hyperoxaemia as SpO$_2$
>95%.

**Statistical analyses**

For this study a convenience sample was used. For the first period, infants were included that were
born one month after the implementation of staff training and an oxygen titration guideline until
the target range was changed. For the second period, infants were included after implementing the
new TR, until the time point automated oxygen control was implemented. Quantitative data are
presented as median (IQR), mean (SD) or number (percentage) where appropriate. The total duration
of SpO$_2$ levels within various ranges for FiO$_2$ >21% was collected for each infant individually before
and after implementation of a narrowed TR and was aggregated as a percentage of recorded time

https://mc.manuscriptcentral.com/adc
(median (IQR)). The Mann-Whitney-U test for non-parametric comparisons for continuous variables is used, to compare the patient’s characteristics and the hypoxaemic event characteristics. A Chi-square test was used to analyse discrete variables. If one of the cells had an expected count of less than five the Fisher’s exact test was used. P-values <0.05 were considered to indicate statistical significance. Statistical analyses were performed using IBM SPSS Statistics version 23 (IBM Software, NY, USA, 2012) and R 3.2.0 (R Core Team (2015). R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. URL https://www.R-project.org/).

Results:

During the study period of 13 months, a total number of 104 infants born <30 weeks of gestation were admitted to our NICU. Of these infants, 57 were born before changing the SpO\textsubscript{2} TR, and 47 infants after this change. No infants were excluded. There were no differences in median (IQR) GA (28+3 (26+4 – 29) vs 27+5 (26+1 – 29) weeks; p 0.25) and BW (1000 (855 – 1206) vs 900 (740 – 1153) grams; p 0.17) or other characteristics (Table 1).

Effect on compliance and SpO\textsubscript{2} distribution

During the TR 85-95% period 630.244 data points were collected and during the TR 90-95% period 402.993 data points of SpO\textsubscript{2} measurements were collected during oxygen therapy. The median (IQR) number of data points per infant, were not different (2359 (377 - 14129) vs 3082 (1352 – 15024) data points; p 0.42).

After changing the TR, there was a slight, but significant increase in median (IQR) SpO\textsubscript{2} (93 (91 – 96)% vs 94 (92 - 97%);p<0.02) (Figure 2), while the FiO\textsubscript{2} slightly decreased (28 (25-32)% vs 26 (24-30%);p 0.01). Narrowing TR was not associated with an increase in median (IQR) time SpO\textsubscript{2} was within 90-95% (49.2 (39.6-59.7)% vs (46.9 (27.1-57.9%);p 0.72). The time SpO\textsubscript{2} was >95% and >98% increased,
but did not reach statistical significance. Changing the TR was associated with a significant decrease in both SpO\textsubscript{2} <90\% (15.7 (7 - 21)\% vs 10.7 (8.4 - 13.7)\%; p<0.05) and SpO\textsubscript{2} <85\% (6.2 (2.5 - 8.0)\% vs 3.5 (2.6 - 5.3)\%; p<0.05), but SpO\textsubscript{2} <80\% was similar (Table 2, Figure 2).

During the TR 85-95\% period 471.642 data points were collected and in the TR 90-95\% period 424.700 data points of SpO\textsubscript{2} measurements were collected when infants were breathing in air. The median (IQR) number of data points per infant, was not different (5722 (3112 - 10395) vs 8102 (3635 – 13363) data points; p 0.24). Changing the TR did not associated with significant changes in SpO\textsubscript{2} distribution and SpO\textsubscript{2} <90\% were similar when infants were breathing in air (Table 3, Figure 3).

**Effect on hypoxaemic events and how oxygen was titrated**

During non-invasive respiratory support 168 hypoxaemic events requiring extra oxygen occurred in 28/57 (49\%) infants before, and 204 events in 32/47 (68\%) infants after the TR was changed. There was no difference in lowest minute value and the count in minute values with bradycardia and SpO\textsubscript{2} <80\% (Table 4). The (median (IQR) count of minute values for SpO\textsubscript{2} <80\% decreased while mean (SD) was not different. There was a non-significant increase in hyperoxaemia after the TR was changed (63\% (106/168) vs 73\% (148/204); p=0.05) (Table 4), while there was no difference in \textDelta FiO\textsubscript{2}, duration of titrating oxygen down to the baseline and count in minute values with hyperoxaemia (Table 4).

**Discussion**

Our study demonstrated the effect of narrowing the SpO\textsubscript{2} TR of 85-95\% towards the higher end to 90-95\% on SpO\textsubscript{2} distribution of preterm infants when oxygen is supplied. We observed that the new, more narrow, TR was associated with a small increase in median SpO\textsubscript{2} and a rightward shift in the distribution. While this was associated with a decrease in the prevalence of SpO\textsubscript{2} < 90\%, it had no effect on hypoxaemia (i.e. SpO\textsubscript{2} <80\%). Changing TR did not affect the duration at which SpO\textsubscript{2} was 90-95\%. However, it was associated with a non-significant increase in the occurrence of hyperoxaemia, (Figure 2). These results could indicate that the nurses attempted to comply with the
new TR, but found it difficult to titrate oxygen sufficiently to stay within the narrow TR. Nevertheless, as we managed to decrease the exposure to SpO\textsubscript{2} less than 90%, narrowing the TR in our unit could lead to similar beneficial effects shown in the recent trials.\textsuperscript{1-3}

A similar effect was observed around hypoxaemic events. There was no change in occurrence and duration of hypoxaemic events and how oxygen titration was performed, but the occurrence of hyperoxaemia increased, although this raise was not significant.

To our knowledge this is the first report of the effect when the TR is significantly narrowed to only the upper part of the original TR when oxygen is manually titrated. Laptook et al. reported the effect of changing the SpO\textsubscript{2} TR, but the change in range was much smaller (from 90-95% to 88-94%) when compared to ours.\textsuperscript{14} It is difficult to compare our results with their findings, but they also reported no change in the time SpO\textsubscript{2} spent within the TR. They observed also no difference in the mean percentage of time spent within the TRs, but this might be attributed to the small change in TR.\textsuperscript{14} Mills et al. reported a lower compliance when a narrow TR for SpO\textsubscript{2} was used, except when preterm infants participated in a trial comparing TRs.\textsuperscript{12}

Changing the TR did not lead to a change in SpO\textsubscript{2} distribution when infants were breathing in air and there was no decrease in lower SpO\textsubscript{2}. This finding, together with the observation that the time SpO\textsubscript{2} was 90-95% did not change when oxygen was given, could indicate that the nurses already had the tendency to keep SpO\textsubscript{2} in the higher end of the intended target range when 85-95% was used. This is in line with previous observation that nurses were less compliant in the upper alarm limits.\textsuperscript{5 6 11 15} Indeed, the clinical trials comparing lower vs higher SpO\textsubscript{2} TR also reported that the median levels of oxygen saturations were higher than intended TR in both treatment groups.\textsuperscript{1-3} It is likely that caregivers favour SpO\textsubscript{2} closer to the higher end of the target range because infants are intrinsically more stable in the higher SpO\textsubscript{2} region, resulting in less FiO\textsubscript{2} fluctuations.
We observed a decrease in time \( \text{SpO}_2 \) spent <90% when oxygen was given, which is comparable to the findings of recent trials comparing low (85-89%) vs high TR (91-95%). These trials showed that a TR above 90% led to a decrease in mortality.\(^1\)\(^-\)\(^3\) A low \( \text{SpO}_2 \) TR has been associated with an increased rate of hypoxaemic events.\(^1\)\(^4\)\(^\,\)\(^1\)\(^6\) However, we did not observe a change in hypoxaemia, or hypoxaemic events and how these were handled, after we increased the lower limit of the TR. This lack of effect is probably also a consequence of how nurses titrated oxygen before the TR was changed. Changing the TR towards the higher end led to a non-significant increase in hyperoxaemia and more often hyperoxaemia after an hypoxaemic event. This has also been observed in previous studies, as also in the trials comparing lower and higher TRs,\(^1\)\(^-\)\(^3\) which could then potentially lead to an increase in ROP.

Titrating oxygen when using a smaller target range in instable premature infants with fluctuating \( \text{SpO}_2 \) requires constant nursing intervention.\(^8\) It has been reported that a narrower TR leads to an inevitable increase of \( \text{SpO}_2 \) alarms.\(^1\)\(^7\) These alarms contribute to all other alarms on a NICU where a high number of alarms are false.\(^1\)\(^8\) Excessive exposure to alarms can effect response from caregivers and lead to alarm fatigue, which is potentially harmful to patients.\(^1\)\(^9\)\(^\,\)\(^2\)\(^0\) Although we have not measured the number of alarms in our study, this can affect the compliance in TR negatively.

While maintaining \( \text{SpO}_2 \) within a narrow TR is a difficult task to perform when oxygen needs to titrated manually, automated oxygen regulation could be more effective and lead to the desired compliance in keeping \( \text{SpO}_2 \) within the narrow range.\(^2\)\(^1\)\(^-\)\(^2\)\(^5\) However, when Wilinska \textit{et al.} used automated oxygen control and compared the TR 87-93% with a more narrow TR (90-93%), similar results as in our study were observed. The narrow range of 90-93%, resulted in less time with lower \( \text{SpO}_2 \) (80-86%), but more time with higher \( \text{SpO}_2 \) (94-98%). In addition, there were also no differences in the amount and duration of hypoxaemic events.\(^2\)\(^6\)
The non-randomized character of this study is a limitation. Although the compared groups were not
different in basic characteristics and there were no further policy changes occurred during the study
period, bias could have been introduced by conditions we did not record or measure. The Masimo
oximeter algorithm could not be updated in the Philips monitors that we used in our unit, which is
reflected by the well described dip\textsuperscript{27} in the frequencies of SpO2 87-90%. However, the same
oximeters and monitors were used in both groups and thus did not influence the observed
distributions when comparing the groups. Furthermore, we did not adjust for the contribution of the
number of hypoxic events of each patient, but we considered every hypoxaemic event as an
independent event because all events are handled similar for each infant. We could only compare
SpO\textsubscript{2} values that were routinely sampled every minute and the value is an average of 8 seconds,
which is less frequent than reported in other studies.\textsuperscript{28, 29, 30} It is possible that in both groups we
missed SpO\textsubscript{2} fluctuations and hypoxaemic events in between the samples taken. These limitations
indicate that the results have to be interpreted with caution, this study was not designed to compare
morbidity and mortality.

In conclusion, narrowing the TR from 85-95% to 90-95% in preterm infants was not associated with a
change in the time SpO\textsubscript{2} spent within 90-95%. There was however a shift of the SpO\textsubscript{2} distribution to
the right with a decrease in SpO\textsubscript{2} less than 90%, but no change in hypoxaemia. This beneficial effect
could be further improved by increasing the compliance to a narrow TR.

count minute value with SpO₂ >95%, min | 1 (1-3) | 1 (0-2) | 0.27b

Data are expressed as median (IQR)

a Chi-square test

b Independent samples Mann-Witney U test

Data is sampled every minute, every hypoxaemic event (ABC) where extra oxygen was titrated was evaluated by documenting the following characteristics: lowest stored minute value (depth) and count in low minute values (duration) of HR <80 bpm, lowest stored minute value (depth) and the count in low minute values (duration) of SpO₂ <80%, ∆FiO₂ (maximum additional FiO₂ minus baseline FiO₂), the count in minute values with additional oxygen, occurrence and count in minute values with SpO₂ >95%. Hypoxaemia was defined as SpO₂ <80% and hyperoxaemia as SpO₂ >95%.
