Anxiety After Stroke
The Importance of Subtyping

Ho-Yan Yvonne Chun, MBBS; William N. Whiteley, PhD; Martin S. Dennis, MD; Gillian E. Mead, MD; Alan J. Carson, MD

Background and Purpose—Anxiety after stroke is common and disabling. Stroke trialists have treated anxiety as a homogenous condition, and intervention studies have followed suit, neglecting the different treatment approaches for phobic and generalized anxiety. Using diagnostic psychiatric interviews, we aimed to report the frequency of phobic and generalized anxiety, phobic avoidance, predictors of anxiety, and patient outcomes at 3 months poststroke/transient ischemic attack.

Methods—We followed prospectively a cohort of new diagnosis of stroke/transient ischemic attack at 3 months with a telephone semistructured psychiatric interview, Fear Questionnaire, modified Rankin Scale, EuroQol-5D5L, and Work and Social Adjustment Scale.

Results—Anxiety disorder was common (any anxiety disorder, 38 of 175 [22%]). Phobic disorder was the predominant anxiety subtype: phobic disorder only, 18 of 175 (10%); phobic and generalized anxiety disorder, 13 of 175 (7%); and generalized anxiety disorder only, 7 of 175 (4%). Participants with anxiety disorder reported higher level of phobic avoidance across all situations on the Fear Questionnaire. Younger age (per decade increase in odds ratio, 0.64; 95% confidence interval, 0.45–0.91) and having previous anxiety/depression (odds ratio, 4.38; 95% confidence interval, 1.94–9.89) were predictors for anxiety poststroke/transient ischemic attack. Participants with anxiety disorder were more dependent (modified Rankin Scale score 3–5, [anxiety] 55% versus [no anxiety] 29%; P<0.0005), had poorer quality of life on EQ-5D5L, and restricted participation (Work and Social Adjustment Scale: median, interquartile range, [anxiety] 19.5, 10–27 versus [no anxiety] 0, 0–5; P<0.001).

Conclusions—Anxiety after stroke/transient ischemic attack is predominantly phobic and is associated with poorer patient outcomes. Trials of anxiety intervention in stroke should consider the different treatment approaches needed for phobic and generalized anxiety. (Stroke. 2018;49:00-00. DOI: 10.1161/STROKEAHA.117.020078.)

Key Words: anxiety ■ ischemic attack, transient ■ neuropsychiatry ■ phobic disorders ■ stroke

Anxiety is common, affecting around a quarter of stroke1 and nearly a third of transient ischemic attack (TIA).2 It can hamper stroke rehabilitation effort and prevent patients from returning to their usual activities. Despite earlier observations that phobic anxiety might be present after stroke,3–5 intervention studies have treated anxiety poststroke as one unitary phenomenon and evaluated general approaches, such as relaxation and antidepressants,6 which are unlikely to be effective in phobic anxiety. Clinical trials have not yielded any definitive evidence to guide treatment for anxiety after stroke.6 It is well recognized in nonstroke populations that phobic disorder and generalized anxiety disorder (GAD) need different treatment approaches.

Phobic and Generalized Anxiety
Phobic anxiety is characterized by a disproportionate fear of well-defined situations or stimuli.2 Exposure to the feared situation triggers unpleasant anxiety symptoms, accompanied by marked avoidant behavior of that feared situation: the hallmark of phobic anxiety.7 Although avoidant behavior may relieve anxiety in the short term, it can become disabling if the behavior becomes consolidated through conditioning; for example, becoming housebound in agoraphobia as a result of learning to associate danger with leaving house. Treatment of phobic disorders requires systematic, repeated, hierarchical exposure to the specific anxiety-provoking stimulus.8 By contrast, GAD is diffuse and unremitting, characterized by persistent and multiple worries; for example, finances, health, and an inability to stop worrying.7 Selective serotonin-reuptake inhibitors, benzodiazepines (in short term only), and other cognitive behavioral therapy (CBT) techniques, for example, cognitive restructuring and problem solving, are effective at treating GAD.9,10
Our Aims
To determine the target for anxiety treatment after stroke, we need to know the proportions of anxiety subtypes; if phobic, the specific stimuli; the predictors for anxiety; the impact of anxiety on functional outcomes and quality of life. We aimed to report (1) the frequency of phobic disorder and GAD at 3 months after stroke and TIA, (2) avoidant behavior of specific anxiety-provoking situations, (3) the predictors of anxiety, and (4) the associations with dependence, quality of life, and social participation.

Methods
The data that support the findings of this study are available from the corresponding author on reasonable request as per the journal’s Transparency and Openness Promotion Guidelines.

Sampling and Recruitment
Prospective Recruitment
We screened consecutive eligible patients admitted to the acute stroke unit and TIA clinics in National Health Service Lothian—the sole provider of stroke and TIA services for the city of Edinburgh, Midlothian, and East Lothian regions in Scotland, between September 9, 2015, and June 28, 2016. We included participants who (1) were aged ≥18, (2) had a new clinical diagnosis of stroke or definite or probable TIA, (3) had mental capacity to give informed consent, and (4) were able to communicate in English on the telephone. We excluded patients with subarachnoid hemorrhage, subdural and extradural hematoma, ocular TIA, patients at terminal stage of life, or who were difficult to follow-up—no fixed abode, current illicit, or alcohol dependence.

Definitions of Stroke and TIA
We used clinical diagnosis of stroke or TIA made by consultant stroke clinicians according to the following: stroke—the sudden loss of focal cerebral function, lasting ≥24 hours, thought to be caused by an inadequate blood supply to part of the brain (ischemic stroke), or spontaneous hemorrhage into the brain substance (primary intracerebral hemorrhagic), where brain imaging was normal or showed evidence of recent ischemia or hemorrhage. TIA—a clinical time-based definition of symptoms lasting <24 hours; TIA was definite when a diagnosis of TIA was the only one considered for the symptoms and probable when a TIA was the most likely of several differential diagnoses.

Baseline Characteristics
We used hospital electronic health records to gather data on age, sex, diagnosis on discharge, vascular territory of stroke/TIA, and the National Institutes of Health Stroke Scale score—a measure of neurological impairment on admission. We assigned a National Institutes of Health Stroke Scale Score of zero to all TIAs. We recorded whether the participants lived alone prestroke or TIA, had a history of stroke or ischemic heart disease, and past diagnosis of anxiety or depression as potential predictors for having anxiety disorder at 3 months after stroke/TIA.

Potential Predictors for Anxiety Disorder at 3 Months After Stroke/TIA
We prespecified age, sex, living alone prestroke/TIA, and a past diagnosis of anxiety or depression as potential predictors for having anxiety disorder at 3 months after stroke/TIA.

Statistical Analyses
We used descriptive statistics to summarize data, exact confidence intervals for proportions, and univariable and multivariable logistic regression to calculate unadjusted and adjusted odds ratios for associations. Group differences were assessed using univariable logistic regression, t tests, and Mann–Whitney U tests as appropriate to data type. Only returned FQs were analyzed for avoidant behavior. All items on the online questionnaire must be scored to permit submission, preventing any unscored items. Any unscored item on a returned postal questionnaire was given the most conservative interpretation and imputed zero, assuming that the item was irrelevant or did not elicit any anxiety symptoms. We performed all statistical analyses using STATA14. We aimed for a target sample size of ≥200 to achieve a desired precision of ±0.05 around our estimated frequency of poststroke anxiety of 0.20.

Results
We recruited 201 participants between September 9, 2015, and June 28, 2016. Twenty-six of 201 participants did not have

CI indicates confidence interval; OR, odds ratio; SCID, Structured Clinical Interview for Diagnostic Statistical Manual-IV-Text Revision; and TIA, transient ischemic attack.

*P<0.05.

SCID at 3 months—3 had died, 1 was on palliation for terminal cancer, 4 had lost mental capacity, 9 withdrew consent for SCID, and 9 were not contactable (Figure I in the online-only Data Supplement). Participants lost to follow-up were more likely to live alone (losses: 15 of 26, 58%; analyzed: 60 of 175, 34%; P=0.024); otherwise, they were similar to those who were analyzed (Table II in the online-only Data Supplement). In the analyzed sample (Table 1), 175 participants (mean age [SD], 70 [12]; women, 70 of 175; 40%) had SCID at 3 months poststroke/TIA. The majority had ischemic stroke, a third had TIA, and few had primary intracerebral hemorrhage (ischemic stroke: 109 of 175, 62%; TIA: 61 of 175, 35%; primary intracerebral hemorrhage: 5 of 175, 3%). We recruited similar numbers from the acute stroke unit and TIA clinic (acute stroke unit: 80 of 175, 46%; TIA clinics: 95 of 175, 54%). Our sample, therefore, consisted of patients with mild stroke and TIA (National Institutes of Health Stroke Scale: median [interquartile range], 0 [0–2]). Nearly all participants were interviewed by telephone (telephone: 168 of 175, 96%; face to face: 7 of 175, 4%).

Frequency of Anxiety Disorders and Psychiatric Comorbidity at 3 Months After Stroke/TIA
A fifth of our sample had at least 1 anxiety disorder at 3 months after stroke/TIA (38 of 175, 22% [95% confidence interval, 16–29%]). Phobic disorder was the most frequent anxiety subtype (phobic disorder only: 18 of 175, 10%; both phobic disorder and GAD: 13 of 175, 7%; GAD only: 7 of 175, 4%; Figure 1A; Table 2). PTSD appeared as a comorbidity in phobic disorder-only cases (6 of 18), GAD-only cases (1 of 7), and both phobic disorder and GAD cases (4 of 13; Table 2). Half of all people with anxiety disorder also had a minor or major depressive episode (20 of 38, 53%; Figure 1B). We found no difference in cognitive function between patients with anxiety disorder and those without (telephone Montreal Cognitive Assessment median, interquartile range: [anxiety disorder] 18, 16–21; [no anxiety disorder] 19, 17–20; P=0.692). Of the TIA patients, 18% (11 of 61) had an anxiety disorder, 10% (6 of 61) had phobic disorder only, 3% (2 of 61) had both phobic disorder and GAD, and 5% (3 of 61) had GAD only.

Avoidant Behavior and Anxiety-Provoking Situations/Stimuli
Eighty-four percent (147 of 175) returned completed FQ for analysis. Nonresponders were younger than the FQ sample analyzed (mean age: nonresponders, 64.8±14.9; FQ analyzed, 70.5±10.6; P=0.017) but did not differ statistically in other characteristics (Table III in the online-only Data Supplement). Participants with an anxiety disorder at 3 months reported significantly higher level of avoidant behavior across all situations on the FQ compared with participants without (Figure 2). Similarly, during SCID, positive responses to all of the 11 predefined situations were more common in participants with anxiety disorder compared with those without (Figure II in the online-only Data Supplement). The fear of stroke recurrence had the most positive responses in those with anxiety disorder (31 of 38, 82%) and in those without (40 of 137; 29%). We
listed any additional anxiety-provoking situations reported during SCID (Table IV in the online-only Data Supplement).

**Associations With Dependence, Health-Related Quality of Life, and Social Participation at 3 Months**

Despite similar baseline neurological impairment (National Institutes of Health Stroke Scale 0–4; [anxiety disorder] 95% versus [no anxiety disorder] 92%; P = 0.575), participants with anxiety disorder were more dependent (modified Rankin Scale score 3–5; [anxiety disorder] 55% versus [no anxiety disorder] 29%; P = 0.0005), reported more problems across all health-related quality of life domains on the EQ-5D5L (Figure 3), and more restriction in social participation (Work and Social Adjustment Scale: median, interquartile range: [anxiety disorder] 19.5, 10–27; [no anxiety disorder] 0, 0–5; P < 0.001).

**Predictors of Anxiety Disorder at 3 Months After Stroke/TIA**

The odds of having an anxiety disorder at 3 months after stroke or TIA decreased by a third per decade increase in age (adjusted odds ratio, 0.64; 95% confidence interval, 0.45–0.91) and increased 4-fold when there was a past diagnosis of anxiety or depression (adjusted odds ratio, 4.38; 95% confidence interval, 1.94–9.89; Table 3). Sex or living alone prestroke/TIA were not statistically associated with anxiety disorder at 3 months.

**Discussion**

**Key Findings**

In our sample of stroke and TIA patients, a fifth had an anxiety disorder diagnosed at psychiatric interview at 3 months. We found phobic disorder to be the predominant anxiety subtype after stroke or TIA. Anxious patients reported more avoidance in agoraphobia-related, social, and other specific situations or stimuli—physical exertion, having sex, being alone at home, activities related to fear of having a headache, another stroke, or a fall. PTSD was more common than we had anticipated. Younger age and having a history of anxiety or depression increased the likelihood of developing anxiety poststroke/TIA. Despite having a similar level of neurological impairment at baseline, participants with anxiety disorder were more dependent, had poorer health-related quality of life, and were more restricted in social participation at 3 months after stroke or TIA compared with those without anxiety disorder.

**Potential Bias in Our Methodology**

Our trained interviewer was a stroke clinician who received training in performing the SCID. We minimized any variability in diagnosis by having all final diagnoses discussed and confirmed with a consultant neuropsychiatrist at weekly meetings. A systematic review of studies assessing the agreement between diagnostic telephone and face-to-face psychiatric interviews found good agreement (κ = 0.69–0.84) between the 2 versions in psychiatric populations, supporting the use of telephone SCID for anxiety disorders and depression. However, there are no such comparability data in stroke. The use of telephone SCID in our study could have influenced the accuracy of the true estimates of our SCID diagnoses. SCID diagnosis was made based on formal diagnostic criteria and coding system, taking into account detailed narrative of the patient’s experience. Temporary distress experienced by the participant at the time of SCID, if any, was unlikely to influence the final diagnosis. Our final sample size of 175 fell short of the 200 we intended to recruit. This impacted slightly on the precision of our frequency estimates for any anxiety disorder, from ±0.05 to ±0.06.

We note a high proportion of previous anxiety or depression in our sample. Case ascertainment relied on participants’ recollection of any past diagnosis made throughout their lifetime, potentially leading to overestimates. We had losses to follow-up in the prospective cohort. More people lived alone in the...
losses compared with those who underwent SCID. This could have led to underestimates of anxiety disorder and depression because living alone is associated with a higher psychiatric morbidity in the general population.\textsuperscript{23} We lost FQ data through nonresponders, and they were younger compared with the FQ sample analyzed. Although over a quarter of participants completed the FQ online as their preferred method, we did not test the agreement between the 2 versions. Our population was at the milder end of the stroke spectrum.

Interpretation

Our frequency estimate falls within the range of frequencies reported in a recent meta-analysis of anxiety poststroke: 18% to 25%.\textsuperscript{1} We found phobic disorder to be the predominant anxiety subtype poststroke/TIA and quantified for the first time, the avoidant behavior of specific anxiety-provoking situations in people with anxiety poststroke/TIA. Our study is the first to have assessed the frequency of anxiety subtypes using diagnostic interview in TIA patients.\textsuperscript{24} Similar to our main analysis, phobic disorder was the most frequent anxiety subtype post-TIA. Our frequency estimate of anxiety disorder post-TIA is similar to that reported using a rating scale cutoff for definite anxiety in a regional stroke registry.\textsuperscript{2}

Figure 2. The thick lines represent median; boxes represent interquartile range; and whiskers represent range. Avoidant behavior in agoraphobic, social, and other specific situations (n=147). FQ indicates Fear Questionnaire.

Earlier studies suggested phobic anxiety might be present after stroke,\textsuperscript{3,4} yet clinical trials of anxiety intervention did not translate this finding, treating anxiety poststroke as a unitary phenomenon. Thus far, only general approaches, such as relaxation and antidepressants, have been evaluated in stroke,\textsuperscript{6} which are unlikely to be effective in patients with predominantly phobic anxiety. Our findings suggest the need to evaluate exposure techniques—an approach known to be effective in phobic disorder in nonstroke populations\textsuperscript{8} but one that has never been evaluated in stroke. We identified the specific situations/stimuli avoided in our anxious participants, which could be potential targets for psychotherapy; for example, CBT.

Fear of Stroke Recurrence

The fear of stroke recurrence was the most commonly reported anxiety-provoking stimulus in our participants, with or without anxiety disorder. In our interviews, we found this anxious anticipation—the experience of anxiety by thinking about an event in the future, to have led to differential behaviors in our participants. In some, this anticipatory anxiety brought about a desire for better health and increased positive health behaviors; for example, complying to medications and doctor’s advice on lifestyle and giving up smoking. In others, this anticipatory anxiety became
disproportionate and perpetuated maladaptive avoidant behaviors of specific situations; for example, travelling alone, crowds, physical exertion, and social gatherings. The fear of stroke recurrence, accompanied by a sense of complete loss of control in a public place, seemed to underlie the agoraphobia in our participants. These maladaptive thinking patterns and avoidant behaviors are potential targets for cognitive restructuring and exposure therapy in a CBT intervention. In exposure therapy, phobic patients confront their specific feared situation in a graduated hierarchical fashion, until the unpleasant anxiety feelings diminish. The individual’s realization that catastrophe has not occurred, despite confronting his/her feared situation, for example, taking the bus, can be used to help challenge a maladaptive belief; for example, “I am going to have a stroke if I travel on the bus.”

Figure 3. Baseline NIHSS, mRS and EuroQol 5D-5L domains, by anxiety disorder at 3 months post-stroke/TIA (n=175). mRS indicates modified Rankin Scale; NIHSS, National Institutes of Health Stroke Scale; and EQ5D-5L, EuroQol-5D5L.
Psychiatric Comorbidity
Psychiatric comorbidity in our sample was common, and its symptoms should be considered in the treatment of anxiety poststroke/TIA. Few studies have estimated the frequency of clinical diagnosis of PTSD poststroke/TIA.25 Like phobic and generalized anxiety, PTSD has specific treatment strategies in nonstroke populations—trauma-focused CBT and eye movement reprocessing.26,27 These now need to be tested in and generalized anxiety, PTSD has specific treatment strategies in nonstroke populations—trauma-focused CBT and eye movement reprocessing.26,27 These now need to be tested in

Predictors of Anxiety Poststroke/TIA
The likelihood of developing anxiety after stroke or TIA increased in younger people and in those with a history of anxiety or depression, consistent with anxiety in the general population. In contrast to the general population, men were as likely as women to develop anxiety poststroke/TIA. We found no association between lesion location and anxiety poststroke/TIA.

Conclusions
Phobic disorder is the predominant anxiety subtype and can occur in the absence of GAD after a mild stroke or TIA. Future trials of anxiety intervention in stroke must consider the presence of phobic disorder and should consider the use of exposure therapy techniques and augmented CBT.
