Abstract. Classification of high dimensional data finds wide-ranging applications. In many of these applications equipping the resulting classification with a measure of uncertainty may be as important as the classification itself. In this paper we introduce, develop algorithms for, and investigate the properties of, a variety of Bayesian models for the task of binary classification; via the posterior distribution on the classification labels, these methods automatically give measures of uncertainty. The methods are all based around the graph formulation of semi-supervised learning.

We provide a unified framework which brings together a variety of methods which have been introduced in different communities within the mathematical sciences. We study probit classification [50] in the graph-based setting, generalize the level-set method for Bayesian inverse problems [27] to the classification setting, and generalize the Ginzburg-Landau optimization-based classifier [7, 46] to a Bayesian setting; we also show that the probit and level set approaches are natural relaxations of the harmonic function approach introduced in [56]. We introduce efficient numerical methods, suited to large data-sets, for both MCMC-based sampling as well as gradient-based MAP estimation. Through numerical experiments we study classification accuracy and uncertainty quantification for our models; these experiments showcase a suite of datasets commonly used to evaluate graph-based semi-supervised learning algorithms.

1. Introduction.

1.1. The Central Idea. Semi-supervised learning has attracted the attention of many researchers because of the importance of combining unlabeled data with labeled data. In many applications the number of unlabeled data points is so large that it is only feasible to label a small subset of these points by hand. Therefore, the problem of effectively utilizing correlation information in unlabeled data to automatically extend the labels to all the data points is an important research question in machine learning.

This paper concerns the issue of how to address uncertainty quantification in such classification methods. In doing so we bring together a variety of themes from the mathematical sciences, including optimization, PDEs, probability and statistics. We will show that a variety of different methods, arising in very distinct communities, can all be formulated around a common objective function

\[ J(w) = \frac{1}{2} \langle w, Pw \rangle + \Phi(w) \]
for a real valued function $w$ on the nodes of a graph representing the data points. The matrix $P$ is proportional to a graph Laplacian derived from the unlabeled data and the function $\Phi$ involves the labelled data. The variable $w$ is used for classification. Minimizing this objective function is one approach to such a classification. However if uncertainty is modeled then it is natural to consider the probability distribution with density $P(w)$ proportional to $\exp(-J(w))$; this will be derived using Bayesian formulations of the problem.

We emphasize that the variety of probabilistic models considered in this paper arise from different assumptions concerning the structure of the data. Our objective is to introduce a unified framework within which to propose and evaluate algorithms to sample $P(w)$ or minimize $J(w)$. We will focus on Monte Carlo Markov Chain (MCMC) and gradient descent. The objective of the paper is not to assess the validity of the assumptions leading to the different models; this is an important modeling question best addressed through understanding of specific classes of data arising in applications.

1.2. Literature Review. There are a large number of possible approaches to the semi-supervised learning problem, developed in both the statistics and machine learning communities. The review [55] provides an excellent overview. In this paper we will concentrate exclusively on graph-based methods. These have the attractive feature of reducing potentially high dimensional unlabeled data to a real-valued function on the edges of a graph, quantifying affinity between the nodes; each node of the graph is identified with an unlabeled data point.

Early graph-based approaches were combinatorial. Blum et al. posed the binary semi-supervised classification problem as a Markov random field (MRF) over the discrete state space of binary labels, the MAP estimation of which can be solved using a graph-cut algorithm in polynomial time [55]. In general, inference for multi-label discrete MRFs is intractable [19]. However, several approximate algorithms exist for the multi-label case [13, 12, 32], and have been applied to many imaging tasks [14, 5, 30].

A different line of work is based on using the affinity function on the edges to define a real-valued function $w$ on the nodes of the graph, a substantial compression of high dimensional unlabelled data at each node. The Dirichlet energy $J_0(w) := \frac{1}{2} \langle w, Pw \rangle$, with $P$ proportional to the graph Laplacian formed from the affinities on the edges, plays a central role. A key conceptual issue in the graph-based approach is then to connect the labels, which are discrete, to this real-valued function. Strategies to link the discrete and continuous data then constitute different modeling assumptions. The line of work initiated in [56] makes the assumption that the labels are also real-valued and take the real values $\pm 1$, linking them directly to the real-valued function on the nodes of the graph; this may be thought of as a continuum relaxation of the discrete state space MRF in [11]. The basic method is to minimize $J_0(w)$ subject to the hard constraint that $w$ agrees with the label values; alternatively this constraint may be relaxed to a soft additional penalty term added to $J_0(w)$. These methods are a form of krigging, or Gaussian process regression [49, 50], on a graph. A Bayesian interpretation of the approach in [56] is given in [57] with further developments in [28]. The Laplacian based approach has since been generalized in [54, 4, 45, 43, 31]; in particular this line of work developed to study the transductive problem of assigning predictions to data points off the graph. A formal framework for graph-based regularization, using $J_0(w)$, can be found in [3, 41]. We also mention related methodologies such as the support vector machine (SVM) [10] and robust convex minimization methods [1, 2] which may be based around minimization of $J_0(w)$ with an
additional soft penalty term; however since these do not have a Bayesian interpretation we do not consider them here. Other forms of regularization have been considered such as the graph wavelet regularization [40, 23].

The underlying assumption in much of the work described in the previous paragraph is that the labels are real-valued. An arguably more natural modelling assumption is that there is a link function, such as the $\text{sign}$ function, connecting a real-valued function on the graph nodes with the labels via thresholding. This way of thinking underlies the probit approach [50] and the Bayesian level set method [27, 20], both of which we will study in this paper. Lying between the approaches initiated by [56] and those based on thresholding are the methods based on optimization over real-valued variables which are penalized from taking values far from $\pm 1$; this idea was introduced in the work of Bertozzi et al. [7, 46]. It is based on a Ginzburg-Landau relaxation of the discrete Total Variation (TV) functional, which coincides with the graph cut energy. This was generalized to multiclass classification in [22]. Following this line of work, several new algorithms were developed for semi-supervised and unsupervised classification problems on weighted graphs [26, 33, 36].

The Bayesian way of thinking is foundational in artificial intelligence and machine learning research [10]. However, whilst the book [50] conducts a number of thorough uncertainty quantification studies for a variety of learning problems using Gaussian process priors, most of the papers studying graph based learning referred to above primarily use the Bayesian approach to learn hyperparameters in an optimization context, and do not consider uncertainty quantification. Thus the careful study of, and development of algorithms for, uncertainty quantification in classification remains largely open. There are a wide range of methodologies employed in the field of uncertainty quantification, and the reader may consult the books [42, 44, 52] and the recent article [38] for details and further references. Underlying all of these methods is a Bayesian methodology which we adopt and which is attractive both for its clarity with respect to modelling assumptions and its basis for application of a range of computational tools. Nonetheless it is important to be aware of limitations in this approach, in particular with regard to its robustness with respect to the specification of the model, and in particular the prior distribution on the unknown of interest [37].

1.3. Our Contribution. In this paper, we focus exclusively on the problem of binary semi-supervised classification; however the methodology and conclusions will extend beyond this setting, and to multi-class classification in particular. Our focus is on a presentation which puts uncertainty quantification at the heart of the problem formulation, and we make four primary contributions:

- we define a number of different Bayesian formulations of the graph-based semi-supervised learning problem and we connect them to one another, to binary classification methods and to a variety of PDE-inspired approaches to classification; in so doing we provide a single framework for a variety of methods which have arisen in distinct communities and we open up a number of new avenues of study for the problem area;
- we highlight the pCN-MCMC method for posterior sampling which, based on analogies with its use for PDE-based inverse problems [18], has the potential to sample the posterior distribution in a number of steps which is independent of the number of graph nodes;
- we introduce approximations exploiting the empirical properties of the spectrum of the graph Laplacian, generalizing methods used in the optimization context in [7], allowing for computations at each MCMC step which scale well
with respect to the number of graph nodes;
• we demonstrate, by means of numerical experiments on a range of problems, both the feasibility, and value, of Bayesian uncertainty quantification in semi-supervised, graph-based, learning, using the algorithmic ideas introduced in this paper.

1.4. Overview and Notation. The paper is organized as follows. In section 2, we give some background material needed for problem specification. In section 3 we formulate the three Bayesian models used for the classification tasks. Section 4 introduces the MCMC and optimization algorithms that we use. In section 5, we present and discuss results of numerical experiments to illustrate our findings; these are based on four examples of increasing size: the house voting records from 1984 (as used in [7]), the tunable two moons data set [16], the MNIST digit data base [29] and the hyperspectral gas plume imaging problem [15]. We conclude in section 6. To aid the reader, we give here an overview of notation used throughout the paper.

• \(Z\) the set of nodes of the graph, with cardinality \(N\);
• \(Z'\) the set of nodes where labels are observed, with cardinality \(J \leq N\);
• \(x: Z \mapsto \mathbb{R}^d\), feature vectors;
• \(u: Z \mapsto \mathbb{R}\) latent variable characterizing nodes, with \(u(j)\) denoting evaluation of \(u\) at node \(j\);
• \(S: \mathbb{R} \mapsto \{-1, 1\}\) the thresholding function;
• \(S_{\epsilon}\) relaxation of \(S\) using gradient flow in double-well potential \(W_{\epsilon}\);
• \(l: Z \mapsto \{-1, 1\}\) the label value at each node with \(l(j) = S(u(j))\);
• \(y: Z' \mapsto \{-1, 1\}\) or \(y: Z' \mapsto \mathbb{R}\), label data;
• \(v: Z \mapsto \mathbb{R}\) with \(v\) being a relaxation of the label variable \(l\);
• \(A\) weight matrix of the graph, \(L\) the resulting normalized graph Laplacian;
• \(P\) the precision matrix and \(C\) the covariance matrix, both found from \(L\);
• \(\{q_k, \lambda_k\}_{k=0}^{N-1}\) eigenpairs of \(L\);
• \(U:\) orthogonal complement of the null space of the graph Laplacian \(L\), given by \(q_0^\perp\);
• \(GL:\) Ginzburg-Landau functional;
• \(\mu_0, \nu_0:\) prior probability measures;
• the measures denoted \(\mu\) typically take argument \(u\) and are real-valued; the measures denoted \(\nu\) take argument \(l\) on label space, or argument \(v\) on a real-valued relaxation of label space;

2. Problem Specification. In subsection 2.1 we formulate semi-supervised learning as a problem on a graph. Subsection 2.2 defines the relevant properties of the graph Laplacian and in subsection 2.3 these properties are used to construct a Gaussian probability distribution; in section 3 this Gaussian will be used to define our prior information about the classification problem. In subsection 2.4 we discuss thresholding which provides a link between the real-valued prior information, and the label data provided for the semi-supervised learning task; in section 3 this will be used to define our likelihood.

2.1. Semi-Supervised Learning on a Graph. We are given a set of feature vectors \(X = \{x(j), \ldots, x(j), \ldots, x(N)\}\) for each \(j \in Z := \{1, \ldots, N\}\). For each \(j\) the feature vector \(x(j)\) is an element of \(\mathbb{R}^d\), so that \(X \in \mathbb{R}^{d \times N}\). Graph learning starts from the construction of an undirected graph \(G\) with vertices \(Z\) and edge weights \(\{A\}_{ij} = a_{ij}\) computed from the feature set \(X\). The weights \(a_{ij}\) will depend only on \(x(i)\) and \(x(j)\) and will decrease monotonically with some measure of distance between
\(x(i)\) and \(x(j)\); the weights thus encode affinities between nodes of the graph. Although a very important modelling problem, we do not discuss how to choose these weights in this paper. For graph semi-supervised learning, we are also given a partial set of (possibly noisy) labels \(y = \{y(j)\mid j \in Z'\}\), where \(Z' \subseteq Z\) has size \(J \leq N\). The task is to infer the labels for all nodes in \(Z\), using the weighted graph \(G = (Z, A)\) and also the set of noisily observed labels \(y\). In the Bayesian formulation which we adopt the feature set \(X\), and hence the graph \(G\), is viewed as prior information, describing correlations amongst the nodes of the graph, and we combine this with a likelihood based on the noisily observed labels \(y\), to obtain a posterior distribution on the labelling of all nodes. Various Bayesian formulations, which differ in the specification of the observation model and/or the prior, are described in section 3. In the remainder of this section we give the background needed to understand all of these formulations, thereby touching on the graph Laplacian itself, its link to Gaussian probability distributions and, via thresholding, to non-Gaussian probability distributions and to the Ginzburg-Landau functional. An important point to appreciate is that building our priors from Gaussians confers considerable computational advantages for large graphs; for this reason the non-Gaussian priors will be built from Gaussians via change of measure or push forward under a nonlinear map.

2.2. The Graph Laplacian. The graph Laplacian is central to many graph-learning algorithms. There are a number of variants used in the literature; see [7, 47] for a discussion. We will work with the normalized Laplacian, defined from the weight matrix \(A = \{a_{ij}\}\) as follows. We define the diagonal matrix \(D = \text{diag}\{d_{ii}\}\) with entries \(d_{ii} = \sum_{j \in Z} a_{ij}\). If we assume that the graph \(G\) is connected, then \(d_{ii} > 0\) for all nodes \(i \in Z\). We can then define the normalized graph Laplacian \(^{1}\) as

\[
L = I - D^{-1/2}AD^{-1/2},
\]

and the graph Dirichlet energy as \(J_0(u) := \frac{1}{2}(u, Lu)\). Then

\[
J_0(D_{\frac{1}{2}}u) = \frac{1}{4} \sum_{(i,j) \in Z \times Z} a_{ij}(u(i) - u(j))^2.
\]

Thus, similarly to the classical Dirichlet energy, this quadratic form penalizes nodes from having different function values, with penalty being weighted with respect to the similarity weights from \(A\). Furthermore the identity shows that \(L\) is positive semi-definite. Indeed the vector of ones \(I\) is in the null-space of \(D - A\) by construction, and hence \(L\) has a zero eigenvalue with corresponding eigenvector \(D_{\frac{1}{2}}I\).

We let \((q_k, \lambda_k)\) denote the eigenpairs of the matrix \(L\), so that \(^{2}\)

\[
\lambda_0 \leq \lambda_1 \leq \cdots \leq \lambda_{N-1} \leq \lambda_{\text{max}} < \infty, \quad (q_j, q_k) = \delta_{jk}.
\]

\(^{1}\)In the majority of the paper the only property of \(L\) that we use is that it is symmetric positive semi-definite. We could therefore use other graph Laplacians, such as the unnormalized choice \(L = D - A\), in most of the paper. The only exception is the spectral approximation sampling algorithm introduced later; that particular algorithm exploits empirical properties of the symmetrized graph Laplacian. Note, though, that the choice of which graph Laplacian to use can make a significant difference – see [7], and Figure 2.1 therein. To make our exposition more concise we confine our presentation to the graph Laplacian (1).

\(^{2}\)For the normalized graph Laplacian, the upper bound \(\lambda_{\text{max}} = 2\) may be found in [17, Lemma 1.7, Chapter 1]; but with further structure on the weights many spectra saturate at \(\lambda_{\text{max}} \approx 1\) (see Appendix), a fact we will exploit later.
The eigenvector corresponding to $\lambda_0 = 0$ is $q_0 = D_1^{-1}1$ and $\lambda_1 > 0$, assuming a fully connected graph. Then $L = Q\Lambda Q^*$ where $Q$ has columns $\{q_k\}_{k=0}^{N-1}$ and $\Lambda$ is a diagonal matrix with entries $\{\lambda_k\}_{k=0}^{N-1}$. Using these eigenpairs the graph Dirichlet energy can be written as

$$\frac{1}{2} \langle u, Lu \rangle = \frac{1}{2} \sum_{j=1}^{N-1} \lambda_j (\langle u, q_j \rangle)^2;$$

this is analogous to decomposing the classical Dirichlet energy using Fourier analysis.

### 2.3. Gaussian Measure

We now show how to build a Gaussian distribution with negative log density proportional to $J_0(u)$. Such a Gaussian prefers functions that have larger components on the first few eigenvectors of the graph Laplacian, where the eigenvalues of $L$ are smaller. The corresponding eigenvectors carry rich geometric information about the weighted graph. For example, the second eigenvector of $L$ is the Fiedler vector and solves a relaxed normalized min-cut problem [47, 25]. The Gaussian distribution thereby connects geometric intuition embedded within the graph Laplacian to a natural probabilistic picture.

To make this connection concrete we define diagonal matrix $\Sigma$ with entries defined by the vector

$$(0, \lambda_1^{-1}, \cdots, \lambda_{N-1}^{-1})$$

and define the positive semi-definite covariance matrix $C = cQ\Sigma Q^*$; choice of the scaling $c$ will be discussed below. We let $\mu_0 := N(0, C)$. Note that the covariance matrix is that of a Gaussian with variance proportional to $\lambda_j^{-1}$ in direction $q_j$ thereby leading to structures which are more likely to favour the Fiedler vector ($j = 1$), and lower values of $j$ in general, than it does for higher values. The fact that the first eigenvalue of $C$ is zero ensures that any draw from $\mu_0$ changes sign, because it will be orthogonal to $q_0$.\(^3\) To make this intuition explicit we recall the Karhunen-Loeve expansion which constructs a sample $u$ from the Gaussian $\mu_0$ according to the random sum

$$u = c^{\frac{1}{2}} \sum_{j=1}^{N-1} \lambda_j^{-\frac{1}{2}} q_j z_j,$$

where the $\{z_j\}$ are i.i.d. $N(0, 1)$. Equation (3) thus implies that $\langle u, q_0 \rangle = 0$.

We choose the constant of proportionality $c$ as a rescaling which enforces the property $\mathbb{E}|u|^2 = N$ for $u \sim \mu_0 := N(0, C)$; in words the per-node variance is 1. Note that, using the orthogonality of the $\{q_j\}$,

$$\mathbb{E}|u|^2 = c \sum_{j=1}^{N-1} \lambda_j^{-1} \mathbb{E}z_j^2 = c \sum_{j=1}^{N-1} \lambda_j^{-1} \quad \Longrightarrow \quad c = N \left( \sum_{j=1}^{N-1} \lambda_j^{-1} \right)^{-1}.$$

We reiterate that the support of the measure $\mu_0$ is the space $U := q_0^\perp = \text{span}\{q_1, \cdots, q_{N-1}\}$ and that, on this space, the probability density function is proportional to

$$\exp\left(-c^{-1} J_0(u)\right) = \exp\left(-\frac{1}{2c} \langle u, Lu \rangle\right),$$

\(^3\)Other treatments of the first eigenvalue are possible and may be useful but for simplicity of exposition we do not consider them in this paper.
so that the precision matrix of the Gaussian is $P = c^{-1}L$. In what follows the sign of $u$ will be related to the classification; since all the entries of $q_0$ are positive, working on the space $U$ ensures a sign change in $u$, and hence a non-trivial classification.

2.4. Thresholding and Non-Gaussian Probability Measure. For the models considered in this paper, the label space of the problem is discrete while the latent variable $u$ through which we will capture the correlations amongst nodes of the graph, encoded in the feature vectors, is real-valued. We describe thresholding, and a relaxation of thresholding, to address the need to connect these two differing sources of information about the problem. In what follows the latent variable $u : Z \to \mathbb{R}$ (appearing in the probit and Bayesian level set methods) is thresholded to obtain the label variable $l : Z \to \{-1, 1\}$. The variable $v : Z \to \mathbb{R}$ (appearing in the Ginzburg-Landau method) is a real-valued relaxation of the label variable $l$. The variable $u$ will be endowed with a Gaussian probability distribution. From this the variable $l$ (which lives on a discrete space) and $v$ (which is real-valued, but concentrates near the discrete space supporting $l$) will be endowed with non-Gaussian probability distributions.

Define the (signum) function $S : \mathbb{R} \mapsto \{-1, 1\}$ by

$$S(u) = 1, \ u \geq 0 \ \text{and} \ S(u) = -1, \ u < 0.$$ 

This will be used to connect the latent variable $u$ with the label variable $l$. The function $S$ may be relaxed by defining $S_\epsilon(u) = v_{|t=1}$ where $v$ solves the gradient flow

$$\dot{v} = -\nabla W_\epsilon(v), \ \ v_{|t=0} = u \ \text{for potential} \ W_\epsilon(v) = \frac{1}{4\epsilon}(v^2 - 1)^2.$$ 

This will be used, indirectly, to connect the latent variable $u$ with the real-valued relaxation of the label variable, $v$. Note that $S_\epsilon(\cdot) \to S(\cdot)$, pointwise, as $\epsilon \to 0$, on $\mathbb{R} \setminus \{0\}$. This reflects the fact that the gradient flow minimizes $W_\epsilon$, asymptotically as $t \to \infty$, whenever started on $\mathbb{R} \setminus \{0\}$.

We have introduced a Gaussian measure $\mu_0$ on the latent variable $u$ which lies in $U \subset \mathbb{R}^N$; we now want to introduce two ways of constructing non-Gaussian measures on the label space $\{-1, 1\}^N$, or on real-valued relaxations of label space, building on the measure $\mu_0$. The first is to consider the push-forward of measure $\mu_0$ under the map $S$: $S^*\mu_0$. When applied to a sequence $l : Z \mapsto \{-1, 1\}^N$ this gives

$$(S^*\mu_0)(l) = \mu_0\left(\{u|S(u(j)) = l(j), \forall 1 \leq j \leq N\}\right),$$

recalling that $N$ is the cardinality of $Z$. The definition is readily extended to components of $l$ defined only on subsets of $Z$. Thus $S^*\mu_0$ is a measure on the label space $\{-1, 1\}^N$. The second approach is to work with a change of measure from the Gaussian $\mu_0$ in such a way that the probability mass on $U \subset \mathbb{R}^N$ concentrates close to the label space $\{-1, 1\}^N$. We may achieve this by defining the measure $\nu_0$ via its Radon-Nykodim derivative

$$\frac{d\nu_0}{d\mu_0}(v) \propto e^{-\sum_{j \in Z} W_\epsilon(v(j))}.$$ 

We name $\nu_0$ the Ginzburg-Landau measure, since the negative log density function of $\nu_0$ is the graph Ginzburg-Landau functional

$$\text{GL}(v) := \frac{1}{2c} \langle v, Lv \rangle + \sum_{j \in Z} W_\epsilon(v(j)).$$
The Ginzburg-Landau distribution defined by $\nu_0$ can be interpreted as a non-convex ground relaxation of the discrete MRF model [55], in contrast to the convex relaxation which is the Gaussian Field [56]. Since the double well has minima at the label values $\{-1, 1\}$, the probability mass of $\nu_0$ is concentrated near the modes $\pm 1$, and $\epsilon$ controls this concentration effect.

3. Bayesian Formulation. In this section we formulate three different Bayesian models for the semi-supervised learning problem. The three models all combine the ideas described in the previous section to define three distinct posterior distributions. It is important to realize that these different models will give different answers to the same questions about uncertainty quantification. The choice of which Bayesian model to use is related to the data itself, and making this choice is beyond the scope of this paper. Currently the choice must be addressed on a case by case basis, as is done when choosing an optimization method for classification. Nonetheless we will demonstrate that the shared structure of the three models means that a common algorithmic framework can be adopted and we will make some conclusions about the relative costs of applying this framework to the three models.

We denote the latent variable by $u(j)$, $j \in \mathbb{Z}$, the thresholded value of $u(j)$ by $l(j) = S(u(j))$ which is interpreted as the label assignment at each node $j$, and noisy observations of the binary labels by $y(j)$, $j \in \mathbb{Z}'$. The variable $v(j)$ will be used to denote the real-valued relaxation of $l(j)$ used for the Ginzburg-Landau model. Recall Bayes formula which transforms a prior density $P(u)$ on a random variable $u$ into a posterior density $P(u|y)$ on the conditional random variable $u|y$:

$$P(u|y) = \frac{1}{P(y)} P(y|u) P(u).$$

We will now apply this formula to condition our graph latent variable $u$, whose thresholded values correspond to labels, on the noisy label data $y$ given at $\mathbb{Z}'$. As prior on $u$ we will always use $P(u)du = \mu_0(du)$; we will describe two different likelihoods. We will also apply the formula to condition relaxed label variable $v$, on the same label data $y$, via the formula

$$P(v|y) = \frac{1}{P(y)} P(y|v) P(v).$$

We will use as prior the non-Gaussian $P(v)dv = \nu_0(dv)$.

For the probit and level-set models we now explicitly state the prior density $P(u)$, the likelihood function $P(y|u)$, and the posterior density $P(u|y)$; in the Ginzburg-Landau case $v$ will replace $u$ and we will define the densities $P(v), P(y|v)$ and $P(v|y)$. Prior and posterior probability measures associated with letter $\mu$ are on the latent variable $u$; measures associated with letter $\nu$ are on the label space, or real-valued relaxation of the label space.

3.1. Probit. The probit method is designed for classification and is described in [50]. In that context Gaussian process priors are used and, unlike the graph Laplacian construction used here, do not depend on the unlabel data. Combining Gaussian process priors and graph Laplacian priors was suggested and studied in [4, 41, 31]. A recent fully Bayesian treatment of the methodology using unweighted graph Laplacians may be found in the paper [24]. In detail our model is as follows.

**Prior** We take as prior on $u$ the Gaussian $\mu_0$. Thus

$$P(u) \propto \exp\left(-\frac{1}{2} \langle u, Pu \rangle \right).$$
Likelihood For any $j \in \mathbb{Z}'$

$$y(j) = S(u(j) + \eta(j))$$

with the $\eta(j)$ drawn i.i.d from $\mathcal{N}(0, \gamma^2)$. We let

$$\Psi(v; \gamma) = \frac{1}{\sqrt{2\pi\gamma^2}} \int_{-\infty}^{v} \exp\left(-\frac{t^2}{2\gamma^2}\right)dt,$$

the cumulative distribution function (cdf) of $\mathcal{N}(0, \gamma^2)$, and note that then

$$P(y(j) = 1 | u(j)) = P(\mathcal{N}(0, \gamma^2) > -u(j)) = \Psi(u(j); \gamma) = \Psi(y(j)u(j); \gamma);$$

similarly

$$P(y(j) = -1 | u(j)) = P(\mathcal{N}(0, \gamma^2) < -u(j)) = \Psi(-u(j); \gamma) = \Psi(y(j)u(j); \gamma).$$

Posterior Bayes’ Theorem gives posterior $\mu_p$ with probability density function (pdf)

$$P_p(u | y) \propto \exp\left(-\frac{1}{2}\langle u, Pu \rangle - \Phi_p(u; y)\right)$$

where

$$\Phi_p(u; y) := -\sum_{j \in \mathbb{Z}'} \log(\Psi(y(j)u(j); \gamma)).$$

We let $\nu_p$ denote the push-forward under $S$ of $\mu_p : \nu_p = S^t \mu_p$.

**MAP Estimator** This is the minimizer of the negative of the log posterior. Thus we minimize the following objective function over $U$:

$$J_p(u) = \frac{1}{2}\langle u, Pu \rangle - \sum_{j \in \mathbb{Z}'} \log(\Psi(y(j)u(j); \gamma)).$$

This is a convex function, a fact which is well-known in related contexts, but which we state and prove in Proposition 1 Section B of the appendix for the sake of completeness. In view of the close relationship between this problem and the level-set formulation described next, for which there are no minimizers, we expect that minimization may not be entirely straightforward in the $\gamma \ll 1$ limit. This is manifested in the presence of near-flat regions in the probit log likelihood function when $\gamma \ll 1$.

Our variant on the probit methodology differs from that in [24] in several ways: (i) our prior Gaussian is scaled to have per-node variance one, whilst in [24] the per node variance is a hyper-parameter to be determined; (ii) our prior is supported on $U = q_0^\perp$ whilst in [24] the prior precision is found by shifting $L$ and taking a possibly fractional power of the resulting matrix, resulting in support on the whole of $\mathbb{R}^N$; (iii) we allow for a scale parameter $\gamma$ in the observational noise, whilst in [24] the parameter $\gamma = 1$.

3.2. Level-Set. This method is designed for problems considerably more general than classification on a graph [27]. For the current application, this model is exactly the same as probit except for the order in which the noise $\eta(j)$ and the thresholding function $S(u)$ is applied in the definition of the data. Thus we again take as **Prior** for $u$, the Gaussian $\mu_0$. Then we have:
Likelihood For any \( j \in Z' \)

\[
y(j) = S(u(j)) + \eta(j)
\]

with the \( \eta(j) \) drawn i.i.d from \( \mathcal{N}(0, \gamma^2) \). Then

\[
\mathbb{P}(y(j)|u(j)) \propto \exp\left(-\frac{1}{2\gamma^2}|y(j) - S(u(j))|^2\right).
\]

Posterior Bayes’ Theorem gives posterior \( \mu_{ls} \) with pdf

\[
\mathbb{P}_{ls}(u|y) \propto \exp\left(-\frac{1}{2}\langle u, Pu \rangle - \Phi_{ls}(u; y)\right)
\]

where

\[
\Phi_{ls}(u; y) = \sum_{j \in Z'} \left(\frac{1}{2\gamma^2}|y(j) - S(u(j))|^2\right).
\]

We let \( \nu_{ls} \) denote the pushforward under \( S \) of \( \mu_{ls} \): \( \nu_{ls} = S^\# \mu_{ls} \).

MAP Estimator Functional The negative of the log posterior is, in this case, given by

\[
J_{ls}(u) = \frac{1}{2}\langle u, Pu \rangle + \Phi_{ls}(u; y).
\]

However, unlike the probit model, the Bayesian level-set method has no MAP estimator – the infimum of \( J_{ls} \) is not attained and this may be seen by noting that, if the infimum was attained at any non-zero point \( u^* \) then \( cu^* \) would reduce the objective function for any \( c \in (0, 1) \); however the point \( u^* = 0 \) does not attain the infimum. This proof is detailed in [27] for a closely related PDE based model, and the proof is easily adapted.

3.3. Ginzburg-Landau. For this model, we take as prior the Ginzburg-Landau measure \( \nu_0 \) defined by (7), and employ a Gaussian likelihood for the observed labels. This construction gives the Bayesian posterior whose MAP estimator is the objective function introduced and studied in [7].

Prior We define prior on \( v \) to be the Ginzburg-Landau measure \( \nu_0 \) given by (7) with density

\[
\mathbb{P}(v) \propto e^{-GL(v)}.
\]

Likelihood For any \( j \in Z' \)

\[
y(j) = v(j) + \eta(j)
\]

with the \( \eta(j) \) drawn i.i.d from \( \mathcal{N}(0, \gamma^2) \). Then

\[
\mathbb{P}(y(j)|v(j)) \propto \exp\left(-\frac{1}{2\gamma^2}|y(j) - v(j)|^2\right).
\]

Posterior Recalling that \( P = c^{-1}L \) we see that Bayes’ Theorem gives posterior \( \nu_{gl} \) with pdf

\[
\mathbb{P}_{gl}(v|y) \propto \exp\left(-\frac{1}{2}\langle v, Pu \rangle - \Phi_{gl}(v; y)\right),
\]

\[
\Phi_{gl}(v; y) := \sum_{j \in Z} W_s(v(j)) + \sum_{j \in Z'} \left(\frac{1}{2\gamma^2}|y(j) - v(j)|^2\right).
\]
**MAP Estimator** This is the minimizer of the negative of the log posterior. Thus we minimize the following objective function over $U$:

$$J_{gl}(v) = \frac{1}{2} \langle v, Pv \rangle + \Phi_{gl}(v; y).$$

This objective function was introduced in [7] as a relaxation of the min-cut problem, penalized by data; the relationship to min-cut was studied rigorously in [46]. The minimization problem for $J_{gl}$ is non-convex and has multiple minimizers, reflecting the combinatorial character of the min-cut problem of which it is a relaxation.

### 3.4. Uncertainty Quantification for Graph Based Learning.

In Figure 1 we plot the component of the negative log likelihood at a labelled node $j$, as a function of the latent variable $u = u(j)$ with data $y = y(j)$ fixed, for the probit and Bayesian level-set models. The log likelihood for the Ginzburg-Landau formulation is not directly comparable as it is a function of the relaxed label variable $v(j)$, with respect to which it is quadratic with minimum at the data point $y(j)$.

![Fig. 1. Plot of a component of the negative log likelihood for a fixed node $j$. We set $\gamma = 1/\sqrt{2}$ for probit and Bayesian level-set. Since $\Phi(u(j); 1) = \Phi(-u(j); -1)$ for probit and Bayesian level-set, we omit the plot for $y(j) = -1$.](image)

The probit and Bayesian level-set models lead to posterior distributions $\mu$ (with different subscripts) in latent variable space, and pushforwards under $S$, denoted $\nu$ (also with different subscripts), in label space. The Ginzburg-Landau formulation leads to a measure $\nu_{gl}$ in (relaxed) label space. Uncertainty quantification for semi-supervised learning is concerned with completely characterizing these posterior distributions. In practice this may be achieved by sampling using MCMC methods. In this paper we will study four measures of uncertainty:

- we will study the empirical pdfs of the latent and label variables at certain nodes;
- we will study the posterior mean of the label variables at certain nodes;
- we will study the posterior variance of the label variables averaged over all nodes;
- we will use the posterior mean or variance to order nodes into those whose classifications are most uncertain and those which are most certain.

For the probit and Bayesian level-set models we interpret the thresholded variable $l = S(u)$ as the binary label assignments corresponding to a real-valued configuration $u$; for Ginzburg-Landau we may simply take $l = v$ as the model is posed on (relaxed) label space. The node-wise posterior mean of $l$ can be used as a useful confidence score.
of the class assignment of each node. The node-wise posterior mean \( s_j \) is defined as

\[
s_j := \mathbb{E}_\nu(l(j)),
\]

with respect to any of the posterior measures \( \nu \) in label space. Note that for probit and Bayesian level set \( l(j) \) is a binary random variable taking values in \( \{\pm 1\} \) and we have \( s_j \in [-1, 1] \). In this case if \( q = \nu(l(j) = 1) \) then \( q = \frac{1}{2}(1 + s_j) \). Furthermore

\[
\text{Var}_\nu(l(j)) = 4q(1 - q) = 1 - (s_j)^2.
\]

Later we will find it useful to consider the variance averaged over all nodes and hence define

\[
\text{Var}(l) = \frac{1}{N} \sum_{j=1}^N \text{Var}_\nu(l(j)).
\]

Note that the maximum value obtained by \( \text{Var}(l) \) is 1. This maximum value is attained under the Gaussian prior \( \mu_0 \) that we use in this paper. The deviation from this maximum under the posterior is a measure of the information content of the labelled data. Note, however, that the prior does contain information about classifications, in the form of correlations between vertices; this is not captured in (10).

4. Algorithms. From Section 3, we see that for all of the models considered, the posterior \( P(w|y) \) has the form

\[
P(w|y) \propto \exp(-J(w)), \quad J(w) = \frac{1}{2} \langle w, Pw \rangle + \Phi(w)
\]

for some function \( \Phi \), different for each of the three models (acknowledging that in the Ginzburg-Landau case the independent variable is \( w = v \), real-valued relaxation of label space, whereas for the other models \( w = u \) an underlying latent variable which may be thresholded by \( S(\cdot) \) into label space.) Furthermore, the MAP estimator is the minimizer of \( J \). Note that \( \Phi \) is differentiable for the Ginzburg-Landau and probit models, but not for the level-set model. We introduce algorithms for both sampling (MCMC) and MAP estimation (optimization) that apply in this general framework. The sampler we employ does not use information about the gradient of \( \Phi \); the MAP estimation algorithm does, but is only employed on the Ginzburg-Landau and probit models. Both sampling and optimization algorithms use spectral properties of the precision matrix \( P \), which is proportional to the graph Laplacian \( L \).

4.1. MCMC. Broadly speaking there are two strong competitors as samplers for this problem: Metropolis-Hastings based methods, and Gibbs based samplers. In this paper we focus entirely on Metropolis-Hastings methods as they may be used on all three models considered here. In order to induce scalability with respect to size of \( Z \) we use the preconditioned Crank-Nicolson (pCN) method described in [18] and introduced in the context of diffusions by Beskos et. al. in [9] and by Neal in the context of machine learning [35]. The method is also robust with respect to the small noise limit \( \gamma \to 0 \) in which the label data is perfect. The pCN based approach is compared with Gibbs like methods for probit, to which they both apply, in [6]; both large data sets \( N \to \infty \) and small noise \( \gamma \to 0 \) limits are considered.

\footnote{Strictly speaking \( \text{Var}(l) = N^{-1}\text{Tr}(\text{Cov}(l)) \).}
The standard random walk Metropolis (RWM) algorithm suffers from the fact that the optimal proposal variance or stepsize scales inverse proportionally to the dimension of the state space \(N\), which is the graph size \(N\) in this case. The pCN method is designed so that the proposal variance required to obtain a given acceptance probability scales independently of the dimension of the state space (here the number of graph nodes \(N\)), hence in practice giving faster convergence of the MCMC when compared with RWM [8]. We restate the pCN method as Algorithm 1, and then follow with various variants on it in Algorithms 2 and 3. In all three algorithms \(\beta \in [0,1]\) is the key parameter which determines the efficiency of the MCMC method: small \(\beta\) leads to high acceptance probability but small moves; large \(\beta\) leads to low acceptance probability and large moves. Somewhere between these extremes is an optimal choice of \(\beta\) which minimizes the asymptotic variance of the algorithm when applied to compute a given expectation.

**Algorithm 1 pCN Algorithm**

1. Input: \(L, \Phi(u), u^{(0)} \in U\).
2. Output: \(M\) Approximate samples from the posterior distribution
3. Define: \(\alpha(u,w) = \min\{1, \exp(\Phi(u) - \Phi(w))\}\).
4. while \(k < M\) do
5. \(w^{(k)} = \sqrt{1 - \beta^2} u^{(k)} + \beta \xi^{(k)}\), where \(\xi^{(k)} \sim N(0, C)\) via equation (11).
6. Calculate acceptance probability \(\alpha(u^{(k)}, w^{(k)})\).
7. Accept \(w^{(k)}\) as \(u^{(k+1)}\) with probability \(\alpha(u^{(k)}, w^{(k)})\), otherwise \(u^{(k+1)} = u^{(k)}\).
8. end while

The value \(\xi^{(k)}\) is a sample from the prior \(\mu_0\). If the eigenvalues and eigenvectors of \(L\) are all known then the Karhunen-Loeve expansion (11) gives

\[
(11) \quad \xi^{(k)} = c^2 N^{-1} \sum_{j=1}^{N-1} \lambda_j^{-\frac{1}{2}} q_j z_j,
\]

where \(c\) is given by (6), the \(z_j, j = 1 \ldots N - 1\) are i.i.d centred unit Gaussians and the equality is in law.

**4.2. Spectral Projection.** For graphs with a large number of nodes \(N\), it is prohibitively costly to directly sample from the distribution \(\mu_0\), since doing so involves knowledge of a complete eigen-decomposition of \(L\), in order to employ (11). A method that is frequently used in classification tasks is to restrict the support of \(u\) to the eigenspace spanned by the first \(\ell\) eigenvectors with the smallest non-zero eigenvalues of \(L\) (hence largest precision) and this idea may be used to approximate the pCN method; this leads to a low rank approximation. In particular we approximate samples from \(\mu_0\) by

\[
(12) \quad \xi^{(k)}_\ell = c^2 \ell^{-\frac{1}{2}} \sum_{j=1}^{\ell-1} \lambda_j^{-\frac{1}{2}} q_j z_j,
\]

where \(c\) is given by (6) truncated after \(j = \ell-1\), the \(z_j\) are i.i.d centred unit Gaussians and the equality is in law. This is a sample from \(N(0, C_\ell)\) where \(C_\ell = c_\ell Q \Sigma_\ell Q^*\) and the diagonal entries of \(\Sigma_\ell\) are set to zero for the entries after \(\ell\). In practice, to implement this algorithm, it is only necessary to compute the first \(\ell\) eigenvectors of the graph Laplacian \(L\). This gives Algorithm 2.
Algorithm 2 pCN Algorithm With Spectral Projection

1: Input: $L$. $\Phi(u)$. $u^{(0)} \in U$.
2: Output: $M$ Approximate samples from the posterior distribution
3: Define: $\alpha(u,w) = \min \{1, \exp(\Phi(u) - \Phi(w))\}$.
4: while $k < M$ do
5: $w^{(k)} = \sqrt{1 - \beta^2} w^{(k)} + \beta \xi^{(k)}$, where $\xi^{(k)} \sim N(0, C_\ell)$ via equation (12).
6: Calculate acceptance probability $\alpha(u^{(k)},w^{(k)})$.
7: Accept $w^{(k)}$ as $u^{(k+1)}$ with probability $\alpha(u^{(k)},w^{(k)})$, otherwise $u^{(k+1)} = u^{(k)}$.
8: end while

4.3. Spectral Approximation. Spectral projection often leads to good classification results, but may lead to reduced posterior variance and a posterior distribution that is overly smooth on the graph domain. We propose an improvement on the method that preserves the variability of the posterior distribution but still only involves calculating the first $\ell$ eigenvectors of $L$. This is based on the empirical observation that in many applications the spectrum of $L$ saturates and satisfies, for $j \geq \ell$, $\lambda_j \approx \tilde{\lambda}$ for some $\tilde{\lambda}$. Such behaviour may be observed in b), c) and d) of Figure 2; in particular note that in the hyperspectral case $\ell \ll N$. We assume such behaviour in deriving the low rank approximation used in this subsection. (See Appendix for a detailed discussion of the graph Laplacian spectrum.) We define $\Sigma_{\ell,o}$ by overwriting the diagonal entries of $\Sigma$ from $\ell$ to $N - 1$ with $\tilde{\lambda}^{-1}$. We then set $C_{\ell,o} = c_{\ell,o} Q \Sigma_{\ell,o} Q^*$, and generate samples from $N(0, C_{\ell,o})$ (which are approximate samples from $\mu_0$) by setting

$$\xi^{(k)}_{\ell,o} = c_{\ell,o}^2 \sum_{j=1}^{\ell-1} \lambda_j^{-\frac{1}{2}} q_j z_j + c_{\ell,o}^2 \tilde{\lambda}^{-\frac{1}{2}} \sum_{j=\ell}^{N-1} q_j z_j,$$

where $c_{\ell,o}$ is given by (6) with $\lambda_j$ replaced by $\tilde{\lambda}$ for $j \geq \ell$, the $\{z_j\}$ are centred unit Gaussians, and the equality is in law. Importantly samples according to (13) can be computed very efficiently. In particular there is no need to compute $q_j$ for $j \geq \ell$, and the quantity $\sum_{j=\ell}^{N-1} q_j z_j$ can be computed by first taking a sample $\tilde{z} \sim N(0,I_N)$, and then projecting $\tilde{z}$ onto $U_\ell := \text{span}(q_1, \ldots, q_{N-1})$. Moreover, projection onto $U_\ell$ can be computed only using $\{q_1, \ldots, q_{\ell-1}\}$, since the vectors span the orthogonal complement of $U_\ell$. Concretely, we have

$$\sum_{j=\ell}^{N-1} q_j z_j = \bar{z} - \sum_{j=1}^{\ell-1} q_j \langle q_j, \bar{z} \rangle,$$

where $\bar{z} \sim N(0,I_N)$ and equality is in law. Hence the samples $\xi^{(k)}_{\ell,o}$ can be computed by

$$\xi^{(k)}_{\ell,o} = c_{\ell,o}^2 \sum_{j=1}^{\ell-1} \lambda_j^{-\frac{1}{2}} q_j z_j + c_{\ell,o}^2 \tilde{\lambda}^{-\frac{1}{2}} \left( \bar{z} - \sum_{j=1}^{\ell-1} q_j \langle q_j, \bar{z} \rangle \right).$$

The vector $\xi^{(k)}_{\ell,o}$ is a sample from $N(0, C_{\ell,o})$ and results in Algorithm 3. Under the stated empirical properties of the graph Laplacian, we expect this to be a better approximation of the prior covariance structure than the approximation of the previous subsection.
Algorithm 3 pCN Algorithm With Spectral Approximation
1: Input: $L$, $\Phi(u)$. $u(0) \in U$.
2: Output: $M$ Approximate samples from the posterior distribution
3: Define: $\alpha(u,w) = \min\{1, \exp(\Phi(u) - \Phi(w))\}$.
4: while $k < M$ do
5: \quad $w^{(k)} = \sqrt{1 - \beta^2 u^{(k)}} + \beta \xi^{(k)}_l$, where $\xi^{(k)}_l \sim N(0, C_{\ell,o})$ via equation (14).
6: \quad Calculate acceptance probability $\alpha(u^{(k)},w^{(k)})$.
7: \quad Accept $w^{(k)}$ as $u^{(k+1)}$ with probability $\alpha(u^{(k)},w^{(k)})$, otherwise $u^{(k+1)} = u^{(k)}$.
8: end while

4.4. MAP Estimation: Optimization. Recall that the objective function for the MAP estimation has the form $\frac{1}{2}(u, Pu) + \Phi(u)$, where $u$ is supported on the space $U$. For Ginzburg-Landau and probit, the function $\Phi$ is smooth, and we can use a standard projected gradient method for the optimization. Since $L$ is typically ill-conditioned, it is preferable to use a semi-implicit discretization as suggested in [7], as convergence to a stationary point can be shown under a graph independent learning rate. Furthermore, the discretization can be performed in terms of the eigenbasis $\{q_1, \ldots, q_{N-1}\}$, which allows us to easily apply spectral projection when only a truncated set of eigenvectors is available. We state the algorithm in terms of the (possibly truncated) eigenbasis below. Here $P_\ell$ is an approximation to $P$ found by setting $P_\ell = Q_\ell D_\ell Q_\ell^*$ where $Q_\ell$ is the matrix with columns $\{q_1, \ldots, q_{N-1}\}$ and $D_\ell = \text{diag}(d)$ for $d(j) = c_\ell \lambda_j$, $j = 1, \ldots, \ell - 1$. Thus $P_{N-1} = P$.

Algorithm 4 Linearly-Implicit Gradient Flow with Spectral Projection
1: Input: $Q_m = (q_1, \ldots, q_m)$, $\Lambda_m = (\lambda_1, \ldots, \lambda_m)$, $\Phi(u)$, $u(0) \in U$.
2: while $k < M$ do
3: \quad $u^{(*)} = u^{(k)} - \beta \nabla \Phi(u^{(k)})$
4: \quad $u^{(k+1)} = (I + \beta P_m)^{-1} u^{(*)}$
5: end while

5. Numerical Experiments. In this section we conduct a series of numerical experiments on four different data sets that are representative of the field of graph semi-supervised learning. There are three main purposes for the experiments. First we perform uncertainty quantification, as explained in subsection 3.4. Secondly, we study the spectral approximation and projection variants on pCN sampling as these
scale well to massive graphs. Finally we make some observations about the cost and practical implementation details of these methods, for the different Bayesian models we adopt; these will help guide the reader in making choices about which algorithm to use. We present the results for MAP estimation in Section B of the Appendix, alongside the proof of convexity of the probit MAP estimator.

The quality of the graph constructed from the feature vectors is central to the performance of any graph learning algorithms. In the experiments below, we follow the graph construction procedures used in the previous papers [7, 26, 33] which applied graph semi-supervised learning to all of the datasets that we consider in this paper. Moreover, we have verified that for all the reported experiments below, the graph parameters are in a range such that spectral clustering [47] (an unsupervised learning method) gives a reasonable performance. The methods we employ lead to refinements over spectral clustering (improved classification) and, of course, to uncertainty quantification (which spectral clustering does not address).

5.1. Data Sets. We introduce the data sets and describe the graph construction for each data set. In all cases we numerically construct the weight matrix $A$, and then the graph Laplacian $L$.

5.1.1. Two Moons. The two moons artificial data set is constructed to give noisy data which lies near a nonlinear low dimensional manifold embedded in a high dimensional space [16]. The data set is constructed by sampling $N$ data points uniformly from two semi-circles centered at $(0,0)$ and $(1,0.5)$ with radius 1, embedding the data in $\mathbb{R}^d$, and adding Gaussian noise with standard deviation $\sigma$. We set $N = 2,000$ and $d = 100$ in this paper; recall that the graph size is $N$ and each feature vector has length $d$. We will conduct a variety of experiments with different labelled data size $J$, and in particular study variation with $J$. The default value, when not varied, is $J$ at 3% of $N$, with the labelled points chosen at random.

We take each data point as a node on the graph, and construct a fully connected graph using the self-tuning weights of Zelnik-Manor and Perona [53], with $K = 10$. Specifically we let $x_i, x_j$ be the coordinates of the data points $i$ and $j$. Then weight $a_{ij}$ between nodes $i$ and $j$ is defined by

$$a_{ij} = \exp\left(\frac{-||x_i - x_j||^2}{2\tau_i \tau_j}\right),$$

where $\tau_j$ is the distance of the $K$-th closest point to the node $j$.

5.1.2. House Voting Records from 1984. This dataset contains the voting records of 435 U.S. House of Representatives; for details see [7] and the references therein. The votes were recorded in 1984 from the 98th United States Congress, 2nd session. The votes for each individual is vectorized by mapping a yes vote to 1, a no vote to $-1$, and an abstention/no-show to 0. The data set contains 16 votes that are believed to be well-correlated with partisanship, and we use only these votes as feature vectors for constructing the graph. Thus the graph size is $N = 435$, and feature vectors have length $d = 16$. The goal is to predict the party affiliation of each individual, given a small number of known affiliations (labels). We pick 3 Democrats and 2 Republicans at random to use as the observed class labels; thus $J = 5$ corresponding to less than 1.2% of fidelity (i.e. labelled) points. We construct a fully connected graph with weights given by (15) with $\tau_j = \tau = 1.25$ for all nodes $j$.

---

5 The weight matrix $A$ is symmetric in theory; in practice we find that symmetrizing via the map $A \mapsto \frac{1}{2}A + \frac{1}{2}A^\ast$ is helpful.
5.1.3. MNIST. The MNIST database consists of 70,000 images of size $28 \times 28$ pixels containing the handwritten digits 0 through 9; see [29] for details. Since in this paper we focus on binary classification, we only consider pairs of digits. To speed up calculations, we subsample randomly 2,000 images from each digit to form a graph with $N = 4,000$ nodes; we use this for all our experiments except in subsection 5.4 where we use the full data set of size $N = \mathcal{O}(10^4)$ for digit pair (4, 9) to benchmark computational cost. The nodes of the graph are the images and as feature vectors we project the images onto the leading 50 principal components given by PCA; thus the feature vectors at each node have length $d = 50$. We construct a $K$-nearest neighbor graph with $K = 20$ for each pair of digits considered. Namely, the weights $a_{ij}$ are non-zero if and only if one of $i$ or $j$ is in the $K$ nearest neighbors of the other. The non-zero weights are set using (15) with $K = 20$.

We choose the four pairs $(5, 7)$, $(0, 6)$, $(3, 8)$ and $(4, 9)$. These four pairs exhibit increasing levels of difficulty for classification. This fact is demonstrated in Figures 3a - 3d, where we visualize the datasets by projecting the dataset onto the second and third eigenvector of the graph Laplacian. Namely, each node $i$ is mapped to the point $(Q(2, i), Q(3, i)) \in \mathbb{R}^2$, where $L = QAQ^*$.

![Fig. 3. Visualization of data by projection onto 2nd and 3rd eigenfunctions of the graph Laplacian for the MNIST data set, where the vertical dimension is the 3rd eigenvector and the horizontal dimension the 2nd. Each subfigure represents a different pair of digits. We construct a 20 nearest neighbour graph under the Zelnik-Manor and Perona scaling [53] as in (15) with $K = 20$.](image)

5.1.4. HyperSpectral Image. The hyperspectral data set analysed for this project was provided by the Applied Physics Laboratory at Johns Hopkins University; see [15] for details. It consists of a series of video sequences recording the release of chemical plumes taken at the Dugway Proving Ground. Each layer in the spectral dimension depicts a particular frequency starting at 7,830 nm and ending with 11,700 nm, with a channel spacing of 30 nm, giving 129 channels; thus the feature vector has length $d = 129$. The spatial dimension of each frame is $128 \times 320$ pixels. We select 7 frames from the video sequence as the input data, and consider each spatial pixel as a node on the graph. Thus the graph size is $N = 128 \times 320 \times 7 = 286,720$. Note that time-ordering of the data is ignored. The classification problem is to classify pixels that represent the chemical plumes against pixels that are the background.

We construct a fully connected graph with weights given by the cosine distance:

$$w_{ij} = \frac{\langle x_i, x_j \rangle}{\|x_i\| \|x_j\|}.$$  

This distance is small for vectors that point in the same direction, and is insensitive to their magnitude. We consider the normalized Laplacian defined in (1). Because it is computationally prohibitive to compute eigenvectors of a Laplacian of this size,
we apply the Nyström extension [51, 21] to obtain an approximation to the true eige
vectors and eigenvalues; see [7] for details pertinent to the set-up here. We en-
phasize that each pixel in the 7 frames is a node on the graph and that, in pa-
ricular, pixels across the 7 time-frames are also connected. Since we have no ground truth
labels for this dataset, we generate known labels by setting the segmentation results
from spectral clustering as ground truth. The default value of $J$ is 8,000, and labels
are chosen at random. This corresponds to labelling around 2.8% of the points. We
only plot results for the last 3 frames of the video sequence in order to ensure that
the information in the figures it not overwhelmingly large.

5.2. Uncertainty Quantification. In this subsection we demonstrate both the
feasibility, and value, of uncertainty quantification in graph classification methods. We
employ the probit and the Bayesian level-set model for most of the experiments in
this subsection; we also employ the Ginzburg-Landau model but since this can be
slow to converge, due to the presence of local minima, it is only demonstrated on the
voting records dataset. The pCN method is used for sampling on various datasets to
demonstrate properties and interpretations of the posterior. In all experiments, all
statistics on the label $l$ are computed under the push-forward posterior measure onto
label space, $\nu$.

5.2.1. Posterior Mean as Confidence Scores. We construct the graph from
the MNIST (4,9) dataset following subsection 5.1. The noise variance $\gamma$ is set to 0.1,
and 4% of fidelity points are chosen randomly from each class. The probit posterior
is used to compute (9). In Figure 4 we demonstrate that nodes with scores $s^l_j$ closer
to the binary ground truth labels $\pm 1$ look visually more uniform than nodes with $s^l_j$
far from those labels. This shows that the posterior mean contains useful information
which differentiates between outliers and inliers that align with human perception.
The scores $s^l_j$ are computed as follows: we let $\{u^{(k)}\}_{k=1}^M$ be a set of samples of the
posterior measure obtained from the pCN algorithm. The probability $P(S(u(j) = l(j))$
is approximated by

$$P(S(u(j) = l(j)) \approx \frac{1}{M} \sum_{k=1}^M 1_{u^{(k)}(j) > 0}$$

for each $j$. Finally the score

$$s^l_j = 2P(S(u(j) = l(j)) - 1.$$

5.2.2. Posterior Variance as Uncertainty Measure. In this set of experi-
ments, we show that the posterior distribution of the label variable $l = S(u)$ captures
the uncertainty of the classification problem. We use the posterior variance of $l$, av-
eraged over all nodes, as a measure of the model variance; specifically formula (10).
We study the behaviour of this quantity as we vary the level of uncertainty within
certain inputs to the problem. We demonstrate empirically that the posterior variance
is approximately monotonic with respect to variations in the levels of uncertainty in
the input data, as it should be; and thus that the posterior variance contains useful
information about the classification. We select quantities that reflect the separability
of the classes in the feature space.

Figure 5 plots the posterior variance $\text{Var}(l)$ against the standard deviation $\sigma$ of the
noise appearing in the feature vectors for the two moons dataset; thus points generated
on the two semi-circles overlap more as $\sigma$ increases. We employ a sequence of posterior
computations, using probit and Bayesian level-set, for $\sigma = 0.02 : 0.01 : 0.12$. Recall
that \( N = 2,000 \) and we choose 3\% of the nodes to have the ground truth labels as observed data. Within both models, \( \gamma \) is fixed at 0.1. A total of \( 1 \times 10^4 \) samples are taken, and the proposal variance \( \beta \) is set to 0.3. We see that the mean posterior variance increases with \( \sigma \), as is intuitively reasonable. Furthermore, because \( \gamma \) is small, probit and Bayesian level-set are very similar models and this is reflected in the similar quantitative values for uncertainty.

A similar experiment studies the posterior label variance \( \text{Var}(l) \) as a function of the pair of digits classified within the MNIST data set. We choose 4\% of the nodes as labelled data, and set \( \gamma = 0.1 \). The number of samples employed is \( 1 \times 10^4 \) and the proposal variance \( \beta \) is set to be 0.3. Table 1 shows the posterior label variance. Recall that Figures 3a - 3d suggest that the pairs (4, 9), (3, 8), (0, 6), (5, 7) are increasingly easy to separate, and this is reflected in the decrease of the posterior label variance.

| TABLE 1 |

Mean Posterior Variance of different digit pairs for the probit model and the BLS model applied to the MNIST Dataset. The pairs are organized from left to right according to the separability of the two classes as shown in Fig.3a - 3d. For each trial, we randomly select 4% of nodes as fidelity. We run 10 trials for each pairs of digits and average the mean posterior variance across trials. We set $\gamma = 0.1$ and $\beta = 0.3$ for both models.

The previous two experiments in this subsection have studied posterior label variance $\text{Var}(l)$ as a function of variation in the prior data. We now turn and study how posterior variance changes as a function of varying the likelihood information, again for both two moons and MNIST data sets. In Figures 6a and 6b, we plot the posterior label variance against the percentage of nodes observed. We observe that the observational variance decreases as the amount of labelled data increases. Figures 6c and 6d show that the posterior label variance increases almost monotonically as observational noise $\gamma$ increases. Furthermore the level set and probit formulations produce similar answers for $\gamma$ small, reflecting the close similarity between those methods when $\gamma$ is small – when $\gamma = 0$ their likelihoods coincide.

In summary of this subsection, the label posterior variance $\text{Var}(l)$ behaves intuitively as expected as a function of varying the prior and likelihood information that specify the statistical probit model and the Bayesian level-set model. The uncertainty quantification thus provides useful, and consistent, information that can be used to inform decisions made on the basis of classifications.

5.2.3. Visualization of Marginal Posterior Density. In this subsection, we contrast the posterior distribution $\mathbb{P}(v|y)$ of the Ginzburg-Landau model with that of the probit and Bayesian level-set (BLS) models. The graph is constructed from the voting records data with the fidelity points chosen as described in subsection 5.1. In Figure 7 we plot the histograms of the empirical marginal posterior distribution on $\mathbb{P}(v(i)|y)$ and $\mathbb{P}(u(i)|y)$ for a selection of nodes on the graph. For the top row of Figure 7, we select 6 nodes with “low confidence” predictions, and plot the empirical marginal distribution of $u$ for probit and BLS, and that of $v$ for the Ginzburg-Landau model. Note that the same set of nodes is chosen for different models. The plots in this row demonstrate the multi-modal nature of the Ginzburg-Landau distribution in contrast to the uni-modal nature of the probit posterior; this uni-modality is a consequence of the log-concavity of the probit likelihood. For the bottom row, we plot the same empirical distributions for 6 nodes with “high confidence” predictions. In contrast with the top row, the Ginzburg-Landau marginal for high confidence nodes is essentially uni-modal since most samples of $v$ evaluated on these nodes have a fixed sign.

5.3. Spectral Approximation and Projection Methods. Here we discuss Algorithms 2 and 3, designed to approximate the full (but expensive on large graphs) Algorithm 1.

First, we examine the quality of the approximation by applying the algorithms to the voting records dataset, a small enough problem where sampling using the full graph Laplacian is feasible. To quantify the quality of approximation, we compute the
The posterior mean of the thresholded variable \( s^j \) for both Algorithm 2 and Algorithm 3, and compare the mean absolute difference \( \frac{1}{N} |s^j - s^{j*}| \) where \( s^{j*} \) is the “ground truth” value computed using the full Laplacian. Using \( \gamma = 0.1, \beta = 0.3, \) and a truncation level of \( \ell = 150, \) we observe that the mean absolute difference for spectral projection is 0.1577, and 0.0261 for spectral approximation. In general, we set \( \lambda \) to be \( \max_{j \leq \ell} \lambda_j \) where \( \ell \) is the truncation level.

Next we apply the spectral projection/approximation algorithms with the Bayesian level-set likelihood to the hyperspectral image dataset; the results for probit are similar (when we use small \( \gamma \)) but have greater cost per step, because of the cdf evaluations required for probit. The first two rows in Fig.8 show that the posterior mean \( s^j \) is able to differentiate between different concentrations of the plume gas. We have also coloured pixels with \( |s^j| < 0.4 \) in red to highlight the regions with greater levels of uncertainty. We observe that the red pixels mainly lie in the edges of the gas plume, which conforms with human intuition. As in the voting records example in the previous subsection, the spectral approximation method has greater posterior uncertainty, demonstrated by the greater number of red pixels in the second row of Fig.8 compared to the first row. We conjecture that the spectral approximation is closer to what would be obtained by sampling the full distribution, but we have not verified this as the full problem is too large to readily sample. The bottom row of Fig.8 shows the result of using optimization based classification, using the Gibzburg-Landau method. This is shown simply to demonstrate consistency with the full UQ approach shown in...
the other two rows, in terms of hard classification.

5.4. Comparative Remarks About The Different Models. At a high level we have shown the following concerning the three models based on probit, level-set and Ginzburg-Landau:

- Bayesian level set is considerably cheaper to implement than probit in Matlab because the norm cdf evaluations required for probit are expensive.
- Probit and Bayesian level-set behave similarly, for posterior sampling, especially for small $\gamma$, since they formally coincide when $\gamma = 0$.
- Probit and Bayesian level-set are superior to Ginzburg-Landau for posterior sampling: this is because probit has log-concave posterior, whilst Ginzburg-Landau is multi-modal.
- Ginzburg-Landau provides the best hard classifiers, when used as an optimizer (MAP estimator), and provided it is initialized well. However it behaves poorly when not initialized carefully because of multi-modal behaviour. In contrast probit provides almost indistinguishable classifiers, comparable or marginally worse in terms of accuracy, and has a convex objective function and hence a unique minimizer. (See Appendix for details of the relevant experiments.)
Fig. 8. Inference results on hyperspectral image dataset using spectral projection (top row), spectral approximation (middle row), and Ginzburg-Landau classification (bottom row). For the top two rows, the values of $s^l_j$ are plotted on a $[-1,1]$ color scale on each pixel location. In addition, we highlight the regions of uncertain classification by coloring the pixels with $|s^l_j| < 0.4$ in red. The bottom row is the classification result from the Ginzburg-Landau model, shown here as a comparison. The truncation level $l = 40$, and for the spectral approximation algorithm, $\lambda = 1$. We set $\gamma = 0.1$, $\beta = 0.08$ and use $M = 2 \times 10^4$ MCMC samples. We create the label data by subsampling 8,000 pixels ($\approx 2.8\%$ of the total) from the labellings obtained by spectral clustering.

We expand on the details of these conclusions by studying run times of the algorithms. All experiments are done on a 1.5GHz machine with Intel Core i7. In Table 2, we compare the running time of the MCMC for different models on various datasets. We use an a posteriori condition on the samples $u^{(k)}$ to empirically determine the sample size $M$ needed for the MCMC to converge. Note that this condition is by no means a replacement for a rigorous analysis of convergence using auto-correlation, but is designed to provide a ballpark estimate of the speed of these algorithms on real applications. We now define the a posteriori condition used. Let the approximate samples be $\{u^{(k)}\}$. We define the cumulative average as $\tilde{u}^{(k)} = \frac{1}{k} \sum_{j=1}^{k} u^{(j)}$, and find the first $k$ such that

$$\|\tilde{u}^{(kT)} - \tilde{u}^{((k-1)T)}\| \leq \text{tol},$$

where $\text{tol}$ is the tolerance and $T$ is the number of iterations skipped. We set $T = 5000$, and also tune the stepsize parameter $\beta$ such that the average acceptance probability of the MCMC is over $50\%$. We choose the model parameters according to the experiments in the sections above so that the posterior mean gives a reasonable classification result.

We note that the number of iterations needed for the Ginzburg-Landau model is much higher compared to probit and the Bayesian level-set (BLS) method; this is caused by the presence of multiple local minima in Ginzburg-Landau, in contrast to the log concavity of probit. probit is slower than BLS due to the fact that evaluations of the cdf function for Gaussians is slow.

**Timing for MCMC methods.** We report both the number of samples M and the running time of the algorithm t. The time for GL on MNIST and Hyperspectral is omitted due to running time being too slow. J denotes the number of fidelity points used. For the voting records, we set γ = 0.2, β = 0.4 for probit and BLS, and γ = 1, β = 0.1 for Ginzburg-Landau. For MNIST, we set γ = 0.1, β = 0.4. For Hyperspectral, we set γ = 1.0, and β = 0.1.

### 6. Conclusions and Future Directions.

We introduce a Bayesian approach to uncertainty quantification for graph-based classification methods. We develop algorithms to sample the posterior and to compute MAP estimators and, through numerical experiments on a suite of applications, we investigate the properties of the different Bayesian models, and the algorithms used to study them.

Some future directions of this work include improvement of the current inference method, connections between the different models in this paper, and generalization to multiclass classification, for example by vectorizing the latent variable (as in existing non-Bayesian multiclass methods [22, 33]), and applying multi-dimensional analogues of the likelihood functions used in this paper. Hierarchical methods could also be applied to account for the uncertainty in the various hyperparameters such as the label noise γ, or the length scale ϵ in the Ginzburg-Landau model. Finally, we could study in more detail the effects of either the spectral projection or the approximation method, either analytically on some tractable toy examples, or empirically on a suite of representative problems.

Studying the modelling assumptions themselves, guided by data, provides a research direction of long term value. Such questions have not been much studied to the best of our knowledge. For example the choice of the signum function to relate the latent variable to the categorial data could be questioned, and other models employed; or the level value of 0 chosen in the level set approach could be chosen differently, or as a hyper-parameter. Furthermore the form of the prior on the latent variable u could be questioned. We use a Gaussian prior which encodes first and second order statistical information about the unlabelled data. This Gaussian could contain hyperparameters, of Whittle-Matern type, which could be learnt from the data; and more generally other non-Gaussian priors could and should be considered. For instance, in image data, it is often useful to model feature vectors as lying on submanifolds embedded in a higher dimensional space; such structure could be exploited. More generally, addressing the question of which generative models are appropriate for which types of data is an interesting and potentially fruitful research direction.
Acknowledgements AMS is grateful to Omiros Papaspiliopoulos for illuminating discussions about the probit model.

Appendix.

A. Spectral Properties of $L$. The spectral properties of $L$ are relevant to the spectral projection and approximation algorithms from the previous section. Figure 2 shows the spectra for our four examples. Note that in all cases the spectrum is contained in the interval $[0, 2]$, consistent with the theoretical result in [17, Lemma 1.7, Chapter 1]. The size of the eigenvalues near to 0 will determine the accuracy of the spectral projection algorithm. The rate at which the spectrum accumulates at a value near 1, an accumulation which happens for all but the MNIST data set in our four examples, affects the accuracy of the spectral approximation algorithm. There is theory that goes some way towards justifying the observed accumulation; see [48, Proposition 9, item 4]. This theory works under the assumption that the features $x_j$ are i.i.d samples from some fixed distribution, and the graph Laplacian is constructed from weights $w_{ij} = k(x_i, x_j)$, and $k$ satisfies symmetry, continuity and uniform positivity. As a consequence the theory does not apply to the graph construction used for the MNIST dataset since the $K$-nearest neighbor graph is local; empirically we find that this results in a graph violating the positivity assumption on the weights. This explains why the MNIST example does not have a spectrum which accumulates at a value near 1. In the case where the spectrum does accumulate at a value near 1, the rate can be controlled by adjusting the parameter $\tau$ appearing in the weight calculations; in the limit $\tau = \infty$ the graph becomes an unweighted complete graph and its spectrum comprises the two points $\{0, \lambda\}$ where $\lambda \to 1$ as $n \to \infty$ – see Lemma 1.7 in Chapter 1 of [17].

B. MAP Estimation as Semi-supervised Classification Method. We first prove the convexity of the probit negative log likelihood.

**Proposition 1.** Let $J_p(u)$ be the MAP estimation function for the probit model:

$$J_p(u) = \frac{1}{2} \langle u, Pu \rangle - \sum_{j \in Z'} \log \left( \Psi(y(j)u(j); \gamma) \right).$$

If $y(j) \in \{\pm 1\}$ for all $j$ then $J_p$ is a convex function in the variable $u$.

**Proof.** Since $P$ is semi positive definite, it suffices to show that

$$\sum_{j \in Z'} \log \left( \Psi(y(j)u(j); \gamma) \right)$$

is convex. Thus, since $y(j) \in \{\pm 1\}$ for all $j$, it suffices to show that $\log \left( \Psi(x; \gamma) \right)$ is concave with respect to $x$. Since

$$\Psi(x; \gamma) = \frac{1}{\sqrt{2\pi\gamma}} \int_{-\infty}^{\infty} \exp \left( -\frac{t^2}{2\gamma^2} \right) dt,$$
we have \( \Psi(\gamma x; \gamma) = \Psi(x; 1) \). Since scaling \( x \) by a constant doesn’t change convexity, it suffices to consider the case \( \gamma = 1 \). Taking the second derivative with \( \gamma = 1 \), we see that it suffices to prove that, for all \( x \in \mathbb{R} \) and all \( \gamma > 0 \),

\[
(17) \quad \Psi''(x; 1)\Psi(x; 1) - \Psi'(x; 1)\Psi'(x; 1) < 0.
\]

Plugging in the definition of \( \Psi \), we have

\[
(18) \quad \Psi''(x; 1)\Psi(x; 1) - \Psi'(x; 1)\Psi'(x; 1) = -\frac{1}{2\pi} \exp(-\frac{x^2}{2})(x \int_{-\infty}^{x} \exp(-\frac{t^2}{2})dt + \exp(-\frac{x^2}{2})).
\]

Clearly the expression in equation (18) is less than 0 for \( x \geq 0 \). For the case \( x < 0 \), divide equation (18) by \( \frac{1}{2\pi} \exp(-\frac{x^2}{2}) \) and note that this gives

\[
(19) \quad -x \int_{-\infty}^{x} \exp(-\frac{t^2}{2})dt - \exp(-\frac{x^2}{2}) = -x \int_{-\infty}^{x} \exp(-\frac{t^2}{2})dt + \int_{-\infty}^{x} t \exp(-\frac{t^2}{2})dt
\]

\[
= \int_{-\infty}^{x} (t - x) \exp(-\frac{t^2}{2})dt < 0
\]

and the proof is complete.

The probit MAP estimator thus has a considerable computational advantage over the Ginzburg-Landau MAP estimator, because the latter is not convex and, indeed, can have large numbers of minimizers. We now discuss numerical results designed to probe the consequences of convexity, or lack of it, for classification accuracy. The purpose of these experiments is not to match state-of-art results for classification, but rather to study properties of the MAP estimator when varying the feature noise and the percentage of labelled data.

We employ the two moons and the MNIST (4, 9) data sets. The methods are evaluated on a range of values for the percentage of labelled data points, and also for a range of values of the feature variance \( \sigma \) in the two moons dataset. The experiments are conducted for 100 trials with different initializations (both two moons and MNIST (4, 9)) and different data realizations (for two moons only). In Figure 9, we plot the median classification accuracy with error bars from the 100 trials against the feature variance \( \sigma \) for the two moons dataset. As well as Ginzburg-Landau and probit classification, we also display results from spectral clustering based on thresholding the Fiedler eigenvector. The percentage of fidelity points used is 0.5%, 1%, and 3% for each column. We do the same in Figure 10 for the 4-9 MNIST data set against the same percentages of labelled points.

The non-convexity of the Ginzburg-Landau model can result in large variance in classification accuracy; the extent of this depends on the percentage of observed labels. The existence of sub-optimal local extrema causes the large variance. If initialized without information about the classification, Ginzburg-Landau can perform very badly in comparison with probit. On the other hand we find that the best performance of the Ginzburg-Landau model, when initialized at the probit minimizer, is typically slightly better than the probit model.

We note that the probit model is convex and theoretically should have results independent of the initialization. However, we see there are still small variations in the classification result from different initializations. This is due to slow convergence of gradient methods caused by the flat-bottomed well of the probit log-likelihood. As mentioned above this can be understood by noting that, for small gamma, probit and
Fig. 9. Classification accuracy of different algorithms for Two Moons Dataset compared with $\sigma$ and percentage of labelled nodes, with $N = 2,000$. The algorithms used are: Ginzburg-Landau MAP estimator with random initialization, Ginzburg-Landau with initialization given by probit model, probit MAP estimation, and spectral clustering (thresholding the Fiedler vector). For each trial, we generate a realization of the two moons dataset with given $\sigma$ and select randomly a certain percentage of nodes as fidelity, and a total of 50 trials are run for each combination of parameters. We use spectral projection with number of eigenvectors $Neig = 150$. We plot the median accuracy along with error bars indicating the 25 and 75-th quantile of the classification accuracy of each method. We set $\gamma = 0.1$ for the probit model, and $\gamma = 1.0$, $\epsilon = 1.0$ for Ginzburg-Landau.

Fig. 10. Classification accuracy of different algorithms for the 4-9 MNIST dataset versus percentage of labelled nodes. The algorithms used are: Ginzburg-Landau with random initialization, Ginzburg-Landau with initialization given by probit model, probit MAP estimation. For each trial, we select randomly a certain percentage of nodes as fidelity, and a total of 50 trials are run. We use spectral projection with number of eigenvectors $Neig = 300$. We plot the median accuracy along with error bars indicating the 25 and 75-th quantile of the classification accuracy of each method. We set $\gamma = 0.1$ for the probit model, and $\gamma = 1.0$, $\epsilon = 1.0$ for Ginzburg-Landau.

level-set are closely related and that the level-set MAP estimator does not exist – minimizing sequences converge to zero, but the infimum is not attained at zero.
