Taking advantage of the high acceptance and axial symmetry of the WASA-at-COSY detector, and the high polarization degree of the proton beam of COSY, the reaction $p p \to p p \eta$ has been measured close to threshold to explore the analyzing power $A_y$. The angular distribution of $A_y$ is determined with the precision

produced via the excitation of one of the nucleons to the \( pp \) and differential cross sections for the \( \eta \) meson. These results rule out the presently available theoretical predictions for the production mechanism of the \( \eta \) meson.

DOI: 10.1103/PhysRevLett.120.022002

In recent decades, hadron physics has been rich in discoveries in the low-energy region where the interaction between hadrons is a manifestation of the strong force between their components [1–5]. However, there are still many open questions involving the nonperturbative dynamics and details of hadron production processes. Spin observables offer an essential tool to yield new insight into this physics. In this Letter, we focus on the \( \eta \) meson production in low-energy proton-proton collisions with a polarized proton beam. We report the first precise measurements of the analyzing power for the \( \bar{p}p \rightarrow pp\eta \) reaction at two energies close to threshold. These measurements yield new powerful constraints on models of the \( \eta \) production.

The presented results are based on about 200 times larger statistics and drastically reduced systematic uncertainties with respect to the previous experiments [6–8]. The main improvement of systematics is due to (i) axial symmetry and full acceptance of the WASA-at-COSY detector (more than 20 times larger than for the COSY-11 experiment [9]), (ii) no magnetic field in the detector; in addition, the systematics was controlled by the measurements (iii) for two spin orientations and (iv) for two different decay channels of the \( \eta \) meson.

Previous studies by the CELSIUS [10–13], COSY [14–18], and SATURNE [19–21] experiments of the total and differential cross sections for \( \eta \) meson production in the \( pp \) and \( pn \) collisions revealed that the \( \eta \) meson is predominantly produced via the excitation of one of the nucleons to the \( S_{11} \) current via exchange of virtual mesons with the subsequent decay into the proton-\( \eta \) pair. This conclusion was obtained from the observation of a large \( \eta \) production cross section relative to the \( \eta' \) meson production and the isotropic angular distribution of the \( \eta \) mesons in the center-of-mass (c.m.) system. Measurements of the total cross section for \( \eta \) production in different isospin channels [13,18] revealed a strong contribution from isovector exchanges that is additive in proton-neutron collisions and that (partially) cancels in proton-proton collisions, bringing more constraints on theoretical models. While much progress has been achieved, the mechanism for the excitation of the colliding proton to a resonance state still remains very much incomplete, with a host of models each with different weighting of exchanges proposed to explain the dynamics.

Here, we use spin as a tool to gain further insights. The experiment involves a polarized proton beam with incident momentum in the \( z \) direction, colliding with an unpolarized fixed proton target. The analyzing power is a sensitive extra constraint on the details of the \( \eta \) production mechanism.

The \( \eta \) meson production process proceeds through exchange of a complete set of virtual meson hadronic states, which, in models, is usually truncated to single-virtual-meson exchange. Theoretical models have been proposed involving \( \pi, \eta, \rho, \omega, \) and \( \sigma \) (correlated two-pion) exchanges [22–27] and excited nucleon resonances, primarily the \( S_{11}(1535) \) plus small contributions from the \( D_{13}(1520) \) and \( P_{13}(1440) \) [23,24]. OZI-violating gluonic excitations might also couple to the flavor-singlet part of the \( \eta \) meson in short-distance proton-proton interactions [28]. These exchanges induce very different spin dependence in the production process. Polarized beams and measurement of the analyzing power can therefore put powerful new constraints on theoretical understanding of the \( \eta \) production process. For example, \( \rho \) exchange and \( \pi \) exchange models predict a near-threshold analyzing power with different signs [22,24]. Isotropic (pure \( s \)-wave) production would give zero analyzing power.

The measurements of the \( \bar{p}p \rightarrow pp\eta \) reaction were conducted by means of the large acceptance close to 4\( \pi \) and an axially symmetric WASA-at-COSY spectrometer, operating as an internal fixed-target facility at the Cooler Synchrotron COSY [29]. The vertically polarized proton beam was circulating through the vertical stream of the hydrogen pellets, leading to the \( \bar{p}p \rightarrow pp\eta \) reaction in the center of the WASA-at-COSY detector. The measurements were performed for the beam momentum values of 2026 MeV/c and 2188 MeV/c, corresponding to excess energies in the c.m. system of \( Q = 15 \) MeV and 72 MeV, respectively. The orientation of the proton beam polarization was flipped for each accelerator cycle, which lasted 90 s.

The charged hadronic ejectiles were registered by means of forward scintillator hodoscopes, and the straw tube trackers were identified using the energy deposited in the subsequent scintillator layers. The \( \eta \) mesons were detected by the electromagnetic calorimeter and the plastic scintillator barrel. The production of the \( \eta \) meson via the \( \bar{p}p \rightarrow pp\eta \) reaction was identified using missing and invariant mass techniques. In total, more than 400 000 \( \eta \) meson events were identified and used for the determination of the analyzing power.

The center of the interaction region where the polarized proton beam collided with the pellet target was monitored.
with a precision of about 0.5 mm by the concurrent measurement of elastically scattered protons. The superconducting solenoid was switched off in order to minimize losses of the spin polarization. Only neutral decay products of the η meson were reconstructed. In particular, the $\eta \rightarrow \gamma\gamma$ and $\eta \rightarrow 3\pi^0 \rightarrow 6\gamma$ decay channels with the highest branching ratios (altogether over 71% [30]) were used in the presented analysis. A detailed description of the WASA-at-COSY experiment, as well as methods and results of the monitoring of the interaction region, was given in the dedicated articles [31–34].

The analyzing power $A_y(\theta_\eta)$ for the given polar angle $\theta_\eta$ of the emission of the η meson in the c.m. system was determined from the asymmetry of the efficiency-corrected η meson production yields $N_\eta$,

$$\text{Asymmetry}(\theta_\eta, \phi_\eta) = \frac{N_\eta(\theta_\eta, \phi_\eta) - N_\eta(\theta_\eta, \phi_\eta + \pi)}{N_\eta(\theta_\eta, \phi_\eta) + N_\eta(\theta_\eta, \phi_\eta + \pi)}$$

(1)

extracted as a function of the azimuthal angle $\phi_\eta$, where $P$ denotes the degree of the spin polarization of the proton beam. In the presented analysis, the Madison convention [35] was applied to fix the sign of the asymmetry.

The yields of the η meson production $N_\eta$ were determined based on the missing-mass spectra, independently for each $(\theta_\eta, \phi_\eta)$ angular range. Examples of spectra for a chosen angular range are presented in Fig. 1. The spectra show only a small range of masses close to the kinematical limit, where a clear signal from the production of the η meson is seen on top of the multipion production background. It is important to stress that the missing mass spectra for the $pp \rightarrow pp2\gamma$ reaction channel shown in Fig. 1 (left panel) include a background that is much larger when compared to the nearly negligible background observed for the $pp \rightarrow p\rho\gamma$ reaction shown in Fig. 1 (right panel) [36]. The contribution of the background was estimated by a fit to the experimental spectra of the shapes of missing mass distributions simulated for the production of the $\pi^0$, $2\pi^0$, and $3\pi^0$. The data simulated for the multipion production reaction included the response of the detector system and were analyzed using the same procedures as used for the analysis of the experimental events. Next, after subtraction of the background, the number of the registered η mesons was determined and corrected for the efficiency. The efficiency for the reconstruction of the $pp \rightarrow pp\eta$ reaction was established for each angular bin $(\theta_\eta, \phi_\eta)$ separately, based on the Monte Carlo simulation performed taking into account the geometrical acceptance of the WASA-at-COSY detector, as well as the experimental detection efficiencies and energy and angular resolutions. The angular bin size (18 degrees for $\theta_\eta$ and 30 degrees for $\phi_\eta$) was chosen based on the statistical significance of events in each bin.

Figure 2 gives an illustration of our results for asymmetries for the $\bar{p}p \rightarrow pp\eta$ reaction yield as a function of the azimuthal angle $\phi_\eta$ of the η meson momentum vector in the c.m. system. A fit of Eq. (2) to the angular dependence of the asymmetry enables one to determine the product $PA_y$, which divided by the polarization $P$, gives the value of the analyzing power $A_y$.

The polarization $P$ was determined for each spin orientation and each excess energy separately, by the simultaneous measurement of asymmetries for the elastically scattered protons for which the analyzing power is known [37,38]. The method of the polarization analysis is described in detail in Refs. [36,39,40], and the resulting

**FIG. 1.** Examples of missing-mass distributions obtained for the excess energy $Q = 15$ MeV: (left panel) $\bar{p}p \rightarrow pp2\gamma$ and (right panel) $\bar{p}p \rightarrow pp3\pi^0 \rightarrow p\rho\gamma$ reactions. The legends above the figures indicate the spin orientation and the angular intervals. Experimental data are denoted by solid blue circles. Vertical bars indicate the statistical uncertainty. The shaded green area denotes the simulated contribution from multipion production background. The shaded red histograms correspond to the η events obtained by subtracting the multipion background.

![Image](https://via.placeholder.com/150)

**FIG. 2.** Example of asymmetry distributions as a function of the $\phi_\eta$ angle for a chosen $\theta_\eta$ angular bin, for an excess energy $Q = 72$ MeV and the $\bar{p}p \rightarrow pp\eta \rightarrow 6\gamma$ reaction. Filled blue points denote extracted asymmetry values with the statistical uncertainty, while the red curves indicates the fit of Eq. (2) to the experimental points. The legend above the figures indicates spin orientation and the angular intervals. The asymmetry for spin-up orientation is about 0.8 times smaller than the asymmetry for spin-down, which is consistent with the ratio of the polarization values determined for different spin orientations (Table I).
values, together with corresponding statistical uncertainties, are listed in Table I. The systematic uncertainty of the polarization determination amounts to about 0.01 and, as it is shown in detail in Ref. [41], it is predominantly due to the uncertainty of the reconstruction of the position of the interaction region. It is also important to stress that the spin polarization was stable during the whole run [36,39,40] and that, as expected, the analysis of the data taken with the unpolarized beam resulted in the asymmetry equal to zero within the uncertainties [36,40].

Calculations of the analyzing power $A_y$ were conducted separately for spin-up and spin-down orientations, and for each spin mode, the $A_y$ was determined separately for two decay channels: $\eta \rightarrow 2\gamma$ and $\eta \rightarrow 6\gamma$. Moreover, for all the above cases, the number of events $N_y$ corresponding to the $\bar{p}p \rightarrow pp\eta$ reactions has been determined for each angular bin ($\theta_y, \phi_y$) separately. This enabled us to control systematic uncertainties that may occur because of the misalignment of the detector and because of the methods of event reconstruction. The final results obtained by averaging values determined for both spin orientations and both decay channels are given in Table II and are presented in Fig. 3. Because of the axial symmetry of the detector, any unknown detector asymmetries and unknown efficiencies should cancel when averaging results obtained for two opposite spin orientations. However, the differences in these results were taken into account in the estimation of the systematic errors. The systematic uncertainties listed in the table have been estimated by calculating changes in the values of $A_y$ to the variation of the parameters used in the analysis. After changing a tested parameter, the full analysis chain was repeated and new $A_y$ values were determined. In particular, the following contributions to the systematic error were taken into account [36]: (i) selection criteria used in the particle identification, (ii) range in the missing mass spectra used for counting the number of produced $\eta$ mesons, (iii) differences between $A_y$ values obtained for different decay channels, (iv) uncertainty of the values of polarization, and (v) differences between $A_y$ values obtained for spin-up and spin-down measurements. The largest impact on the systematic error comes from the $A_y$ measurement combining different decay channels of the $\eta$ meson.

Integrating over the proton degrees of freedom results in the analyzing power $A_y(\theta_y)$, which, in a partial-wave decomposition, may be expressed as follows:

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline

\end{tabular}
\caption{Analyzing power $A_y$ with statistical and systematic uncertainties determined for the $\bar{p}p \rightarrow pp\eta$ reaction at excess energies of $Q = 15$ MeV and $Q = 72$ MeV.}
\end{table}
\[ A_y(\theta_\eta) \frac{d\sigma}{d\Omega_\eta} = 2\pi[G_1^0 \sin \theta_\eta + (H_1^0 + I_0^0) \sin 2\theta_\eta], \quad (3) \]

Here, the form factors \( G_1^0, H_1^0, \) and \( I_0^0 \) are defined by Winter et al. [6], who generalize the analysis of spin dependence of \( \pi^0 \) production with polarized proton beams to \( \eta \) production [42]. The superscript \( 0 \) indicates beam polarization along the \( y \) axis and an unpolarized target.

We apply the usual spectroscopic notation to describe the \( pp \to pp\eta \) process, viz. \( 2S+1L^J_p \to 2S+1L_J^J, \) \( J. \) Here, the relative orbital angular momentum of the two outgoing protons in their rest frame is denoted by capital letters \( L_p = S, P, D, \ldots, \) and the one of the \( \eta \) meson in the c.m. system by the lowercase letters \( l_q = s, p, d, \ldots. \) With this notation, the individual terms \( G_1^0, H_1^0, \) and \( I_0^0 \) correspond to \( (P\rho PP), (PP)^2, \) and \( (S\rho Sd) \) interference, respectively. The Pauli principle means that even and odd partial waves in the final state cannot interfere with each other. In total, with polarized beams there are one \( Ss, \) two \( Ps, \) nine \( Pp, \) and two \( Sd \) final-state production amplitudes [42]. For example, the \( Ss \) amplitude corresponds to the process \( ^3P_0 \to ^1S_0, s. \) The \( (PP)^2 \) and \( S\rho Sd \) interference amplitudes always appear together in the analyzing power and angular distribution [42].

Following Eq. (3), we fit the data as

\[ A_y(\theta_\eta) \frac{d\sigma}{d\Omega_\eta} = C_1 \sin \theta_\eta + C_2 \cos \theta_\eta \sin \theta_\eta, \quad (4) \]

where \( C_1 \) and \( C_2 \) are treated as free parameters. For \( Q = 15 \) MeV, the angular distribution of the cross section \( (d\sigma/d\Omega_\eta) \) is assumed to be constant as determined by the COSY-11 [16] and COSY-TOF [15] experiments. For the fit at \( Q = 72 \) MeV, the \( (d\sigma/d\Omega_\eta) \) determined by the WASA-CELSIUS Collaboration [12] is used. For \( Q = 15 \) MeV, we find \( C_1 = (0.001 \pm 0.001) \, \mu b/\text{sr} \) and \( C_2 = (-0.002 \pm 0.003) \, \mu b/\text{sr}. \) For \( Q = 72 \) MeV, we obtain the fit parameters \( C_1 = (0.104 \pm 0.006) \, \mu b/\text{sr} \) and \( C_2 = (0.020 \pm 0.012) \, \mu b/\text{sr}. \)

At \( Q = 15 \) MeV, we find no evidence for partial waves beyond \( s \)-wave production. At \( Q = 72 \) MeV, we find evidence for significant contributions of higher partial waves. If we conclude from the finite coefficient \( C_1 \) of the \( \sin \theta_\eta \) term that both \( Ps \) and \( Pp \) give significant contributions, then the vanishing (within errors) coefficient \( C_2 \) points to a cancellation between \( (PP)^2 \) and \( S\rho Sd \) contributions.

Previously, in the COSY-11 analysis of the 15.5 MeV \( M(pp) \) shape, it was suggested that the high-mass region was a signal for a \( Ps \) contribution at \( Q = 15 \) MeV [16]. If this is indeed present in the data, then the small coefficient \( C_1 \) would indicate a small \( Pp \) contribution at this excess energy. At \( Q = 72 \) MeV, Peten et al. [12] found that a sizable \( Pp \) contribution is needed to get the valley along the diagonal of the Dalitz plot for the \( pp \to pp\eta \) reaction.

Maximal \( Ss\rho Sd \) interference there was suggested to explain the angular distribution of \( \eta \) production at \( Q = 40 \) MeV.

Altogether, the previous results and the ones presented in this Letter have the following interpretation.

First, the data indicate just \( s \)-wave production at \( Q = 15 \) MeV. This result contradicts predictions based on single meson exchange, as shown in Fig. 3.

Measurements of the isospin dependence of \( \eta \) meson production in proton-nucleon collisions have revealed that the total cross section for the quasifree \( pn \to p\eta n \) exceeds the corresponding cross section for \( pp \to pp\eta \) by a factor of about 3 at threshold and by a factor of 6 at higher excess energies between about 25 and 100 MeV [13,18]. This isospin dependence is interpreted as evidence for a strong isovector exchange contribution, which exhibits (partial) cancellation in proton-proton collisions and addition in proton-neutron collisions. This isovector exchange was interpreted in terms of the \( \rho \) meson in Ref. [22] and \( \pi \) exchange in Ref. [24]. These one-boson exchange models, when fit to early data on \( \eta \) production, made predictions for \( A_\eta \), as shown in Fig. 3 with \( A_\eta(\theta_\eta) = \hat{A} \sin 2\theta_\eta \), where \( |\hat{A}| = 0.18 \) at \( Q = 15 \) MeV. Note here that these \( \rho \) [22] and \( \pi \) [24] exchange curves come with opposite signs; i.e., the distribution is shifted by \( \theta_\eta = 90 \) degrees. One possible explanation might be cancellation through destructive interference between \( \pi \) and \( \rho \) exchanges in \( \eta \) production in proton-proton collisions very close to threshold, together with a strong (spin-independent) scalar \( \sigma \) exchange contribution.

Cancellation of \( (PP)^2 \) and \( S\rho Sd \) interference terms at \( Q = 72 \) MeV suggests a phase cancellation of various meson exchanges and resonance contributions, e.g., associated with the nucleon resonances \( S_{11}(1535), D_{13}(1520), \) and \( P_{11}(1440). \)

To summarize, we have measured the spin analyzing power for \( \eta \) production close to threshold with precision improved by 1 order of magnitude. For excess energy \( Q = 15 \) MeV, the data are consistent with the \( \eta \) production process in the pure \( s \) wave. We find evidence of higher partial waves at \( Q = 72 \) MeV. The \( Ps\rho Pp \) interference determines the shape of the measured analyzing power with cancellation of \( S\rho Sd \) and \( (PP)^2 \) interference terms. The data contradict predictions of presently available meson exchange models of the production mechanism. The analyzing power complements previous measurements of the energy and angular distribution of \( \eta \) meson production and provides new valuable constraints for future model building.
