On the Codd Semantics of SQL Nulls

Paolo Guagliardo, Leonid Libkin

School of Informatics, University of Edinburgh

Abstract

Theoretical models used in database research often have subtle differences with those occurring in practice. One particular mismatch that is usually neglected concerns the use of marked nulls to represent missing values in theoretical models of incompleteness, while in an SQL database these are all denoted by the same syntactic NULL object. It is commonly argued that results obtained in the model with marked nulls carry over to SQL, because SQL nulls can be interpreted as Codd nulls, which are simply marked nulls that do not repeat. This argument, however, does not take into account that even simple queries may produce answers where distinct occurrences of NULL do in fact denote the same unknown value. For such queries, interpreting SQL nulls as Codd nulls would incorrectly change the semantics of query answers.

To use results about Codd nulls for real-life SQL queries, we need to understand which queries preserve the Codd interpretation of SQL nulls. We show, however, that the class of relational algebra queries preserving Codd interpretation is not recursively enumerable, which necessitates looking for sufficient conditions for such preservation. Those can be obtained by exploiting the information provided by NOT NULL constraints on the database schema. We devise mild syntactic restrictions on queries that guarantee preservation, do not limit the full expressiveness of queries on databases without nulls, and can be checked efficiently.

Keywords: SQL, null, semantics, relational database

1. Introduction

Query evaluation is a fundamental task in data management, and very often it must be performed on databases with incomplete information. This is especially true in applications such as data integration [1, 2], data exchange [3] and ontology-based data access [4, 5] that rely on the standard tools of existing relational database technology, in particular SQL, in order to take advantage of its efficiency. Much theoretical research on query answering and its applications uses well established models of incompleteness; however, there is an important mismatch between theoretical models and real-life SQL, which has an impact on the semantics of query answers.

Theoretical research traditionally adopts a model of incompleteness where missing values in a database are represented by marked (also called naive or labeled) nulls. In SQL, on the other hand, missing values are all represented by the same syntactic object: the ill-famed NULL. To reconcile the two approaches, there is a standard argument in the literature: SQL nulls are modeled by Codd nulls, i.e., non-repeating marked nulls. Then each occurrence of NULL is interpreted as a fresh marked null that does not appear anywhere else in the database, e.g., as shown in Figure 1.

Do Codd nulls properly model SQL nulls? Sometimes (e.g., in [6]) it is argued that they are different, but this assumes a special type of query evaluation, called naive [7], under which marked nulls are simply viewed as new constants, e.g., $\bot_1 = \bot_1$ but $\bot_1 \neq \bot_2$. Under naive evaluation, on the database $D'$ in Figure 1, the relational algebra query $\sigma_{A=A}(R)$ will produce $\{\bot_1\}$. However, the same query in SQL, \texttt{SELECT * FROM R WHERE $A=A$}, returns the empty set on the database $D$ in Figure 1. The reason for this is that, in SQL, comparisons involving nulls evaluate to the truth value unknown, even if a null is compared with itself. This mismatch, however, is easily fixed by simply using the same comparison semantics for Codd nulls: every condition $x \equiv y$ or $x \neq y$ evaluates to unknown if $x$ or $y$ is a null. In fact, we do not even need SQL's three-valued logic: the same evaluation strategy can be captured using only the usual Boolean logic with true and false [8].

So, is this sufficient to reconcile the mismatch between Codd nulls and SQL nulls? The answer is still negative, because we have not taken into account the role of queries. If SQL nulls are to be interpreted as Codd nulls, this interpretation should apply to input databases as well as query

\begin{align*}
D & \quad D' \nonumber
\begin{array}{c|c|c|}
R & S & \text{R} & S \nonumber
\hline
A & B & A & B \nonumber
\hline
\text{NULL} & 0 & \bot_1 & 0 \nonumber
\end{array}
\end{align*}

Figure 1: SQL nulls are interpreted as Codd nulls.
answers, which are incomplete databases themselves. To explain this point, let \( \text{codd}(D) \) be the result of replacing SQL nulls, in the database \( D \), by distinct marked nulls, as shown in Figure 1. Technically, \( \text{codd}(D) \) is the set of such databases, because we can choose distinct marked nulls arbitrarily (e.g., \( \bot_3, \bot_4 \)) instead of \( \bot_1, \bot_2 \) for the database \( D' \) (Figure 1), but these databases are all isomorphic. To ensure that Codd nulls faithfully represent SQL nulls for a query \( Q \), the condition in Figure 2 must be enforced. Intuitively, the diagram says the following: take an SQL database \( D \), and compute the answer to \( Q \) on it, i.e., \( Q(D) \). Now take some \( D' \in \text{codd}(D) \) and compute \( Q(D') \); then \( Q(D') \) must be in \( \text{codd}(Q(D)) \), i.e., there must be a way of assigning Codd nulls to SQL nulls in \( Q(D) \) that will result in \( Q(D') \).

Does this condition hold for queries in some sufficiently expressive language like relational algebra? Unfortunately, the answer is negative, even for very simple queries. Take for example the database \( D \) and its Codd interpretation \( D' \) shown in Figure 1, and consider the query \( Q \) that computes the Cartesian product of \( R \) and \( S \). Then, we have

\[
\begin{array}{c|c|c}
A & B & A' \\
NULL & 0 & \bot_1 \\
NULL & NULL & \bot_1 \\
\end{array}
\]

and since \( \bot_1 \) is repeated in \( Q(D) \), we cannot obtain \( Q(D') \) from \( Q(D) \) by replacing SQL nulls with Codd nulls.

The culprit in this example is that the query, evaluated on the Codd interpretation of the original SQL database, produces an answer that is not a Codd table, as it contains repeated nulls. While in this specific example it is easy to detect such an undesirable behavior, we show that in general the class of relational algebra queries that transform SQL databases into Codd databases is not recursively enumerable, and so it is impossible to capture it by a syntactic fragment of the language.

Due to the lack of an effective syntax for queries that preserve Codd semantics in answers, we can only hope for sufficient conditions, that is, finding reasonable syntactic fragments that guarantee this property. However, simply choosing a subset of relational algebra operations will not give us a useful restriction: as we saw, one of the problematic constructs is Cartesian product, and we obviously do not want a fragment that precludes joins. Thus, we must look for a more refined solution.

The idea here is to consider database schemas with \textbf{NOT NULL} constraints, which are very common in practice: base relations in real SQL databases will almost always have a \textbf{PRIMARY KEY} declared on them, and this implies \textbf{NOT NULL}. We then exploit these constraints to come up with mild restrictions on queries, which have the following properties:

- they guarantee the preservation of Codd semantics of SQL nulls in query answers on all databases;
- they can be checked efficiently; and
- they do not restrict the expressiveness of relational algebra queries on databases without nulls, where all attributes are declared as \textbf{NOT NULL}.

**Organization.** The paper is structured as follows:

- In Section 2 we introduce an underlying data model based on bags, and define the syntax and semantics of the query language we work with.
- In Section 3 we formally define the notion of preservation of Codd semantics in query answers and show that the class of queries having this property is not recursively enumerable.
- In Section 4 we devise syntactic restrictions on the syntax tree of queries to ensure preservation of Codd semantics, and we show that these are easy to check.
- In Section 5 we show that adding some operations to the query language may result in milder restrictions, which allow one to recognize more queries preserving Codd semantics.
- In Section 5 we study the preservation of Codd semantics for queries that are interpreted under set semantics, i.e., when duplicate rows in tables are not allowed.
- In Section 7 we conclude by summarizing the lessons learned and pointing out future research directions.

This paper is a revised and extended version of [9]. In addition to including the proofs, here we strengthen the main results of [9] by relaxing the conditions that ensure preservation of Codd semantics in query answers. Furthermore, we investigate the case of queries interpreted under set semantics, which is prominent in the literature. These new results are not a straightforward consequence of those in [9] and require some non-trivial additional work.

### 2. Preliminaries

A \textit{bag} (or \textit{multiset}) is an unordered collection of objects, where the same object – unlike in a set – can occur multiple times. The multiplicity (i.e., number of occurrences) of an element \( e \) in a bag \( B \) is denoted by \( \#(e, B) \), and we write

\[
\begin{array}{c|c|c}
A & B & A' \\
NULL & 0 & \bot_1 \\
NULL & NULL & \bot_1 \\
\end{array}
\]

Figure 2: Preservation of Codd semantics for SQL nulls.
\( e \in B \) for \( \#(e, B) = k \). We also use the notation \( e \in B \) to indicate that \( e \in B \) for some \( k > 0 \), and we write \( e \notin B \) for \( e \notin B \) (i.e., \( e \) does not occur in \( B \)). For two bags \( B \) and \( B' \), we say that \( B \) is contained in \( B' \), written \( B \subseteq B' \), if \( \#(e, B) \leq \#(e, B') \) for every \( e \in B \). The bag operations of union \( \cup \), intersection \( \cap \) and difference \( - \) are defined as follows:

\[
B \cup B' \equiv \{ e, \ldots, e \mid e \in B, e \in B' \};
\]

\[
B \cap B' \equiv \{ e, \ldots, e \mid e \in B, e \in B' \};
\]

\[
B - B' \equiv \{ e, \ldots, e \mid e \in B, e \in B' \}.
\]

where \( - \) is the \textit{minus} operator: \( m - n = \max(0, m - n) \).
Observe that union and intersection are commutative and associative, while difference is not.

For a bag \( B \), \textit{duplicate elimination} \( \varepsilon \) returns a new bag consisting of a single occurrence of each element in \( B \); i.e., \( \varepsilon(B) \) is the bag such that, for any element \( e \),

\[
\#(e, \varepsilon(B)) = \begin{cases} 1 & \text{if } e \in B, \\ 0 & \text{otherwise}. \end{cases}
\]

\[ \text{2.2. Schemas and incomplete databases} \]

A (relational) schema consists of a signature of relation names and a function \( \text{sig} \) that maps each relation name \( R \) to a signature \( \text{sig}(R) \), whose elements are called the \textit{attributes} of \( R \). A database \( D \) associates each relation name \( R \) (of a given schema) with a table \([R]_D\) over \( \text{sig}(R) \).

Databases are populated with two kinds of values: \textit{constants} and nulls, which come from countably infinite and disjoint sets \( \text{Const} \) and \( \text{Null} \), respectively. We assume that \( \text{Null} \) contains the special value \( \mathbf{N} \) for SQL’s \text{NULL}; all other elements of \( \text{Null} \) will be denoted by \( \bigwedge \), with sub- or superscripts. We denote the sets of constants and nulls that occur in a database \( D \) by \( \text{Const}(D) \) and \( \text{Null}(D) \), respectively, and we say that \( D \) is \textit{complete} if \( \text{Null}(D) = \varnothing \).

A database \( D \) is called a \textit{naive database} if \( \mathbf{N} \notin \text{Null}(D) \), and an \textit{SQL database} if \( \text{Null}(D) \subseteq \{ \mathbf{N} \} \). In other words, the special value \( \mathbf{N} \) cannot appear in naive databases, while it is the only value allowed for denoting nulls in SQL databases. This terminology extends naturally to tables.

A \textit{Codd database} (resp., \textit{Codd table}) is a naive database (resp., naive table) in which nulls do not repeat, i.e., there can be at most one occurrence of each element from \( \text{Null} \). Note that a Codd database is a set of Codd tables, but the converse need not hold.

\[ \text{2.3. Query language} \]

We use relational algebra (RA) for bags, whose syntax is defined by the grammar in Figure 3. This consists of two main syntactic constructs, \textit{expressions} \( E \) and \textit{conditions} \( \theta \), whose semantics is given in Figure 4.

A \textit{term} \( t \) is either a name or a value, and its semantics \( [t]_r \) is given w.r.t. a record \( r \); if \( t \) is a name in \( \text{sig}(r) \), then \( [t]_r = r(t) \); else, if \( t \) is a value, \( [t]_r = t \); otherwise, \( [t]_r \) is undefined.

Atomic conditions are equality/inequality comparisons between terms, and tests that determine whether a term is null or constant; complex conditions are constructed from atomic ones by means of conjunction and disjunction. We do not use explicit negation, as this can be propagated all the way down to atoms.

The signature of a condition \( \theta \), denoted by \( \text{sig}(\theta) \), is the set of names appearing in it. Its semantics \( [\theta]_r \) is defined w.r.t. a record \( r \) such that \( \text{sig}(\theta) \subseteq \text{sig}(r) \); it can be either \( \text{true} \) (true) or \( \text{false} \) (false), as determined by the rules in Figure 4b.

For a table \( T \) and a condition \( \theta \) s.t. \( \text{sig}(\theta) \subseteq \text{sig}(T) \), we can then define the following \textit{selection} operation:

\[
\sigma_\theta(T) \equiv \{ r, \ldots, r \mid r \in_k T, [\theta]_r = t \}.
\]

Atomic RA expressions are simply names (of base relations in the schema), and complex ones are constructed by means of the usual operations of projection \( \pi \), selection \( \sigma \), Cartesian product \( \times \), union \( \cup \), difference \( - \), intersection \( \cap \), renaming \( \rho \), and duplicate elimination \( \varepsilon \). The signature of an expression is defined inductively as follows:

\[ \text{sig}(R) \] is given for any relation name \( R \)

\[ \text{sig}(\pi \sigma \rho \varepsilon R) \] is given for a projection, selection, renaming, and duplicate elimination expression, respectively.
\[
E := N \\
| E \times E \\
| E \cup E \\
| E \cap E \\
| E - E \\
| \pi_\alpha(E) \\
| \sigma_\theta(E) \\
| \varepsilon(E) \\
| \rho_{N\rightarrow N}(E)
\]

(a) Expressions

\[
\theta := t = t \\
| t \neq t \\
| \text{null}(t) \\
| \text{const}(t) \\
| \theta \land \theta \\
| \theta \lor \theta
\]

(b) Conditions

Whether an expression is well-defined w.r.t. a schema is inductively determined as follows:

- an atomic expression \( R \) is well-defined if \( R \) is a relation name in the schema;
- \( E_1 \times E_2 \) is well-defined if \( E_1 \) and \( E_2 \) are well-defined and \( \text{sig}(E_1) \) is disjoint with \( \text{sig}(E_2) \);
- \( E_1 \text{ op } E_2 \), for \( \text{op} \in \{ \cap, \cup, - \} \), is well-defined if \( E_1 \) and \( E_2 \) are well-defined and \( \text{sig}(E_1) = \text{sig}(E_2) \);
- \( \pi_\alpha(E) \) is well-defined if \( E \) is well-defined and \( \text{sig}(\alpha) \subseteq \text{sig}(E) \);
- \( \sigma_\theta(E) \) is well-defined if \( E \) is well-defined and \( \text{sig}(\theta) \subseteq \text{sig}(E) \);
- \( \varepsilon(E) \) is well-defined if \( E \) is well-defined;
- \( \rho_{A\rightarrow B}(E) \) is well-defined if \( E \) is well-defined and \( A \in \text{sig}(E) \) and \( B \notin \text{sig}(E) \\setminus \{ A \} \);

The RA queries over a given schema are all of the RA expressions that are well-defined w.r.t. that schema. Their semantics is given with respect to a database \( D \) (over the same schema) as shown in Figure 4a.

This language captures the basic fragment of SQL [8]; \text{SELECT DISTINCT-FROM-WHERE} queries, with (correlated) subqueries preceded by possibly negated \text{IN} and \text{EXISTS}, combined by \text{UNION}, \text{INTERSECT} and \text{EXCEPT}, with or without the \text{ALL} modifier.

3. Codd Interpretation of SQL Nulls

Differently from naive databases, where nulls are elements of Null, missing values in SQL are all denoted by the special symbol \( \text{Null} \). To reconcile this mismatch, the occurrences of \( \text{Null} \) in an SQL database are typically interpreted as \textit{non-repeating} elements of Null. That is, an SQL database is seen as a Codd database where each occurrence of \( \text{Null} \) is replaced by a fresh distinct marked null. Obviously, these nulls can be chosen arbitrarily as long as they do not repeat, so an SQL database may admit infinitely many Codd interpretations in general.

To make this notion more precise, given a record \( r \), we denote by \( \text{sql}(r) \) the record \( r' \) over \( \text{sql}(r) \) such that
\[ r'(A) = \begin{cases} r(A) & \text{if } r(A) \in \text{Const} \\ \text{Null} & \text{otherwise} \end{cases} \]
for every \( A \in \text{sig}(r) \). We also denote by \( \text{sql}^{-1}(r) \) the preimage of \( r \) under \( \text{sql} \), that is:
\[ \text{sql}^{-1}(r) = \{ s \mid s \text{ is a record such that } \text{sql}(s) = r \} . \]

The properties below follow easily from the definitions:

\textbf{Lemma 1.} Let \( r \) be a record. Then,
\begin{itemize}
  \item[a)] for every \( \alpha \subseteq \text{sig}(r) \), \[ \text{sql}(\pi_\alpha(r)) = \pi_\alpha(\text{sql}(r)) ; \]
  \item[b)] for every \( A \in \text{sig}(r) \) and \( B \notin \{ \text{sig}(r) \setminus \{ A \} \} \), \[ \text{sql}(\rho_{A\rightarrow B}(r)) = \rho_{A\rightarrow B}(\text{sql}(r)) ; \]
  \item[c)] for every record \( s \) such that \( \text{sig}(s) \cap \text{sig}(r) = \emptyset \), \[ \text{sql}(r \times s) = \text{sql}(r) \times \text{sql}(s) ; \]
  \item[d)] for every selection condition \( \theta \) s.t. \( \text{sig}(\theta) \subseteq \text{sig}(r) \), \[ [\theta]_r = [\theta]_{\text{sql}(r)} . \]
\end{itemize}

These notions are extended to tables and databases as follows. For a table \( T \), \( \text{sql}(T) \) is the table over \( \text{sig}(T) \) such that, for every record \( r \),
\[ \#(r, \text{sql}(T)) = \sum_{s \in \text{sql}^{-1}(r)} \#(s, T) ; \]
Figure 4: Semantics of Relational Algebra

\[
\begin{align*}
[R]_D & \quad [E_1 \text{ op } E_2]_D \quad \pi_{\alpha}([E]_D) \quad [\sigma_{\theta}([E]_D) \quad [\varepsilon([E]_D) \quad [\rho_{N \rightarrow N'}([E]_D) \\
& \quad \text{is given for any base relation name } R \quad \text{def} \quad \text{def} \quad \text{def} \quad \text{def} \quad \text{def} \\
& \quad [E_1 \text{ op } E_2]_D \quad \pi_{\alpha}([E]_D) \quad \sigma_{\theta}([E]_D) \quad \varepsilon([E]_D) \quad \rho_{N \rightarrow N'}([E]_D)
\end{align*}
\]

(a) Expressions

Then, for an SQL database \( D \), denoted as the set of all databases \( D' \) such that \( \text{sql}(D') = D \). Then, an SQL database \( D \), we define \( \text{codd}(D) \) as the set of all Codd databases in \( \text{sql}^{-1}(D) \). Note that, even though this set may be infinite, all of its elements are isomorphic. So, with some abuse of terminology, we speak of the Codd interpretation of an SQL database, which is unique up to renaming of nulls.

If SQL nulls are interpreted as Codd nulls, this should apply to input databases as well as query answers. Given a query \( Q \), for every SQL database \( D \) there should always be a way of assigning Codd nulls to SQL nulls in \( [Q]_D \) so as to obtain \( [Q]_{D'} \), where \( D' \) is the Codd interpretation of \( D \). In other words, the Codd interpretation of \( [Q]_D \) must be isomorphic to \( [Q]_{D'} \).

This requirement was shown in the diagram in the introduction – where \( Q(D) \) denotes \( [Q]_D \) – and it is formally defined below.

**Definition 1.** A query \( Q \) preserves Codd semantics if for every SQL database \( D \) it holds that

\[
[Q]_{D'} \in \text{codd}([Q]_D),
\]

where \( D' \) is the Codd interpretation of \( D \).

The above definition can be equivalently formulated as follows: a query \( Q \) preserves Codd semantics if, for every Codd database \( D \), it holds that

\[
\text{sql}([Q]_D) = [Q]_{\text{sql}(D)}
\]

and

\[
[Q]_D \text{ is a Codd table.}
\]

These two requirements are in fact independent of one another, as the following example shows.

**Example 1.** Consider a schema with two unary relation names \( R \) and \( S \) over attribute \( A \), and the Codd database \( D \) where

\[
\begin{align*}
[t_1 = t_2]_r = t \iff [t_1]_r = [t_2]_r \in \text{Const} \\
[t_1 \neq t_2]_r = t \iff [t_1]_r \neq [t_2]_r \\
null(t)_r = t \iff [t]_r \in \text{Null} \\
[\text{const}(t)]_r = t \iff [t]_r \in \text{Const} \\
[\theta_1 \land \theta_2]_r = t \iff [\theta_1]_r = [\theta_2]_r = t \\
[\theta_1 \lor \theta_2]_r = t \iff [\theta_1]_r = \text{t or } [\theta_2]_r = \text{t}
\end{align*}
\]

Then, \( \text{sql}(D) \) is the SQL database \( D' \) such that

\[
[Q]_{D'} = \begin{pmatrix}
A & B \\
\bot_1 & \bot_2 \\
0 & \bot_2
\end{pmatrix} \quad ; \quad [Q]_{D'} = \begin{pmatrix}
A & B \\
\bot & \bot \\
0 & \bot
\end{pmatrix}
\]

Now, take the queries \( Q_1 = R \times \rho_{A \rightarrow B}(S) \) and \( Q_2 = R - S \), whose answers on \( D \) and \( D' \) are as follows:

\[
[Q_1]_D = \begin{pmatrix}
A & B \\
\bot_1 & \bot_2 \\
0 & \bot_2
\end{pmatrix} \quad ; \quad [Q_1]_{D'} = \begin{pmatrix}
A & B \\
\bot & \bot \\
0 & \bot
\end{pmatrix}
\]

and

\[
[Q_2]_D = \begin{pmatrix}
A \\
\bot_1 \\
0
\end{pmatrix} \quad ; \quad [Q_2]_{D'} = \begin{pmatrix}
A \\
\bot \\
0
\end{pmatrix}
\]

Thus, w.r.t. \( D, Q_1 \) satisfies (1a) but not (1b), since \( [Q_1]_D \) contains multiple occurrences of the same null, namely \( \bot_2 \). On the other hand, \( Q_2 \) satisfies (1b) but not (1a), because \( [Q_2]_{D'} \neq \text{sql}([Q_2]_{D'}) \).

A natural question at this point is whether we can syntactically capture the class of RA queries that satisfy both (1a) and (1b) for every Codd database. Unfortunately, the answer is no.

**Proposition 1.** For every schema with at least one binary relation symbol, the set of RA queries that preserve Codd semantics is not recursively enumerable.

**Proof.** To prove this, we can show that the set of preserving queries is not recursive, by reduction from the undecidability of emptiness of relational algebra expressions; since the complement of the set is clearly r.e. (by simultaneous enumeration of queries and databases), the result follows.
extension \( Q_{R,S} \) over all three relations defined as follows: if \( Q \) produces nonempty result on \( E \), output \( R \times S \), otherwise output the empty table. This can be expressed as

\[
\pi_{R,S}(\pi_{\sigma}(Q) \times (R \times S)),
\]

where \( \pi_{R,S} \) means projecting on all attributes of \( R \) and \( S \). Due to the above observation, \( Q_{R,S} \) preserves Codd semantics if and only if \( Q \) always produces the empty set. Since the latter is well known to be undecidable \([10, 11]\), it implies that, for the schema with relations \( R, S, E \), preserving Codd semantics is undecidable.

We now explain how to encode \( R, S, E \) in one binary relation. First we encode them in a ternary relation \( T \). For this, assume three new constants \( r, s, e \) and add to \( T \) tuples \((r, a, b)\) for every \((a, b) \in R \) and likewise \((s, c, d)\) and \((e, u, v)\) for \((c, d) \in S \) and \((u, v) \in E \). In addition, add a tuple \((r, s, e)\). This tuple can be recognized as the only one whose components are precisely the elements of the first column: this is a condition that one easily checks in first-order logic and hence in relational algebra. Once we have a first-order query selecting this tuple, we can extract \( R, S, E \) from \( T \). Since there is a first-order query that checks whether \( T \) properly encodes three relations (i.e., there exists a tuple whose elements are precisely the elements that occur in the first column and nowhere else), then the previous proof applies.

Finally we show how to encode \( T \) in a binary relation \( B \). Then for each tuple \((a, b, c)\) in \( T \), create a new constant \( i \) for its id and add tuples \((i, b, c, i, a, i, a, i, 1\) to \( B \). Then one can check, using a first-order query, if \( B \) is a code for \( T \). Indeed, one needs to look for all elements \( i \) for which \((i, i) \in B \), and see if the only remaining tuples that use \( i \) are of the form \((i, b, c, i, a, i, a, i, 1\). Since in tuples \((a, b, c) \in T \) we have \( a \neq b \) and \( a \neq c \), there is a simple way to decouple the triple \((a, b, c)\) from them, again using a first-order query, as all of \( a, b, c \) can be unambiguously identified. Thus, the construction that uses the schema with relations \( R, S, E \) can be done using a single binary relation \( B \), which proves the proposition.

In light of the negative result above, we should look for syntactic restrictions that provide sufficient conditions for the preservation of Codd semantics. This is what we do in the next section.

4. Queries Preserving Codd Semantics

Since the set of RA queries that preserve Codd semantics cannot be captured syntactically, we can only hope for syntactic restrictions that are sufficient to guarantee this property. However, simply choosing a subset of relational algebra operations would be too restrictive to be useful: as we have seen in the examples, Cartesian product is one of the operations causing problems with the preservation of Codd semantics, and we certainly do not want a fragment that forbids joins altogether.

This suggests that, in order to come up with useful restrictions, we need some additional information beyond the query itself. Real databases typically must satisfy some integrity constraints, and when it comes to incomplete SQL databases the most basic form of constraints is to declare some of the attributes in the schema as **NOT NULL**. The use of this kind of constraints is extremely common in practice, as each base table in a real-life SQL database almost always has a subset of its attributes declared as **PRIMARY KEY**, which implies **NOT NULL**.

We model **NOT NULL** constraints as follows: the signature \( \text{sig}(R) \) of each base relation \( R \) is partitioned into two sets \( \text{n-sig}(R) \) and \( \text{c-sig}(R) \) of nullable and non-nullable attributes, so that \( \pi_{\text{c-sig}(R)}(\{R\}_D) \) contains only elements of \( \text{Const} \), for every database \( D \). That is, nulls are not allowed as values of the attributes in \( \text{c-sig}(R) \), while there is no restriction on the values of the attributes in \( \text{n-sig}(R) \). Below, we extend these notions to queries.

**Definition 2.** The set \( \text{n-sig}(Q) \) of nullable attributes of an RA query \( Q \) is inductively defined as follows:

- \( \text{n-sig}(R) \) is given for every relation name \( R \)
- \( \text{n-sig}(\text{op}\ Q_1\ Q_2) \overset{\text{def}}{=} \text{n-sig}(Q_1) \cup \text{n-sig}(Q_2) \) for \( \text{op} \in \{\times, \cup\} \)
- \( \text{n-sig}(Q_1 \cap Q_2) \overset{\text{def}}{=} \text{n-sig}(Q_1) \cap \text{n-sig}(Q_2) \)
- \( \text{n-sig}(Q_1 - Q_2) \overset{\text{def}}{=} \text{n-sig}(Q_1) \)
- \( \text{n-sig}(\pi_i(Q)) \overset{\text{def}}{=} \text{n-sig}(\pi_i(Q)) \)
- \( \text{n-sig}(\sigma_i(Q)) \overset{\text{def}}{=} \text{n-sig}(\sigma_i(Q)) \)
- \( \text{n-sig}(\rho_{A \rightarrow B}(Q)) \overset{\text{def}}{=} \text{n-sig}(Q)[A/B] \)

where \( \text{n-sig}(Q)[A/B] \) is obtained by replacing \( A \) with \( B \) in \( \text{n-sig}(Q) \). We also define \( \text{c-sig}(Q) = \text{sig}(Q) - \text{n-sig}(Q) \), and we say that \( Q \) is **non-nullable** if \( \text{n-sig}(Q) = \emptyset \).

From the above definition we immediately obtain:

**Proposition 2.** For every RA query \( Q \) and every database \( D \), \( \pi_{\text{c-sig}(Q)}(\{Q\}_D) \) consists only of elements of \( \text{Const} \). That is, independently of the data, the answer to a query \( Q \) can only have null values for the attributes in \( \text{n-sig}(Q) \).

To explain the restrictions that ensure preservation of Codd semantics, we need two additional definitions.

**Definition 3.** The **syntax tree** of an RA query \( Q \) is a binary (ordered) tree constructed as follows:

- Each relation symbol \( R \) is a single node labeled \( R \).
- For each unary operation symbol \( \text{op}_1 \), the syntax tree of \( \text{op}_1(Q) \) has root labeled \( \text{op}_1 \) and the syntax tree of \( Q \) rooted at its single child.
- For each binary operation symbol \( \text{op}_2 \), the syntax tree of \( Q \) has \( Q' \) root labeled \( \text{op}_2 \) and the syntax tree of \( Q \) and \( Q' \) rooted at its left child and right child, respectively.
Note that each node in the syntax tree of \( Q \) defines a sub-query of \( Q \), so we can associate properties of such queries with properties of syntax tree nodes.

The base of a query \( Q \), denoted by \( \text{base}(Q) \), is the set of relation names that appear in it (i.e., the set of its atomic subexpressions).

**Definition 4.** A node in the syntax tree of a query satisfies:

- **NNC (non-nullable child)** if one of its children is non-nullable;
- **NNA (non-nullable ancestor or self)** if either itself or one of its ancestors is non-nullable;
- **DJN (disjoint nullable attributes)** if its children have no common nullable attributes;
- **DJB (disjoint bases)** if its children have bases with no relation names in common.

We now state the main result.

**Theorem 1.** Let \( Q \) be an RA query whose syntax tree is such that:

a) each \( \varepsilon \) node satisfies NNC;

b) each \( \cap \) and \( \neg \) node satisfies DJN;

c) each \( \times \) node satisfies NNA;

d) each \( \cup \) node satisfies NNC or DJB or NNA.

Then, \( Q \) preserves Codd semantics.

These conditions do not restrict the full expressiveness of relational algebra on databases without nulls: when all attributes in the schema are non-nullable, every query is such, hence the restrictions are trivially satisfied.

**Corollary 1.** On database schemas without nullable attributes, every relational algebra query satisfies the conditions of Theorem 1.

Also, the restrictions are easy to check:

**Proposition 3.** Deciding whether an RA query satisfies the conditions of Theorem 1 can be done in linear time w.r.t. the number of nodes in its syntax tree.

**Proof.** Let \( n \) be the number of nodes in the syntax tree of the query, and proceed as follows:

1. Compute the base and the nullable attributes of each node. This step requires visiting all nodes in the tree and so its cost is \( n \).

2. Mark all \( \varepsilon \) and \( \cup \) nodes satisfying NNC, all \( \cap \) and \( \neg \) nodes satisfying DJN, all \( \times \) nodes satisfying DJB, all \( \sigma, \pi, \rho \) nodes, and all leaves. Since for each node we visit up to two child nodes, this step costs \( 2n \).

3. Mark all \( \cap \) and \( \times \) nodes in each subtree with a non-nullable root. This step can be carried out by visiting all nodes once, independently of how many of them are non-nullable, so its cost is \( n \).

4. The query satisfies the conditions of Theorem 1 iff all nodes in the resulting tree are marked. This can be checked in one more pass, so the cost of this step is \( n \).

The time required by the above algorithm is \( O(n) \).

Below we give an example query that satisfies the conditions of Theorem 1.

**Example 2.** Consider the following RA query \( \left( \rho_{B \to C}(R \cup S) - \rho_{D \to A}(\varepsilon(T)) \right) \cup \pi_{A,C}(\sigma_{A=1 \lor B=C}(R \times T)) \)

whose syntax tree is shown in Figure 5. To the left of each node we indicate the corresponding signature, where non-nullable attributes are underlined. For the leaves, this information is provided by the schema.

On the left side of the tree, the innermost \( \cup \) node satisfies DJB (but not NNC), the \( \varepsilon \) node satisfies NNC and so it is non-nullable, and the \( \neg \) node satisfies DJN as its children have no nullable attributes in common.

On the right side of the tree, the \( \times \) node satisfies NNA because its ancestor \( \pi \) is non-nullable, which also ensures that the root node satisfies NNC (but not DJB). Thus, the query preserves Codd semantics.

In what follows, we will outline the main intuition and ideas behind the conditions of Theorem 1, and develop the technical results needed to provide its formal proof.

If a query is non-nullable, then it trivially satisfies (1b), because the answer to it will not contain nulls for any database. However, there are non-nullable queries for which (1a) does not hold: for instance, \( \pi_{A}(\varepsilon(R)) \) when \( R \) has attributes \( A \) and \( B \), of which only \( A \) is non-nullable. Hence, non-nullability must be used more carefully, on the subqueries of \( Q \).

Duplicate elimination, intersection and difference may cause problems with (1a). What these operations have in common is that they match nulls syntactically, i.e., as if they were constants. Now, while SQL nulls are all syntactically the same, this is not the case for Codd nulls, so for these operations it makes a difference which model of nulls we use. Indeed, replacing nulls with \( \mathbf{N} \) before or after each of these operations is applied may give different results, as shown in Figure 6.

On the other hand, the remaining operations are not affected: projection, renaming, union and Cartesian product do not rely on any kind of value matching, and nulls in selection conditions are not compared syntactically. Indeed, the sql transformation commutes with projection, selection and renaming, and it distributes over union and Cartesian product, on all input tables (not necessarily Codd or even naive) for which each of these operations is well defined, but without further restrictions.
Lemma 2. Let $T$ be a table. Then,

a) $sql(\pi_\alpha(T)) = \pi_\alpha(sql(T))$ for every $\alpha \subseteq \text{sig}(T)$;

b) $sql(\sigma(\theta)(T)) = \sigma(\theta)(sql(T))$ for every selection condition $\theta$ such that $\text{sig}(\theta) \subseteq \text{sig}(T)$;

c) $sql(\rho_{A \rightarrow B}(T)) = \rho_{A \rightarrow B}(sql(T))$ for every $A \in \text{sig}(T)$ and $B \notin \text{sig}(T) - \{A\}$.

Lemma 3. Let $T_1$ and $T_2$ be tables. Then,

a) $sql(T_1 \cup T_2) = sql(T_1) \cup sql(T_2)$ whenever $T_1$ and $T_2$ have the same signature;

b) $sql(T_1 \times T_2) = sql(T_1) \times sql(T_2)$ whenever $T_1$ and $T_2$ have disjoint signatures.

The proofs of these lemmas are given in the appendix.

In light of the above, w.r.t. (1a), we only need to take care of $\varepsilon$, $-$ and $\cap$. It is obvious from the definitions that $\varepsilon$ commutes with $sql$ on complete tables (i.e., tables without nulls). In particular, we have that

$$sql(\varepsilon(T)) = \varepsilon(sql(T)) = \varepsilon(T)$$

for every table $T$ such that $\text{Null}(T) = \emptyset$. For queries, the NNC condition then ensures that the input table of each $\varepsilon$ operation is indeed complete.

Below, we provide a sufficient condition on tables that guarantees that $sql$ distributes over intersection and difference.

Lemma 4. Let $T_1$ and $T_2$ be tables with the same signature. Assume that, for every attribute $A$, there do not exist records $r_1$ and $r_2$ such that $r_1 \in T_1$ and $r_1(A) \in \text{Null}$, for $i = 1, 2$. Then, all of the following hold:

a) $sql(T_1 - T_2) = sql(T_1) - sql(T_2)$;

b) $sql(T_1 \cap T_2) = sql(T_1) \cap sql(T_2) = T_1 \cap T_2$.

The proof of the above lemma is given in the appendix.
Requiring \texttt{NNC} for each \( \epsilon, \cap \) and \(-\) subquery, as we did in \cite{footnote}, is enough to ensure that the overall query satisfies (1a). Intuitively, if at least one of the input subqueries to each of these operations is non-nullable, then no syntactic matching of nulls can occur, because one of the operands (the only one for \( \epsilon \)) will not have nulls at all. As a matter of fact, for \( \cap \) and \(-\), \texttt{NNC} is a special case of DJN, which only requires that the input subqueries do not share nullable attributes, and it suffices for the tables produced by such subqueries to satisfy the assumptions of Lemma 4.

**Proposition 4.** Every RA query whose syntax tree satisfies conditions a) and b) of Theorem 1 satisfies (1a) on all databases (not only Codd ones).

**Proof.** Let \( Q \) be an RA query whose syntax tree is such that every \( \cap \) and \(-\) node satisfies DJN, and every \( \epsilon \) node satisfies NNC. Let \( D \) be a database and let \( D' = \text{sql}(D) \). By induction on the structure of \( Q \), we will show that \([Q]_{D'} = \text{sql}([Q]_{D})\) in (1a) and \( [Q]_{D'} = \text{sql}([Q]_{D}) \) since \( D' = \text{sql}(D) \).

**Induction:**

- **\( Q \) is \( \epsilon(Q_1) \) for \( \epsilon \in \{\pi, \sigma, \rho_{A\rightarrow B}\} \)**

  By applying (i) the semantics of \( \epsilon \) in queries, (ii) the induction hypothesis, and (iii) Lemma 2, we obtain:
  
  \[ \text{op}_1(Q_1)_{D'} \overset{\text{(i)}}{=} \text{op}_1([Q_1]_{D'}) \overset{\text{(ii)}}{=} \text{op}_1(\text{sql}([Q_1]_{D})) \overset{\text{(ii)}}{=} \text{sql}(\text{op}_1([Q_1]_{D})) \overset{\text{Lemma 2}}{=}[Q]_{D'} \text{sql}(\text{op}_1([Q_1]_{D})) \]

- **\( Q \) is \( \text{op}_1 \text{op}_2 \) for \( \text{op}_2 \in \{\cap, \cup, \cap, \cap\} \)**

  By applying (i) the semantics of \( \text{op}_2 \) in queries, (ii) the induction hypothesis, (iii) Lemma 3 for Cartesian product and union) and Lemma 4 (for intersection and difference), we obtain:

  \[ [Q_1 \text{op}_2 Q_2]_{D'} \overset{\text{(i)}}{=} [Q_1]_{D'} \text{op}_2 [Q_2]_{D'} \overset{\text{(i)}}{=} \text{sql}([Q_1]_{D}) \text{op}_2 \text{sql}([Q_2]_{D}) \overset{\text{Lemma 4}}{=} \text{sql}([Q_1]_{D} \text{op}_2 [Q_2]_{D}) \overset{\text{(ii)}}{=} \text{sql}([Q_1]_{D}) \text{op}_2 [Q_2]_{D} \overset{\text{(i)}}{=} \text{sql}([Q_1 \text{op}_2 Q_2]_{D}) \]

The only observation is that, since \( \cap \) and \(-\) are required to satisfy DJN, in these cases \( n\text{-sig}(Q_1) \) and \( n\text{-sig}(Q_2) \) are disjoint, ensuring that the assumptions of Lemma 4 hold for the tables \( [Q_1]_{D} \) and \( [Q_2]_{D} \).

At this point, if in addition to the conditions of Proposition 4 we also required the query itself to be non-nullable, then preservation of Codd semantics would be guaranteed.

**Corollary 2.** Every non-nullable RA query that satisfies the conditions of Proposition 4 preserves Codd semantics.

**Proof.** Let \( Q \) be a non-nullable RA query, and let \( D \) be a Codd database. If \( Q \) satisfies the conditions of Proposition 4, then it satisfies (1a) on all databases, in particular \( D \). Since \( Q \) is non-nullable, \([Q]_{D} \) is complete by Proposition 2, and so it is trivially a Codd table; therefore, \( Q \) also satisfies (1b) on \( D \). \( \square \)

However, this is too restrictive, as it would forbid even the simple retrieval of a base relation whenever some of its attributes are nullable. For example, if \( R \) has a nullable attribute \( A \), the query \( Q = R \) would not be allowed because it is nullable, even though \( Q \) satisfies (1a) by Proposition 4 and its output is trivially guaranteed to be a Codd table on every Codd database. Thus, we need more refined ways of ensuring (1b) by restricting only the problematic operations.

Duplicate elimination, difference, selection and intersection always produce a table that is contained in at least one of the input tables, so their output may have repeated nulls only if these repetitions were already in the input. The same holds for projection, for a similar reason. The problematic operations w.r.t. (1b) are \( \cup \) and \( \cap \). Both can create repetitions of nulls across records, and the latter can also create repetitions of nulls within a record. To restrict these operations appropriately, we use the \texttt{NNA} condition. Requiring this condition for each \( \cap \) and \( \cup \) node is enough to ensure that the query satisfies (1b). Intuitively, repetitions of nulls that may be created by \( \cup \) and \( \cap \) are allowed in the intermediate results of a query, but only as long as they will be eventually discarded, at the latest when the final output is produced.

In fact, the \texttt{NNA} condition for union can be relaxed. We want to restrict this operation when it may create “new” repetitions of nulls, but we need not do so when the only repetitions it may produce are those inherited from the input, which were introduced by the application of previous operations. There are two cases in which this happens: when one of the operands is non-nullable, or when the input tables are built from disjoint sets of base relations. The first is captured by the \texttt{NNC} condition, and the second by the DJB condition. We can then allow for these additional possibilities by requiring each \( \cup \) node in the syntax tree of a query to satisfy \texttt{NNA or NNC or DJB}.

Now that we explained why and how the conditions of Definition 4 are needed, we can finally prove Theorem 1.

**Proof of Theorem 1.** Let \( Q \) be an RA query whose syntax tree satisfies the conditions of Theorem 1. Clearly, \( Q \) satisfies (1a) on all databases by Proposition 4, thus we only need to show that \([Q]_{D} \) is a Codd table for every Codd
database $D$. To this end, we proceed by induction on the structure of $Q$.

**Base:**
- $Q$ is non-nullable. Then, $[Q]_D$ is complete and so it is trivially a Codd table.
- $Q$ is a relation name $R$. Then, $[Q]_D = [R]_D$, which is a Codd table since $D$ is a Codd database by assumption.

**Induction:** Observe that the case when $Q = Q_1 \times Q_2$ is already covered in the base case, since the $\text{NNC}$ condition implies that $Q$ is non-nullable. For the same reason, we need not consider the case when $Q$ is $Q_1 \cup Q_2$ and satisfies $\text{NNC}$, as this again implies non-nullable. Similarly, the cases when $Q$ is $\sigma(Q_1)$ or $Q_1 \cap Q_2$ are also covered in the base case, because of the $\text{NNC}$ and $\text{DJN}$ conditions.

$Q$ is $\pi_a(Q_1)$

Towards a contradiction, suppose that $[\pi_a(Q_1)]_D$ is not a Codd table. There are three possibilities:

1. There is a record $r \in [\pi_a(Q_1)]_D$ such that $r(A) = r(B) = \text{Null}$ for two distinct attributes $A, B \in \alpha$. As $r \in [\pi_a(Q_1)]_D$, there must be $r' \in [Q_1]_D$ such that $r = \pi_a(r')$. But then $r'(A) = r(A) = r(B) = \text{Null} \in \text{Null}$, which is impossible because $[Q_1]_D$ is a Codd table by the induction hypothesis.

2. There exist distinct records $r, s \in [\pi_a(Q_1)]_D$ such that $r(A) = s(B) = \text{Null}$ for two (not necessarily distinct) attributes $A, B \in \alpha$. Since $r, s \in [\pi_a(Q_1)]_D$, there must be distinct $r', s' \in [Q_1]_D$ s.t. $r = \pi_a(r')$ and $s = \pi_a(s')$. But then $r'(A) = r(A) = s(B) = s'(B) = \text{Null}$, which is impossible because $[Q_1]_D$ is a Codd table by the induction hypothesis.

3. There is a record $r \in [\pi_a(Q_1)]_D$ with $k > 1$ such that $r(A) = \text{Null}$ for some attribute $A \in \alpha$. Since $r \in [\pi_a(Q_1)]_D$, there must be records $r_1, \ldots, r_n \in [Q_1]_D$ such that $r = \sum_{i=1}^n \# (r_i, [Q_1]_D)$ and $r_i = \pi_a(r)$ for $i = 1, \ldots, n$. But then $r(A) = r_1(A) = \cdots = r_n(A) = \text{Null}$, which is impossible since $[Q_1]_D$ is a Codd table by the induction hypothesis.

$Q$ is $\sigma(Q_1)$ or $Q_1 - Q_2$

The claim follows from the fact that $[Q]_D \subseteq [Q_1]_D$ and, by the induction hypothesis, $[Q_1]_D$ is a Codd table.

$Q$ is $\rho_{A \rightarrow B}(Q_1)$

The claim trivially follows from the fact that $\rho_{A \rightarrow B}$ only changes the name of attribute $A$ in each record in $[Q_1]_D$, which is a Codd table by the induction hypothesis, but not the value this attribute is mapped to.

$Q$ is $Q_1 \cup Q_2$ and satisfies NNC

We have $[Q]_D = [Q_1]_D \cup [Q_2]_D$. As union is commutative, we assume w.l.o.g. that $Q_1$ is non-nullable; then $[Q_1]_D$ is complete and thus $\text{Null}([Q]_D) = \text{Null}([Q_2]_D)$.

Since $[Q_2]_D$ is a Codd table by the induction hypothesis, this implies that $[Q]_D$ is a Codd table as well.

$Q$ is $Q_1 \cup Q_2$ and satisfies DJB

By the induction hypothesis $[Q_1]_D$ and $[Q_2]_D$ are Codd tables; if we show that they have no nulls in common, we can conclude that $[Q]_D$ is a Codd table as well. For $i = 1, 2$ we have

$$\text{Null}([Q_i]_D) \subseteq \bigcup_{Q \in \text{base}(Q_i)} \text{Null}([R]_D).$$

As $D$ is a Codd database, $\text{Null}([R]_D) \cap \text{Null}([S]_D) = \emptyset$ for any two distinct relation names in the schema. Then, as $\text{base}(Q_1) \cap \text{base}(Q_2) = \emptyset$, we obtain that $\text{Null}([Q_1]_D)$ and $\text{Null}([Q_2]_D)$ are disjoint as desired.

5. Derived Operations and Further Refinements

In our query language we explicitly included intersection, even though this operation is expressible in terms of difference. While it may seem redundant to have $\cap$ in the syntax of queries, it is not so w.r.t. our restrictions for the preservation of Codd semantics. To see why, suppose we want the intersection of base relations $R$ and $S$ (with the same signature), but we do not have $\cap$ available as a primitive operation in our query language. Of course, we can always write $R - (R - S)$ or $S - (S - R)$; the problem is that, even though these queries are equivalent, the former satisfies the conditions of Theorem 1 iff $R$ is non-nullable, while the latter satisfies them iff $S$ is non-nullable. In either case, each requirement (and even their disjunction) is stronger than the one for $R \cap S$ (i.e., DJN), which only requires $R$ and $S$ not to have nullable attributes in common.

This suggests that adding some derived operations explicitly to the syntax of queries may lead to milder restrictions, allowing us to recognize more queries that preserve Codd semantics. We will show two such refinements: constant selections and anti/semijoins.

Selections. Looking at $\alpha$ may seem counterintuitive as this operation did not need to be restricted in any way. However, consider the query $\sigma_{\text{const}(A)}(R) \cap S$, for unary relation symbols $R$ and $S$ over a nullable attribute $A$. This query clearly does not satisfy the conditions of Theorem 1, as $A$ is nullable in both $\sigma_{\text{const}(A)}(R)$ and $S$. But even though $A$ is nullable in $\sigma_{\text{const}(A)}(R)$, we can rest assured that, for every database $D$, no nulls will in fact appear in $[\sigma_{\text{const}(A)}(R)]_D$, because only records where the value of $A$ is a constant will be selected from $[R]_D$.

The idea here is to extend the query language with an explicit operation of constant selection $\sigma_{\text{const}(\alpha)}$, by adding the production rule $\sigma_{\text{const}(\alpha)}(E)$ to the grammar of expressions in Figure 3a. The signature of $\sigma_{\text{const}(\alpha)}(E)$ is $\text{sig}(E)$, as for regular selections, and the expression is well-defined as $E$ is well-defined and $\alpha \subseteq \text{sig}(E)$. Its semantics is given
as follows:
\[ [\sigma_{\text{const}(\alpha)}(E)]_D \overset{\text{def}}{=} \sigma_{\theta}([I]_D), \quad \text{where } \theta = \bigwedge_{A \in \alpha} \text{const}(A) \]

Finally – and this is the crucial bit – its nullable attributes are given by
\[ n\text{-sig}(\sigma_{\text{const}(\alpha)}(Q)) = n\text{-sig}(Q) - \alpha \]

Semijoins and antijoins. The \( \times \) of two tables \( T_1 \) and \( T_2 \) with disjoint sets of attributes is defined as
\[ T_1 \times \sigma \overset{\text{def}}{=} \sigma_{\theta}(T_1 \times T_2) \]
where \( \theta \) is a condition such that \( \sigma(\theta) \subseteq \sigma(T_1) \cup \sigma(T_2) \).

Adding \( \sigma \) to the language does not change anything: we impose no restriction on selections, and \( \sigma \) would have to be restricted in the same way \( \times \) is. But two operations derived from it can be added: semijoin \( \sigma \) and antijoin \( \bar{\sigma} \), which essentially correspond to \texttt{EXISTS} and \texttt{NOT EXISTS} in SQL.

For tables \( T_1 \) and \( T_2 \) with disjoint signatures and a condition \( \theta \) such that \( \sigma(\theta) \subseteq \sigma(T_1) \cup \sigma(T_2) \), these are defined as:
\[ T_1 \times \sigma \overset{\text{def}}{=} \sigma_{\theta}(T_1 \times T_2) \]
\[ T_1 \bar{\sigma} \overset{\text{def}}{=} T_1 - T_1 \times \sigma \]

That is, \( T_1 \times \sigma \) returns all occurrences of each record \( r \) in \( T_1 \) for which there exists a record \( s \) in \( T_2 \) such that \( \theta \) is true on \( r \times s \). Similarly, \( T_1 \bar{\sigma} \) returns all occurrences of each record \( r \) in \( T_1 \) for which there is no record \( s \) in \( T_2 \) such that \( \sigma(\theta) \) returns a \( t \).

To include these operations in the query language, we add the production rules \( E \times \sigma \equiv E \bar{\sigma} \) and \( E \bar{\sigma} \) to the grammar of expressions in Figure 3a. The signature of \( E_1 \times \sigma \) and \( E_1 \bar{\sigma} \) is \( \sigma(E_1) \). The expressions are well-defined if \( E_1 \) and \( E_2 \) are well-defined and \( \sigma(\theta) \subseteq \sigma(E_1) \cup \sigma(E_2) \). Their semantics is given by
\[ [E_1 \times \sigma E_2]_D \overset{\text{def}}{=} [E_1]_D \times [E_2]_D \]
\[ [E_1 \bar{\sigma} E_2]_D \overset{\text{def}}{=} [E_1]_D \bar{\sigma} [E_2]_D \]
and, finally, we define
\[ n\text{-sig}(Q_1 \times \sigma Q_2) = n\text{-sig}(Q_1 \bar{\sigma} Q_2) = n\text{-sig}(Q_1) \]

Since repetitions of nulls that might have been created in the right operand of \( \times \) or \( \bar{\sigma} \) are discarded, we can use an alternative to \texttt{NNA}, called \texttt{RDS}: a node in the syntax tree of a query satisfies this condition if it is the right-descendant of a node labeled \( \times \) or \( \bar{\sigma} \).

We denote by \( \text{RA}^\text{ext} \) the language of Figure 3 extended with the operations of constant selection, semijoin and antijoin described above. Then, we have:

**Theorem 2.** Let \( Q \) be an \( \text{RA}^\text{ext} \) query whose syntax tree is such that:

a) each \( r \times \sigma \) node satisfies \texttt{NNA};

b) each \( \bar{\sigma} \) node satisfies \texttt{DJN};

c) each \( \times \sigma \) node satisfies \texttt{NNA} or \texttt{RDS};

d) each \( \bar{\sigma} \) node satisfies \texttt{NDA} or \texttt{RDA} or \texttt{RDS}.

Then, \( Q \) preserves Codd semantics.

An analog of Corollary 1 follows, and simple modifications to the algorithm of Proposition 3 show that these conditions are still linear-time testable.

To prove the result, we first show that the \( \text{sql} \) operation on tables distributes over semijoin and antijoin.

**Lemma 5.** Let \( T_1 \) and \( T_2 \) be tables with disjoint signatures and \( \theta \) be a selection condition over \( \sigma(T_1) \cup \sigma(T_2) \). Then,

a) \( \text{sql}(T_1 \times \sigma T_2) = \text{sql}(T_1) \times \text{sql}(T_2) \);

b) \( \text{sql}(T_1 \bar{\sigma} T_2) = \text{sql}(T_1) \bar{\sigma} \text{sql}(T_2) \).

Proof. We only prove a); the proof of b) is analogous. To this, let \( r \) be a record over \( \sigma(T_1) \). Then, we have:

\[ m = \#(r, \text{sql}(T_1) \times \sigma \text{sql}(T_2)) = \begin{cases} \#(r, \text{sql}(T_1)) & \text{if } \exists r' \in \text{sql}(T_2): [\theta]_{r \times r'} = t \\ 0 & \text{otherwise} \end{cases} \]

and

\[ n = \#(r, \text{sql}(T_1 \bar{\sigma} T_2)) = \sum_{s \in \text{sql}^{-1}(r)} \#(s, T_1 \times \sigma T_2) = \begin{cases} \sum_{s \in \text{sql}^{-1}(r)} & \text{if } \exists s' \in \text{sql}(T_2): [\theta]_{s \times s'} = t \\ 0 & \text{otherwise} \end{cases} \]

Obviously, for every \( r' \in \text{sql}(T_2) \) there is \( s' \in T_2 \) such that \( r' = \text{sql}(s') \), and for every \( s' \in T_2 \) there exists \( r' \in \text{sql}(T_2) \) such that \( r' = \text{sql}(s') \). Moreover, for records \( s \in \text{sql}^{-1}(r) \) and \( r' = \text{sql}(s') \), by Lemma 1 we have that

\[ [\theta]_{r \times r'} = [\theta]\text{sql}(r \times r') = [\theta]\text{sql}(r) \times \text{sql}(r') = [\theta]_{s \times s'} \]
and therefore \( m = n \).
Next, we can show that:

**Proposition 5.** Every RA^{ext} query whose syntax tree satisfies conditions a) and b) of Theorem 2 satisfies (1a) on all databases (not only Codd ones).

**Proof.** This is the same as the proof of Proposition 4, with the only difference that, in the induction, we additionally need to address the cases for the operations of RA^{ext} that are not in RA. Constant selection is simply a special case of selection and so there is nothing new to show. The cases for semijoin and antijoin follow directly from the inductive hypothesis and Lemma 5 above.

Finally, we can prove Theorem 2 by adapting the proof of Theorem 1.

**Proof of Theorem 2.** Let Q be an RA^{ext} query whose syntax tree satisfies the conditions of Theorem 2. By Proposition 5, Q satisfies (1a) on all databases, so we only need to show that \([Q]_D\) is a Codd table for every Codd database D. To this end, we proceed by induction on the structure of Q as in the proof of Theorem 1, with the only difference that we additionally need to show also the following cases for the inductive step:

- \(Q = \pi_{\theta} Q_1\).
- \(Q = Q_1 \Join Q_2\) for \(\Join \in \{\times, \cap, \setminus\}\)

The claim follows from the fact that \([Q]_D \subseteq [Q_1]_D\) and, by the induction hypothesis, \([Q_1]_D\) is a Codd table.

**6. Set Semantics**

Without changing our underlying data model based on bags, we now discuss the case of queries interpreted under set semantics. To this end, we let RA^{set} be the fragment of RA without duplicate elimination, and we call set database one where no record occurs more than once within a table. The set semantics of an RA^{set} query Q on a set database D is denoted by \([Q]^{set}_D\) and is defined inductively as follows:

\[
[R]^{set}_D \overset{\text{def}}{=} [R]_D
\]

\[
[Q_1 \Join Q_2]^{set}_D \overset{\text{def}}{=} [Q_1]^{set}_D \Join [Q_2]^{set}_D \text{ for } \Join \in \{\cap, -, \times\}
\]

\[
[Q]^{set}_D \overset{\text{def}}{=} [Q^{set}_D]^{set}_D
\]

The above is well-defined because D is a set database and, even though the semantics of each subexpression returns a table that is formally a bag, each record in it is guaranteed to occur exactly once.

The notion of preservation of Codd semantics for RA^{set} queries in the context of sets is modified as follows:

**Definition 5.** An RA^{set} query Q preserves Codd semantics over sets if, for every SQL set database D and for every \(D' \in \text{codd}(D)\), it holds that \([Q]^{set}_D \subseteq [Q]^{set}_{D'}\).

From the definition of \([Q]^{set}_D\), it is immediate to see that every RA^{set} query Q can always be rewritten into an RA query \(Q'\) with duplicate elimination, so that, on every set database D, evaluating Q under set semantics is equivalent to evaluating \(Q'\) under bag semantics, i.e., \([Q]^{set}_D = [Q']_D\).

This translation – shown in Figure 7 for completeness – is straightforward: each projection and union operation must be immediately followed by duplicate elimination. Now, if \(Q'\) satisfies the condition of Theorem 1, then \(Q'\) preserves Codd semantics on all databases, in particular set ones; in turn, \(Q\) preserves Codd semantics over sets.

**Proposition 6.** Let Q be an RA^{set} query, and let \(Q'\) be obtained from Q by applying the translation in Figure 7. If \(Q'\) satisfies the conditions of Theorem 1, then Q preserves Codd semantics over sets.

However, this is too restrictive for even simple queries, as the following example shows.

**Example 3.** Consider a schema with R and S over a single attribute A that is nullable in R but not in S, and take the RA^{set} query \(Q = R \cup S\). The translation of Figure 7 yields \(Q' = \varepsilon(R \cup S)\), which does not satisfy the conditions of Theorem 1, since \(R \cup S\) is nullable and so \(\varepsilon(R \cup S)\) does not satisfy NWC as required. Thus, we cannot use Proposition 6 to conclude that Q preserves Codd semantics over sets, although this is easily seen – in this particular example – because, on every SQL set database D, \([R]_D\) will not have duplicates and \([S]_D\) will not contain nulls.

This tells us that specific restrictions should be devised to deal with set semantics. To this end, we observe that the fundamental difference with the interpretation under bag semantics is that projection and union operations are immediately followed by duplicate elimination. As we know, this is problematic because records that differ only on nullable attributes will become the same when the nulls are all replaced by N. Under set semantics, this can be allowed as
long as nullable attributes are eventually discarded, which is enforced by requiring \( \pi_n \) and \( \cup \) to satisfy the \texttt{NNA} condition. For \( \cup \) we can further allow \texttt{NNC} as before, and this is indeed the reason why the query \( Q \) in Example 3 preserves Codd semantics over sets.

**Theorem 3.** Let \( Q \) be an RA\textsuperscript{set} query whose syntax tree is such that:

a) \( \text{each } \cap \text{ and } - \text{ node satisfies DJN} \);

b) \( \text{each } \times \text{ and } \pi_\alpha \text{ node satisfies NNA} \);

c) \( \text{each } \cup \text{ node satisfies NNC or NNA} \).

Then, \( Q \) preserves Codd semantics over sets.

An analog of Corollary 1 follows, and straightforward modifications to the algorithms of Proposition 3 show that these conditions are still linear-time testable.

Note that, under set semantics, the DJB condition for \( \cup \) does not work any longer, as the following example shows.

**Example 4.** Consider a schema with \( R \) and \( S \) over a single nullable attribute \( A \). The RA\textsuperscript{set} query \( Q = R \cup S \) trivially satisfies DJB, but it does not preserve Codd semantics over sets. To see this, take the SQL set database \( D \) where

\[
[R]_D = \begin{array}{c|c|c}
A & N & \text{N} \\
\hline
\end{array} \\
[S]_D = \begin{array}{c|c|c}
A & N & \text{N} \\
\hline
\end{array}
\]

and the Codd set database \( D' \) where

\[
[R]_{D'} = \begin{array}{c|c|c}
A & \downarrow_1 & \text{N} \\
\hline
\end{array} \\
[S]_{D'} = \begin{array}{c|c|c}
A & \downarrow_1 & \text{N} \\
\hline
\end{array}
\]

Clearly, \( D' \in \text{codd}(D) \). However, we have:

\[
[R \cup S]_{\text{set}}^{\text{set}} = \begin{array}{c|c|c}
A & \downarrow_1 & \text{N} \\
\hline
\end{array} \\
[R \cup S]_{D'} = \begin{array}{c|c|c}
A & \downarrow_1 & \text{N} \\
\hline
\end{array}
\]

Therefore \( [Q]_{\text{set}}^{\text{set}} \notin \text{codd}([Q]_{D}^{\text{set}}) \).

The restrictions of Theorem 3 for an RA\textsuperscript{set} query \( Q \) are weaker than those of Theorem 1 one would have to impose on the RA translation of \( Q \).

**Proposition 7.** Let \( Q \) be an RA\textsuperscript{set} query, and let \( Q' \) be obtained from \( Q \) by applying the translation in Figure 7. If \( Q' \) satisfies the conditions of Theorem 1, then \( Q \) satisfies the conditions of Theorem 3.

**Proof.** The only difference between \( Q \) and \( Q' \) is that every \( \pi_\alpha \) and \( \cup \) node in (the syntax tree of) \( Q \) will have as parent an \( \varepsilon \) node in (the syntax tree of) \( Q' \), and the parent of such \( \varepsilon \) node in \( Q' \) is in turn the parent of the corresponding \( \pi_\alpha \) or \( \cup \) node in \( Q \).

Now, if \( Q' \) satisfies the conditions of Theorem 1, then each \( \varepsilon \) node in its syntax tree must satisfy \texttt{NNA}, and thus its only child is non-nillable. In turn, every \( \pi_\alpha \) and \( \cup \) node in \( Q \) will trivially satisfy \texttt{NNA}.

As witnessed by the query in Example 3, the converse of Proposition 7 is obviously not true. This means that the conditions of Theorem 3 allow us to identify strictly more RA\textsuperscript{set} queries that preserve Codd semantics over sets than Proposition 6, and without any increase in complexity.

We conclude this section by providing the formal proof of Theorem 3. Towards this goal, we first need a few lemmas about the interaction between duplicate elimination and other operations on tables. These follow immediately from the definitions.

**Lemma 6.** Let \( T \) be a table. Then,

a) \( \varepsilon(\sigma_\theta(T)) = \sigma_\theta(\varepsilon(T)) \) for every condition \( \theta \) such that \( \text{sig}(\theta) \subseteq \text{sig}(T) \);

b) \( \varepsilon(\rho_{A \rightarrow B}(T)) = \rho_{A \rightarrow B}(\varepsilon(T)) \) for every \( A \) and \( B \) such that \( A \in \text{sig}(T) \) and \( B \notin \text{sig}(T) - \{A\} \);

c) \( \varepsilon(\pi_\alpha(T)) = \varepsilon(\pi_\alpha(T)) \) for every \( \alpha \subseteq \text{sig}(T) \);

**Lemma 7.**

a) \( \varepsilon(T_1 \times T_2) = \varepsilon(T_1) \times \varepsilon(T_2) \) for all tables \( T_1, T_2 \) with disjoint signatures.

b) \( \varepsilon(T_1 \cap T_2) = \varepsilon(T_1) \cap \varepsilon(T_2) \) for all tables \( T_1, T_2 \) of the same signature.

c) \( \varepsilon(T_1 \cup T_2) = \varepsilon(T_1) \cup \varepsilon(T_2) \) for all tables \( T_1, T_2 \) of the same signature.

d) \( \varepsilon(T_1) - T_2 = \varepsilon(T_1) - \varepsilon(T_2) \) for all tables \( T_1, T_2 \) of the same signature.

**Lemma 8.** Let \( T_1, T_2 \) and \( T_2 \) be tables of the same signature and such that \( T_1 \neq T_2 \) is disjoint with \( T_1 \) and \( T_2 \). Then,

\[
\varepsilon((T_1 \cup T_2) - T_2) = \varepsilon(T_1 - T_2)
\]

Next, we show a technical result that will be crucial in the proof of Theorem 3.

**Lemma 9.** Let \( Q \) be an RA\textsuperscript{set} query whose syntax tree satisfies condition a) of Theorem 3. Then, for all set databases \( D \) and \( D' \) such that \( D' = \text{sql}(D) \), it holds that

\[
\varepsilon(\text{sql}([Q]_{\text{set}})) = [Q]_{D'}^{\text{set}}
\]

**Proof.** We proceed by induction on the structure of \( Q \).

**Base:** \( Q \) is a relation name \( R \). Then, obviously, \( [R]_{D'}^{\text{set}} = \text{sql}([R]_{D}^{\text{set}}) = \varepsilon(\text{sql}([R]_{D}^{\text{set}})) \) because \( D \) and \( D' \) are set databases such that \( D' = \text{sql}(D) \).

**Induction:**

- \( Q \) is \( \text{op}_1(Q_1) \) for \( \text{op}_1 \in \{\sigma_\theta, \rho_{A \rightarrow B}\} \)

\[
\text{op}_1([Q_1]_{\text{set}}) = \text{op}_1(\varepsilon([Q_1]_{\text{set}})) = \varepsilon(\text{sql}([Q_1]_{\text{set}})) \] (by def. of \([Q_1]_{\text{set}}\))

(by the I.H.)
Since \( J_Q = 1 \) (by Lemma 6),
\[
\varepsilon(\text{sql}(\langle Q_1 \rangle_D^{\text{set}})) = \varepsilon(\text{sql}(\langle Q_1 \rangle_D^{\text{set}})) - \varepsilon(\text{sql}(\langle Q_2 \rangle_D^{\text{set}}))
\] (by Lemma 7)

Now, we let \( T_1 = \text{sql}(\langle Q_1 \rangle_D^{\text{set}}) \) and \( T_2 = \text{sql}(\langle Q_2 \rangle_D^{\text{set}}) \), and we partition \( T_1 \) into two tables \( T_1' \) and \( T_1'' \) such that \( T_1' \) consists of every occurrence of all and only the constant records in \( T_2 \). Since \( Q_1 - Q_2 \) satisfies DJN by assumption, \( n\text{-sig}(Q_1) \) and \( n\text{-sig}(Q_2) \) are disjoint. In turn, \([Q_1]_D^{\text{set}}\) and \([Q_2]_D^{\text{set}}\), and thus also \( T_1 \) and \( T_2 \), satisfy the assumptions of Lemma 4. Moreover, \( T_2 \) is disjoint with \( T_1'' \), and \( T_1 \) is trivially disjoint with \( T_1' \), so these three tables satisfy the assumptions of Lemma 8. Then, we have:

The conclusion of the proof of the lemma.

Now, observe that Definition 5 can be equivalently reformulated as follows: an RA\textsuperscript{set} query preserves Codd semantics over sets if, for all set databases \( D \) and \( D' \) such that \( D' = \text{sql}(D) \) and \( D \) is a Codd database, it holds that

\[
\text{sql}(\langle Q \rangle_D^{\text{set}}) = \langle Q \rangle_{D'}^{\text{set}}
\] (2a)

and

\[
\langle Q \rangle_D^{\text{set}} \text{ is a Codd table.}
\] (2b)

With all of this in place, we can finally proceed to prove Theorem 3.

**Proof of Theorem 3.** Let \( Q \) be an RA\textsuperscript{set} query whose syntax tree is s.t. every \( \land \) and \( \neg \) node satisfies DJN, every \( \pi_n \) node satisfies \( \text{NNA} \), and every \( \forall \) node satisfies \( \text{NNC} \) or \( \text{NNA} \). Let \( D \) and \( D' \) be set databases such that \( D' = \text{sql}(D) \) and \( D \) is a Codd database. We need to show (2a) and (2b). By Lemma 9, \( \text{sql}(\langle Q \rangle_D^{\text{set}}) = \langle Q \rangle_D^{\text{set}} \), hence showing (2a) amounts to proving that \( \text{sql}(\langle Q \rangle_D^{\text{set}}) \) is a set. We show this, along with (2b), by induction on the structure of \( Q \).

**Base:**

- \( Q \) is non-nullable. Then, \( \langle Q \rangle_D^{\text{set}} \) is a complete set, so it is a Codd table and \( \text{sql}(\langle Q \rangle_D^{\text{set}}) = \langle Q \rangle_D^{\text{set}} \) is a set.

- \( Q \) is a relation name \( R \). Then, \( \langle Q \rangle_D^{\text{set}} = \langle R \rangle_D \), which is a Codd table by assumption. Moreover, as \( D' = \text{sql}(D) \) is a set database by assumption, we have that \( \text{sql}(\langle R \rangle_D) = \langle R \rangle_{D'} \) is a set.

**Induction:** The cases when \( Q = \pi_n(Q_1) \) or \( Q_1 \times Q_2 \) are already covered in the base case, because the \( \text{NNA} \) condition implies that such queries are non-nullable. For the same reason, we need not consider the case when \( Q = Q_1 \cup Q_2 \) and satisfies \( \text{NNA} \). Similarly, the case when \( Q = Q_1 \cap Q_2 \) is...
also covered in the base case, as the D.N. condition for this query again implies non-nullability.

From the definition of \( \text{sql} (\cdot) \) on tables, we also have that \( \text{sql}(T) \subseteq \text{sql}(T') \) for all tables \( T, T' \) of the same signature such that \( T \subseteq T' \).

- \( Q \) is \( \sigma_A(Q_1) \) or \( Q_1 - Q_2 \)

Clearly \( [Q_1]_{D}^{\text{set}} \subseteq [Q_1]_{D}^{\text{set}} \) and, in turn, we also have that \( \text{sql}([Q_2]_{D}^{\text{set}}) \subseteq \text{sql}([Q_1]_{D}^{\text{set}}) \). By the induction hypotheses, \( [Q_1]_{D} \) is a Codd relation and \( \text{sql}([Q_1]_{D}^{\text{set}}) \) is a set table, hence the claims follow.

- \( Q \) is \( \rho_{A \rightarrow B}(Q_1) \)

The claims trivially follow from the induction hypotheses, because \( \rho_{A \rightarrow B} \) only changes the name of attribute \( A \) in each record in \( [Q_1]_{D}^{\text{set}} \) but not the value this attribute is mapped to.

- \( Q \) is \( Q_1 \cup Q_2 \) and satisfies NNC

We have \( [Q_1]_{D}^{\text{set}} = \varepsilon ([Q_1]_{D}^{\text{set}} \cup [Q_2]_{D}^{\text{set}}) \). As union is commutative, we assume w.l.o.g. that \( Q_1 \) is non-nullable, so \( [Q_1]_{D}^{\text{set}} \) is complete. We then partition \( [Q_2]_{D}^{\text{set}} \) into two tables \( T_2, T_2'' \) such that \( T_2 \) contains every occurrence of all and only the constant records in \( [Q_2]_{D}^{\text{set}} \). As \( D \) is a set database, \( [Q_2]_{D}^{\text{set}} \) is a set and, by the I.H., it is also a Codd table. Therefore, \( T_2'' \) is a Codd set table because \( T_2'' \subseteq [Q_2]_{D}^{\text{set}} \). Now, as \( T_2 '' \) is a set disjoint with \( [Q_1]_{D}^{\text{set}} \) and \( T_1 \), we have \( [Q]_{D}^{\text{set}} = \varepsilon ([Q_1]_{D}^{\text{set}} \cup T_2) \cup T_2'' \)

Let \( T_1 = \varepsilon ([Q_1]_{D}^{\text{set}} \cup T_2) \); since \( T_1 \) is complete and \( T_2 '' \) is a Codd table, \( [Q]_{D}^{\text{set}} \) is a Codd table too. Moreover, by Lemma 3 we get \( \text{sql}([Q]_{D}^{\text{set}}) = \text{sql}(T_1) \cup \text{sql}(T_2) \)

where \( \text{sql}(T_1) = T_1 \) and \( \text{sql}(T_2) = \text{sql}([Q_2]_{D}^{\text{set}}) \). By the induction hypotheses, \( \text{sql}([Q_2]_{D}^{\text{set}}) \) is a set, hence \( \text{sql}(T_2) \) as a set as well. Therefore, since \( T_1 \) and \( T_2 \) are disjoint sets, \( \text{sql}(T_2) \) is also a set.

7. Conclusions and Future Work

The main lesson to be learned from this work is that, contrary to what is commonly believed, Codd nulls do not properly model SQL nulls, as even simple queries may produce answers that break such interpretation. In turn, this also means that theoretical results devised within the general model of incompleteness with marked nulls are not directly applicable in practical scenarios where SQL is used, unless queries are appropriately restricted.

Unfortunately, the class of relational algebra queries for which the Codd interpretation of SQL nulls is preserved in answers cannot be captured by a syntactic fragment of the language. Thus, we can only hope for reasonable syntactic restrictions that are sufficient to guarantee preservation. In this paper we presented mild restrictions on the syntax tree of queries, which ensure preservation and are easy to check. One obvious direction for future research is to look for more refined restrictions that allow one to recognize an even larger set of queries preserving Codd semantics.

As we have shown for intersection, semijoins and anti-joins, including derived operations to the query language, while redundant from the expressivity point of view, may allow for restrictions that are milder than the general ones. Thus, the query language could be tailored to specific applications, e.g., by adding operations such as division (\( \div \)), or by abstracting other commonly used query patterns.

Another possibility is to propagate nullable attributes in selections in a more refined way, along the lines of what we have done for constant selection. For example, we can be sure that the values of attributes \( A \) and \( B \) in the answer to \( \pi_{A,B}(Q) \) will always be constants, independently of whether they are non-nullable in \( Q \). On the other hand, we cannot say the same for \( \pi_{A \cup B}(Q) \), so this requires a careful handling of selection conditions.

Yet another opportunity for additional refinement may be offered by intersection and union, which are commutative and associative operations. While commutativity does not affect whether a query satisfies our restrictions or not, associativity does have an impact. For example, consider a schema with relation names \( R \) and \( S \) over attributes \( A \) and \( B \), where \( A \) is nullable only in \( R \) and \( B \) is nullable only in \( S \); then the query \( (R \cup S) \cup (R \cap S) \) satisfies the conditions of Theorem 1, while \( R \cup (S \cup (R \cap S)) \) does not. Moreover, there exist also queries that preserve Codd semantics but for which no permutation of the operands results in an expression that satisfies our restrictions; e.g., \( R_A \cap R_B \cap R_C \) on a schema with relation names \( R_A, R_B \) and \( R_C \) over attributes \( A, B, C \) such that the only non-nullable attribute of each \( R_i \) is \( i \), for \( i \in \{A, B, C\} \). To overcome these limitations, the idea would be to view \( \cap \) and \( \cup \) in the syntax tree of queries as variadic, rather than binary. This could allow for appropriate restrictions to be imposed on a single node with \( \geq 2 \) children, instead of multiple nodes with exactly two children.

Future work is not limited to further refinement of the restrictions that ensure preservation of Codd semantics. The notion of Codd database we adopted in this paper only allows for constant tuples to occur multiple times, as nulls cannot repeat. Relaxing this requirement to also allow for duplicates of non-constant tuples raises several interesting questions: How do we interpret multiple occurrences of a tuple with nulls in an SQL database? What is preservation of Codd semantics in this context? Do our restrictions still guarantee it? One possible approach would be to explicitly represent a table as a pair consisting of a set \( S \) of records and an associated multiplicity function that indicates the number of occurrences of each record of \( S \) within the table. Then, the notion of Codd preservation, and the conditions that enforce it, would probably be similar to those we used for the case of queries interpreted under set semantics.
There are then questions related to more practical aspects. For instance, how can we check that a query written in (an appropriate fragment of) SQL satisfies our restrictions? We could translate the query to RA (e.g., by using the translation in [8]) and then check whether the resulting expression satisfies the restrictions, but this of course depends on the particular translation one chooses. A better solution would be to devise explicit restrictions on the actual SQL syntax.

Finally, another interesting direction for future work is to implement marked nulls in SQL, instead of limiting the expressivity of queries in an attempt to fit a flawed model. It remains to be seen whether such an implementation is feasible using only Standard features of the SQL language and whether it requires custom extensions. In any case, an implementation of marked nulls does not detract from the work in this paper, which would still be relevant for closed or legacy systems that cannot be extended, or applications where the Standard must be strictly followed.

Appendix: Additional Proofs

Proof of Lemma 2.

a) Let $T$ be a table and let $\alpha \subseteq \Sigma(T)$. Obviously, the tables $T_1 = \text{sql}(\pi_{\alpha}(T))$ and $T_2 = \pi_{\alpha}(\text{sql}(T))$ are well defined and $\text{sig}(T_1) = \text{sig}(T_2) = \text{sig}(T)$.

Let $r$ be a record over $\text{sql}(T)$; we need to show that $\#(r, T_1) = \#(r, T_2)$. On the one hand, we have

$$\#(r, T_1) = \sum_{s \in \text{sql}^{-1}(r)} \#(s, \pi_{\alpha}(T)) = \sum_{s' : \text{sql}(\pi_{\alpha}(s')) = r} \#(s', T)$$

because

$$\#(s, \pi_{\alpha}(T)) = \sum_{s' : \pi_{\alpha}(s') = s} \#(s', T)$$

and $\text{sql}(s) = r$ since $s \in \text{sql}^{-1}(r)$. On the other hand,

$$\#(r, T_2) = \sum_{r' : \pi_{\alpha}(r') = r} \#(r', \text{sql}(T)) = \sum_{s' : \pi_{\alpha}(\text{sql}(s')) = r} \#(s', T)$$

because

$$\#(r', \text{sql}(T)) = \sum_{s' : \text{sql}(s') = r} \#(s', T)$$

and $r'$ is such that $\pi_{\alpha}(r') = r$.

By Lemma 1, we have that $\pi_{\alpha}(\text{sql}(s')) = \text{sql}(\pi_{\alpha}(s'))$, and therefore the claim follows.

b) Let $T$ be a table, and let $\theta$ be a selection condition such that $\text{sig}(\theta) \subseteq \text{sig}(T)$. Obviously, the tables $T_1 = \text{sql}(\sigma_{\theta}(T))$ and $T_2 = \sigma_{\theta}(\text{sql}(T))$ are well defined and $\text{sig}(T_1) = \text{sig}(T_2) = \text{sig}(T)$.

Let $r$ be a record over $\text{sig}(T)$; we need to show that $\#(r, T_1) = \#(r, T_2)$. We have the following:

$$\#(r, T_1) = \sum_{s \in \text{sql}^{-1}(r)} \#(s, \sigma_{\theta}(T))$$

$$= \sum_{s \in \text{sql}^{-1}(r)} \#(s, T)$$

$$\overset{(\dagger)}{=} \begin{cases} \#(s, T) & \text{if } [\theta]_r = t \\ 0 & \text{if } [\theta]_r = f \end{cases}$$

$$= \#(r, \text{sql}(T)) = \#(r, T)$$

$$= \#(r, T_2)$$

where $(\dagger)$ is because, for every record $s \in \text{sql}^{-1}(r)$, it holds that $\text{sql}(s) = r$ and so $[\theta]_r = [\theta]_s$, by Lemma 1, and

$$\#(s, \sigma_{\theta}(T)) = \begin{cases} \#(s, T) & \text{if } [\theta]_s = t \\ 0 & \text{if } [\theta]_s = f \end{cases}$$

by definition of the selection operation on tables.

c) Let $T$ be a table, let $A \in \text{sig}(T)$ and let $B \not\subseteq (\text{sig}(T) - \{A\})$. Obviously, the tables $T_1 = \text{sql}(\rho_{A\rightarrow B}(T))$ and $T_2 = \rho_{A\rightarrow B}(\text{sql}(T))$ are well defined, and both have signature $(\text{sig}(T) - \{A\}) \cup \{B\}$.

Let $r$ be a record over $\text{sig}(T_1)$; we need to show that $\#(r, T_1) = \#(r, T_2)$. On the one hand, we have

$$\#(r, T_1) = \sum_{s \in \text{sql}^{-1}(r)} \#(s, \rho_{A\rightarrow B}(T)) = \sum_{s' : \text{sql}(\rho_{A\rightarrow B}(s')) = r} \#(s', T)$$

as $\#(s, \rho_{A\rightarrow B}(T)) = \#(s', T)$, where $\rho_{A\rightarrow B}(s') = s$, and $\text{sql}(s) = r$ since $s \in \text{sql}^{-1}(r)$. On the other hand,
Proof of Lemma 3.

for every record and both are over \( \sigma(T) \). Then, since \( \rhoA\rightarrow B(s') = \rhoA\rightarrow B(s) \) by Lemma 1, the claim follows.

Proof of Lemma 3.

a) Let \( T1 \) and \( T2 \) be tables of the same signature. Obviously, the tables \( \sigma(T1 \cup T2) \) and \( \sigma(T1) \cup \sigma(T2) \) are well defined and they are both over \( \sigma(T1) = \sigma(T2) \). Then, for every record \( r \) over \( \sigma(T1) \), we have:

\[
\#(r, \sigma(T1 \cup T2)) = \sum_{s \in \sigma^{-1}(T)} \#(s, T1 \cup T2) \\
\text{by definition of } \sigma \text{ on tables}
\]

where \( \dagger \) are by definition of \( \sigma \) on tables, and \( \ddagger \) are by definition of the union operation on tables.

b) Let \( T1 \) and \( T2 \) be tables with disjoint signatures, and let \( \alpha = \sigma(T1) \) and \( \beta = \sigma(T2) \). Obviously, the tables \( \sigma(T1 \times T2) \) and \( \sigma(T1) \times \sigma(T2) \) are well defined and both are over \( \alpha \cup \beta \). Since \( \alpha \) and \( \beta \) are disjoint, every record \( r \) over \( \alpha \cup \beta \) union is the product of the projections of \( r \) on \( \alpha \) and \( \beta \), denoted for simplicity by \( r_{\alpha} \) and \( r_{\beta} \), respectively. By Lemma 1, \( \sigma(s_{\alpha} \times s_{\beta}) = \sigma(s_{\alpha}) \times \sigma(s_{\beta}) \); therefore, \( s_{\alpha} \times s_{\beta} \in \sigma^{-1}(r_{\alpha} \times r_{\beta}) \) if and only if \( s_{\alpha} \in \sigma^{-1}(r_{\alpha}) \) and \( s_{\beta} \in \sigma^{-1}(r_{\beta}) \). Then, for every record \( r \) over \( \alpha \cup \beta \), we have:

\[
\#(r_{\alpha} \times r_{\beta}, \sigma(T1 \times T2)) = \sum_{s \in \sigma^{-1}(r_{\alpha} \times r_{\beta})} \#(s, T1 \times T2) \\
\text{by definition of } \sigma \text{ on tables}
\]

Proof of Lemma 4. Let us denote by \( \alpha \) the signature of \( T1 \) and \( T2 \).

a) Clearly, the tables \( \sigma(T1) \times \sigma(T2) \) and \( \sigma(T1 - T2) \) are well defined and both have signature \( \alpha \). Let \( r \) be a record over \( \alpha \); to prove the claim we will show the following:

\[
\#(r, \sigma(T1 - T2)) = \sum_{s \in \sigma^{-1}(r_{\alpha})} \#(s, T1 - T2) \\
\text{by definition of } \sigma \text{ on tables}
\]

In particular, we only need to show \((i)\), as the other equalities hold by definition of \( \sigma \) and \( \sigma \) on tables. If \( r \) maps all attributes to constants, then \( \sigma^{-1}(r) = \{ r \} \) and \((i)\) holds, as both its l.h.s. and r.h.s. are trivially equal to \( \#(r, T1) \neq \#(r, T2) \) in this case. Thus, assume \( r(A) \in Null \) for some attribute \( A \). By definition, every \( s \in \sigma^{-1}(r) \) is such that \( \sigma(s) = r \) and so \( s(A) \in \sigma \). In turn, by the assumption on \( T1 \) and \( T2 \), there cannot exist records \( s1 \) and \( s2 \) in \( \sigma^{-1}(r) \) such that \( s1 \in T1 \) and \( s2 \in T2 \). Therefore, the l.h.s. and r.h.s. of \((i)\) will both be \( \sum_{s \in \sigma^{-1}(r)} \#(s, T1) \) if some record in \( \sigma^{-1}(r) \) occurs in \( T1 \), and they will both be 0 otherwise.

b) Obviously, all of the tables \( T1 \cap T2, \sigma(T1) \cap \sigma(T2) \) and \( \sigma(T1 \cap T2) \) are well defined and have signature \( \alpha \). By assumption, there is no record that assigns a null to some attribute and occurs in both \( T1 \) and \( T2 \). Thus, \( T1 \cap T2 \) is complete and \( T1 \cap T2 = \sigma(T1 \cap T2) \). Now, let \( r \) be a record over \( \alpha \); to prove that \( \sigma(T1 \cap T2 = \sigma(T1) \cap \sigma(T2)) \), we will show the following:

\[
\#(r, T1 \cap T2) = \min \left\{ \#(r, T1), \#(r, T2) \right\} \\
\text{by definition of } \sigma \text{ on tables}
\]

In particular, we only need to show \((*)\), as the other equalities hold by definition of \( \cap \) and \( \sigma \) on tables. If \( r \) maps all attributes to constants, then \( \sigma^{-1}(r) = \{ r \} \) and \((*)\) trivially holds. Thus, assume \( r(A) \in Null \) for some attribute \( A \). Then, as \( T1 \cap T2 \) is complete, \( r \notin T1 \cap T2 \), i.e., the l.h.s. of \((*)\) is 0. By definition, every \( s \in \sigma^{-1}(r) \) is such that \( \sigma(s) = r \) and so \( s(A) \in \sigma \). In turn, by the assumption on \( T1 \) and \( T2 \), there cannot exist records \( s1 \) and \( s2 \) in \( \sigma^{-1}(r) \) such that \( s1 \in T1 \) and \( s2 \in T2 \). Therefore, the r.h.s. of \((*)\) is also 0, as \( m = 0 \) whenever \( n > 0 \), and \( n = 0 \) whenever \( m > 0 \).
