Self-assembly is a promising route for micro- and nano-fabrication with potential to revolutionise many areas of technology, including personalised medicine. Here we demonstrate that external control of the swimming speed of microswimmers can be used to self assemble reconfigurable designer structures in situ. We implement such ‘smart templated active self assembly’ in a fluid environment by using spatially patterned light fields to control photon-powered strains of motile Escherichia coli bacteria. The physics and biology governing the sharpness and formation speed of patterns is investigated using a bespoke strain designed to respond quickly to changes in light intensity. Our protocol provides a distinct paradigm for self-assembly of structures on the 10 μm to mm scale.

There are two conceptually distinct ways to construct nano-and micro-structures: ‘top-down’ techniques such as lithography use ‘scapels’ (chemical etching or electron beams, etc.), whereas microscopic ‘Lego components’ move themselves into position—self assembly—in ‘bottom-up’ techniques. Both equilibrium phase transitions (e.g., crystallisation) and non-equilibrium processes are exploited for self assembly. In either case, external templates can be used to direct the process, with reconfigurable templates offering programmability. Self assembly was originally inspired by viral biology, where the components are biomacromolecules. Increasingly, synthetic colloidal building blocks are used, with bespoke particle shape, size and interaction, e.g., ‘patchy’ particles with heterogeneous surface chemistry. Active, or self-propelled, colloids open up further opportunities.

Such self-propelled micro-swimmers are attracting significant recent attention as ‘active matter’ and may be used to transport colloidal ‘cargoes’. For both fundamental physics and applications, external control of swimming, e.g., using particles with light-activated self- propulsion, opens up many new possibilities. For example, light-activated motile bacteria can be used to actuate and control micro-machinery.

The self-assembly of micro-swimmers into clusters of tens of particles has already been demonstrated and may be used to transport colloidal ‘cargoes’ and ‘cargoes’.

For both fundamental physics and applications, external control of swimming, e.g., using particles with light-activated self-propulsion, opens up many new possibilities. For example, light-activated motile bacteria can be used to actuate and control micro-machinery.

An E. coli bacterium swims by turning 7–10 μm long helical flagella attached to the cell body (∼2 μm × 1 μm) using membrane-embedded rotary motors powered by a protonotive force (PMF), which arises from the active pumping of H⁺ to the extracellular medium. Unlike all synthetic active colloids to date and most bacteria, E. coli can generate PMF in nutrient-free motility buffer by utilising internal resources and oxygen (O₂) to produce energetic electron pairs. These release their energy stepwise along an electrochemical potential ladder of respiratory enzymes located in the inner cell membrane, generating a PMF of ≈ −150 mV. The electron pair ultimately passes to and reduces O₂ to water. Thus, with no O₂, PMF = 0 and swimming ceases.

If cells under anaerobic conditions can express proteorhodopsin (PR), a green-photon-driven proton pump, then they will swim only when suitably illuminated: these are living analogues of synthetic light-activated microswimmers.

In the following we demonstrate STASA using light-controlled E. coli bacteria. We show that the rapidity with which this bacteria react to changes in light intensity has a major influence on the pattern formation, and we construct a bespoke strain for which this response is fast on the 1 s time scale. We characterise the dynamics of pattern formation and explain the different scaling laws observed for protocols in which the bacteria are either initially stationary or already swimming. Finally, we explore the physics controlling the sharpness and resolution of patterns.

**Results**

**Temporal response of light-controlled E. coli strains.** We suspended cells in phosphate motility buffer at optical density OD ≤ 8 (cell-body volume fraction ≈ 1.1%) and sealed 2 μl into 20 μm-high, flat capillaries, where cells swim in two dimensions but have enough room to ‘overtake’ each other in all three spatial dimensions. Differential dynamic microscopy (DDM) returned an averaged speed v ≈ 30 μm s⁻¹ and a non-motile fraction β = 20% at OD = 1 under fully oxygenated conditions. (We use ‘non-motile’ to refer to cells that can never swim and ‘stationary’ for non-swimming cells capable of motility when illuminated.)

Motile cells were allowed to swim until O₂ was depleted and v dropped abruptly to zero after a few minutes (see Supplementary Fig. 1). After these cells were left in the dark for ∼10 min, green illumination was turned on (510–560 nm, intensity I ≈ 5 mW cm⁻² at the sample). The stationary cells accelerated uniformly before saturating in speed (Fig. 1a). Fitting the data for freshly prepared cells to v(t) = v_sat/(1 + t/τ_off) gives v_sat = 9.5 μm s⁻¹, τ_off = 30 s. v_sat can be controlled by the illumination intensity I (Fig. 1a, inset), up to ≲28 μm s⁻¹. We find that {V, β, v_sat, τ_off} changed over hours as cells aged.

What happens when illumination ceases can be optimised by genetic modification. In the strain we constructed for this work (AD10), in which the unc gene cluster has been deleted (see Methods), v has dropped sharply by the time the first data point was taken after the illumination was switched off, so that τ_off < 1 s, the same time period in this part of the experiment (Fig. 1b). It is unclear why a few cells (<1%) continued to swim, so that v never quite reached zero. In a strain without unc deletion (AD57), v dropped much slower upon cessation of illumination (Fig. 1b) as seen previously. The unc cluster codes for F₁/Fₒ-ATPase, which is normally powered by the PMF to generate ATP. However, in darkness the unc wild type can use this membrane protein complex in reverse to export protons and so sustains a PMF for some time; this is not possible with unc deletion.

In the absence of any source of PMF in darkness, τ_off should be controlled by the discharging of the PMF through an effective resistor–capacitor circuit (see Supplementary Note 1 for details). The effective membrane capacitance is C ≈ 10⁻¹⁴ F. The effective resistance, R_sat, combines in parallel the resistance of the membrane, the motors (each of which is R_m ≲ 10¹⁴ Ω) and other transmembrane components, so that R_sat < R_sat is an upper bound, and we expect R_mC < 1 s, as observed. Consistent with this interpretation, τ_off is approximately independent of the starting speed of decelerating cells at our experimental time resolution (Fig. 1c).

The fitted ‘on time’ for freshly prepared cells, τ_on = 40 s (Fig. 1a, black points), is likely controlled by the rate constant for stator units to come on and off motors, k_on ≈ 0.04 s⁻¹ ~ τ_off. In sustained darkness, motors disassemble in PR-bearing E. coli, and full ‘motor resurrection’ upon illumination takes ~200 s, in agreement with our data (Fig. 1a). Consistent with this, if illumination is lowered and then restored rapidly (i.e., within a time interval ≪ k⁻¹), motors do not have time to disassemble and τ_off ≈ τ_off (Fig. 1d).

**Smart templated active self assembly.** Our STASA protocol uses a digital mirror device to project patterns of illumination onto a uniform field of cells rendered stationary by O₂ exhaustion. We first projected a positive mask with bright features on a dark background (Fig. 2a, inset). The width of the features, 90 μm, is comparable to the persistence length of the smooth-swimming E. coli strains used in this work (i.e., the length scale over which cells effectively swim in straight lines). Over time, the mask pattern was replicated in the cell population with increasing clarity: cells react to changes in light intensity has a major influence on the pattern formation and we construct a bespoke strain for which this response is fast on the 1 s time scale. We characterise the dynamics of pattern formation and explain the different scaling laws observed for protocols in which the bacteria are either initially stationary or already swimming. Finally, we explore the physics controlling the sharpness and resolution of patterns.

features immediately and stop within $\tau_{off}$, rapidly outlining the inside edge of the masked areas (Fig. 2c). Thereafter, the dark areas progressively filled up: bacteria continually arrive from the outside, which acts as an essentially infinite reservoir of swimming cells (Fig. 2d, e and see also Supplementary Movies 2 and 3). Other patterns can be ‘painted’ using this method (Fig. 2g), their shape can be updated in situ and the patterns can be erased by illuminating them with a uniform light field (see Supplementary Movie 4). In contrast to the recently demonstrated painting of one-off polychromatic patterns using mixed colonies of differently coloured bacteria on solid agar,$^{32}$ our method produces dynamic monochrome patterns that are reconfigurable in real time inside a liquid medium.

**Dynamics of pattern formation.** To understand how fast spatial patterns can be established, we experimented with square masks (Fig. 2f) starting from two initial conditions: a (dark) field of stationary cells ($\bar{\nu}(0) = 0$, i.e., diffusive) and a field of illuminated cells that have reached speed saturation ($\bar{\nu}(0) = \bar{\nu}_{sat}$). We studied the evolution of cell density (see Methods) and the speed inside bright squares against a dark background. Starting with diffusive cells, $\bar{\nu}(t) = \bar{\nu}_{sat} t / (t + \tau_{on}) \approx a t$ with $a = \bar{\nu}_{sat} / \tau_{on}$ for $t \lesssim \tau_{on}$. The time to empty an $L \times L$ square should thus scale as $t_{D}(L) \sim (2L/a)^{0.5}$.

The measured evolution of the density of 1 h-old cells, $\rho_{tot}(t)$, in illuminated squares of different sizes is shown in Fig. 3a, from which we extracted $t_{D}$, the time for $\rho_{tot}$ to drop to $1/e$ of its decay. As expected, $t_{D}(L) \sim L^{0.5}$ (Fig. 3c). Fitting Eq. (1) gives $a = 0.05 \mu m s^{-2}$, which is a reasonable average acceleration over the first ~100 s for the magenta data points in Fig. 1 for 1 h-old cells (where the dot-dash line has slope 0.05 $\mu m s^{-2}$). Moreover, $\bar{\nu}_{D,max}$, the maximum average swimming speed reached during emptying depends on the box size, displaying a $L^{0.3}$ scaling, which is also consistent with our model (Fig. 3c and Supplementary Note 2).

On the other hand, starting with cells all swimming (on average) at $\bar{\nu}_{sat}$, a square should empty in $t_{S}(L) \sim L / \bar{\nu}_{sat}$.

From the measured $\rho_{tot}(t)$ in this case (Fig. 3b), we deduced a ‘box emptying time’ and find (Fig. 3c) the expected scaling, $t_{S}(L) \sim L$. Fitting Eq. (2) gives $\bar{\nu}_{sat} \approx 8 \mu m s^{-1}$, consistent with the measured $\bar{\nu}_{sat} = 8.8 \mu m s^{-1}$. Equations (1) and (2) are also

---

**Fig. 1** Response to light. **a** Population-averaged speed vs. time for initially stationary *E. coli* AD10, light on at $t = 0$ and off at $t \approx 1400 s$ (black circles); green shading = illuminated, and the data point just after switch-off are 1 s apart. This sample was measured soon after the cells had run out of O2. One hour later, cells accelerated less rapidly (magenta crosses). Full lines: fits to $\bar{\nu}(t) = \bar{\nu}_{sat} t / (t + \tau_{on})$. The dot-dashed line shows the acceleration (0.05 $\mu m s^{-2}$) obtained from ‘box emptying’ experiments starting from stationary cells. Inset: dependence of $\bar{\nu}_{sat}$ on incident light intensity (points) fitted to $\bar{\nu}_{sat}(I) = \bar{\nu}_{max} I / (I + I_{1/2})$ (see Supplementary Note 1). **b** Strain AD10 with *unc*-cluster deletion shows a rapid decrease in speed ($\approx 8.8 \mu m s^{-1}$) on switching off, rapidly outlining the field of illuminated squares of different sizes is shown in Fig. 3a, from which we extracted $t_{D}$. As expected, $t_{D}$ is $\approx 1 s$ independent of the initial swimming speed at the resolution limit of our technique. **c** AD10 bacteria adapt their swimming speed within 1 s as the green light is alternated between low and high intensity. In this case $\tau_{on} \approx \tau_{off}$. Error bars in all these plots depict SD from the mean speed over a range of $0.5-1.5 \mu m s^{-1}$.
confirmed by the data collapse achieved for $\rho_{\text{off}}(t)$ when we scale the time axis by $L^{0.5}$ and $L$, respectively (Fig. 3a, b).

Further insight on the time scale for feature formation comes from studying cells moving into a dark area. We projected a 270 $\mu$m-wide dark strip onto a field of initially diffusive cells (Fig. 2h). An edge rapidly developed just inside the darkened area, corresponding to twin peaks in the spatial cell density profile (Fig. 2i; as measured by the variance of image intensity, see Methods), which broaden and fill the stripe over time. The squared displacement of this peak shows diffusive dynamics, $\Delta x^2 = 2D\tau$ (Fig. 3d) with a fitted $D = 0.74\, \mu m^2\, s^{-1}$. The interface between bright and dark areas acts as an absorber of swimmers arriving with an effective diffusive process. Owing to conservation of mass, the diffusive propagation of the peak is thus expected, although quantitative aspects remain to be elucidated.

**Pattern sharpness and resolution.** Finally, we seek to understand what controls the sharpness of the self-assembled features using our method. A stark demonstration of the answer comes from projecting a step-function pattern of light–dark illumination on initially uniformly swimming cells (see Supplementary Note 3 for details). Figure 4 shows the resulting cell density profile (from the intensity variance, see Methods) for two strains, AD10, with $\tau_{\text{stop}} \lesssim 1$ s, and AD57, a strain lacking the $unc$ cluster deletion and having $\tau_{\text{off}} > 1$ min. In the case of AD10, the illumination pattern is clearly replicated in cell density within 1 min and the steady state shows a sharp feature with half width $\lesssim 10\, \mu m$. For AD57, it takes $\gg 1$ min to establish a corresponding density pattern, which, in the steady state, is $\geq 50\, \mu m$ wide. Thus, a short enough $\tau_{\text{off}}$ or more specifically a short mean stopping distance $\bar{\tau}_{\text{stop}} = \bar{\tau}_{\text{off}}$, is necessary for the fast establishment of sharp features using our protocol.

The resolution achievable with STASA depends on the mean stopping distance $\bar{\tau}_{\text{stop}}$ of the bacteria, as well as the sharpness and contrast of the projected light template. In our current experimental implementation, the optics projecting the templating pattern is designed to illuminate a large area of the sample at the expense of spatial resolution. This allowed us to reliably construct features of about 10 $\mu m$ in width (Fig. 5). However, ultimately the stopping distance $\bar{\tau}_{\text{stop}}$ will prove the practical limit of STASA, which at low swimming speeds is comparable to the size of individual bacteria. The use of more complex grayscale templates and dynamically adjustable patterns will help reaching this limit more rapidly and reliably.

**Discussion**

We have demonstrated how to perform smart templated self assembly using a proteorhodopsin-bearing strain of *E. coli* with *unc* cluster deletion dispersed in anaerobic motility buffer. Spatial patterns of light are reproduced sharply as patterns in cell density. The time scale of pattern formation is controlled by the (saturation) swimming speed and the ‘on time’, and the sharpness of the features by the ‘off time’. Once established, the patterns persist for as long as the light template is applied. Uniform light can be used to quickly erase the patterning, whereas removing the light completely will lead to a slow diffusion driven ‘dissolution’ of the pattern.
The successful implementation of this protocol opens up many opportunities. In terms of fundamental active matter physics, it should now be possible to test the fundamental prediction that the product of density and speed is constant in a system with spatially dependent activity. For practical applications, it should now be possible to demonstrate an ‘all biological’ version of the controlled actuation of lithographed micro-devices using light-activated bacteria: STASA allows the assembly and real-time reconfiguration of the devices themselves using the same bacteria used to actuate the devices. On the other hand, if high cell density is used to trigger the secretion of adhesive biopolymers, and/or bacteria can be turned into microparticles of refractory ceramic-precursor materials such as silica, then bacterial STASA offers a route for manufacturing bespoke 10–100 μm microstructures, which remains a challenging length scale for current additive manufacturing methods.

**Methods**

**Bacterial strains.** Both AD10 and AD37 are smooth-swimming mutants, which were constructed using our laboratory stock of E.coli AB1157. For AD10, all of the genes present within the operon encoding the ATP synthase complex (atpB, atpE, atpF, atpH, atpA, atpG, atpD, atpC) were deleted in a single step by allelic replacement using a recombinant pTOR24 vector containing 400 bp homology arms flanking the deletion on each side. This resulted in the Δunc strain AD10 with a deletion of 7504 bp (corresponding to position 3,915,552 of the E.coli K12 MG1655 chromosome). P1 transduction was used to delete the cheY gene in both this strain and the parental strain (to generate AD57) using JW1871 (BW25113 cheY) as donor. Diagnostic PCR reactions were performed to confirm genotypes. Both strains were transformed with plasmid pBAD-His C (a kind gift...
from Jan Lifshirts, UC Berkeley) encoding the SAR86 γ-proteobacterial photodhopsin variant.27

Sample preparation. Overnight cultures were grown aerobically in 10 ml Luria–Bertani broth using an orbital shaker at 30 °C and 200 r.p.m. A fresh culture was inoculated as 1:100 dilution of overnight-grown cells in 35 ml tryptone broth and grown for 4 h, by which point AD10 has reached an optical density of OD600 ≈ 0.2 (whereas AD57 reached OD ≈ 0.35). The production of PR was induced by adding arabinose to a concentration of 1 mM, as well as the necessary cofactor allo-trans-retinal to 10 μM in the growth medium. Cells were incubated under the same conditions for a further hour to allow protein expression to take place and then transferred to motility buffer (MB, pH 7.0, 6.2 mM K₂HPO₄, 3.8 mM KH₂PO₄, 67 mM NaCl and 0.1 mM EDTA). Cells were re-suspended in MB after a single filtration (0.45 μm HATF filter, Millipore), yielding high-concentration stock solutions (OD = 8–10), which were then diluted with MB as required.

Suspensions were loaded into 2 μl sample chambers (SC-20-01-08-B, Leja NL, = 6 mm × 10 mm × 20 μm), giving a quasi-two-dimensional environment for E. coli swimming. The chamber was sealed using vaseline to stop flow and oxygen supply, and placed onto a microscope for video recording. E. coli initially swims under endogenous metabolism, which depletes the oxygen within the sample cells.25 Once oxygen is depleted, the cells stop swimming unless illuminated by green light.

Optical setup. The samples were observed using a Nikon TE2000 inverted microscope with a phase-contrast objective (PF 10×/0.3). Time series of 40 s movies were recorded at 100 frames per second using a fast CMOS camera (MC 1362, Mikrotron). A long-pass filter (RG630, Schott Glass) was introduced into the bright-field light path to ensure that the light required for imaging did not activate PR. The light controlling the swimming behaviour of the bacteria was provided by an LED light source (Sola SE II, Lumencor) filtered to a green wavelength range (510–560 nm) to overlap with the absorption peak of PR.27 This light was reflected off a digital mirror device (DLP6500, Texas Instruments), which was imaged onto the microscope sample plane using demagnifying relay optics (see Supplementary Fig. 4 for a schematic of the complete optical setup). The light was coupled into the transmission path by introducing a dichroic mirror in between the long working distance phase-contrast condenser and the sample. This ‘trans’ geometry allowed us to uniformly illuminate a circular area of ≈ 2.9 mm in diameter, larger than the objective’s field of view. As the digital mirror chip is conjugate with the sample plane, any pattern applied to it is directly imaged onto the sample, with the edge length of a digital mirror ‘pixel’ corresponding to 2.7 μm. Computer control of the pattern displayed on the digital mirror device gave us precise spatial and temporal control of the illumination pattern. For the work presented here, we restricted ourselves to binary patterns and simply toggled between a few selected patterns, rather than small while at the same time leading to a significant characteristic variance per object.

Data availability. The research data presented in this publication is available on the Edinburgh DataShare repository.34
