Centromere DNA Destabilizes H3 Nucleosomes to Promote CENP-A Deposition during the Cell Cycle

Highlights

- Histone H3 levels increase at centromeres during S phase
- New CENP-A replaces H3 during G2
- Centromere DNA drives H3 dynamics independent of centromere proteins
- Eviction of H3 is coincident with recruitment of elongating RNAPII

In Brief

Shukla et al. show that histone H3 is transiently deposited as a placeholder in centromeric chromatin during S phase and subsequently replaced by new centromere-specific CENP-A$^{Cnp1}$ during G2. Eviction of H3 coincides with RNAPII recruitment, suggesting that transcription-coupled events may be involved.
Centromere DNA Destabilizes H3 Nucleosomes to Promote CENP-A Deposition during the Cell Cycle

SUMMARY

Active centromeres are defined by the presence of nucleosomes containing CENP-A, a histone H3 variant, which alone is sufficient to direct kinetochore assembly. Once assembled at a location, CENP-A chromatin and kinetochores are maintained at that location through a positive feedback loop where kinetochore proteins recruited by CENP-A promote deposition of new CENP-A following replication. Although CENP-A chromatin itself is a heritable entity, it is normally associated with specific sequences. Intrinsic properties of centromeric DNA may favor the assembly of CENP-A rather than H3 nucleosomes. Here we investigate histone dynamics on centromere DNA. We show that during S phase, histone H3 is deposited as a placeholder at fission yeast centromeres and is subsequently evicted in G2, when we detect deposition of the majority of new CENP-A following replication. Although CENP-A chromatin itself is a heritable entity, it is normally associated with specific sequences. Intrinsic properties of centromeric DNA may favor the assembly of CENP-A rather than H3 nucleosomes. Here we investigate histone dynamics on centromere DNA. We show that during S phase, histone H3 is deposited as a placeholder at fission yeast centromeres and is subsequently evicted in G2, when we detect deposition of the majority of new CENP-A<sup>Cnp1</sup>. We also find that centromere DNA has an innate property of driving high rates of turnover of H3-containing nucleosomes, resulting in low nucleosome occupancy. When placed at an ectopic chromosomal location in the absence of any CENP-A<sup>Cnp1</sup> assembly, centromere DNA appears to retain its ability to impose S phase deposition and G2 eviction of H3, suggesting that features within centromere DNA program H3 dynamics. Because RNA polymerase II (RNAPII) occupancy on this centromere DNA coincides with H3 eviction in G2, we propose a model in which RNAPII-coupled chromatin remodeling promotes replacement of H3 with CENP-A<sup>Cnp1</sup> nucleosomes.

INTRODUCTION

Centromeres are the defined locations on chromosomes where kinetochores are assembled and that ensure accurate chromosome segregation. In many species, centromere chromatin is distinguished by the presence of CENP-A (also known as cenH3; CID in Drosophila, Cse4 in Saccharomyces, and Cnp1 in Schizosaccharomyces), a histone H3 variant, which substitutes for canonical H3 in specialized nucleosomes that form the foundation for kinetochore assembly [1]. The point centromeres of budding yeast (Saccharomyces cerevisiae) are unusual in that they are entirely DNA sequence dependent, because sequence-specific DNA-binding proteins direct CENP-A<sup>Cse4</sup> and kinetochore assembly [2]. In contrast, regional eukaryotic centromeres (human, fruit fly, plant, fission yeast) assemble CENP-A nucleosomes across extensive DNA regions that are often repetitive [3].

CENP-A is critical in defining where kinetochores are assembled, because its artificial recruitment to non-centromeric chromosomal locations is sufficient to mediate kinetochore assembly [4–6]. Centromere position is normally stable; however, deletion of a normal centromere can allow neocentromere formation at unusual chromosomal locations [7–9]. Moreover, dicentric chromosomes with two centromeres can be stabilized by the inactivation of one centromere without DNA loss [10, 11]. Such observations indicate that CENP-A incorporation and thus centromere positioning exhibits epigenetic plasticity [12, 13].

Overexpression of CENP-A allows its incorporation at novel locations, but the low frequency of kinetochore assembly suggests that several CENP-A nucleosomes may be required [14, 15]. Despite the flexibility associated with CENP-A and thus centromere location, neocentromeres are rare and centromeres usually remain associated with specific DNA sequences [3, 7, 8, 16, 17]. However, despite the conservation of CENP-A and many kinetochore proteins, underlying centromeric DNA is highly divergent [18]. Nevertheless, these centromere sequences allow de novo CENP-A and kinetochore assembly following their introduction as naked DNA into cells [19, 20]. Such analyses indicate that centromere DNA is a preferred substrate for CENP-A assembly. The CENP-B DNA-binding protein somehow designates mammalian satellite repeats for CENP-A assembly. However, the mechanisms that promote assembly of CENP-A rather than H3 nucleosomes remain largely unknown [20].

During replication, parental nucleosomes are distributed to both sister chromatids, and new nucleosomes assemble in the resulting gaps by a replication-coupled process. Consequently, half of the histones in nucleosomes on G2 chromatids represent...
“old,” pre-existing subunits, whereas the other half are newly synthesized histones incorporated during replication [21]. Measurements at vertebrate and Drosophila centromeres indicate that CENP-A levels are reduced by half during replication [22, 23]. Thus, CENP-A must be replenished each cell cycle outside S phase. Various analyses reveal that in contrast to canonical H3, new CENP-A is incorporated in a replication-independent process confined to a specific portion of the cell cycle. The timing of CENP-A incorporation varies between organisms, cell types, and developmental stages. In mammalian cultured cells and Drosophila somatic tissues, new CENP-A is deposited at centromeres in late telophase/early G1 [24, 25]. However, new CENP-A\textsuperscript{CID} is incorporated at Drosophila centromeres in cultured cells at metaphase and during anaphase in early embryos [23, 26], whereas it is loaded during G2 in plant tissues [27].

Such studies reveal that some cell types initiate chromosome segregation with a full complement of CENP-A at centromeres, whereas others carry only half the maximal amount and replenish CENP-A levels only after mitotic entry, between metaphase and G1. Nevertheless, the key shared feature is that new CENP-A incorporation is temporally separated from bulk H3 chromatin assembly during S phase. From S phase until the time of new CENP-A deposition, placeholder H3 nucleosomes might be temporarily assembled in place of CENP-A, or gaps completely devoid of nucleosomes may be generated at centromeres [3, 28, 29]. Analysis of human centromere chromatin fibers suggested that H3.3 is deposited as a placeholder in S phase that is later replaced by new CENP-A [30]. However, such repetitive centromeres lack specific sequence landmarks, making precise interpretation difficult, while the cell-cycle dynamics of H3 relative to CENP-A have not been explored in substantial detail at other more tractable regional centromeres. Moreover, cell-cycle-specific replacement of H3 with CENP-A nucleosomes may be directly associated with HJURP/Mis18-mediated CENP-A deposition [31–33]. Alternatively, processes such as transcription, known to induce histone exchange [34], might aid CENP-A deposition by facilitating H3 eviction prior to or coincident with CENP-A deposition. Indeed, transcription has been observed at centromeres and is implicated in CENP-A deposition in several systems [35–45].

Once established, CENP-A chromatin has an innate ability to self-propagate through multiple cell divisions. Such persistence is ensured by associated factors that recognize pre-existing CENP-A nucleosomes and mediate assembly of new CENP-A particles nearby [46–48]. However, the features that distinguish normal centromere DNA as being the preferred location for de novo CENP-A chromatin assembly remain unknown, although DNA-binding factors such as CENP-B appear to be involved [20].

Fission yeast, Schizosaccharomyces pombe, centromeres are regional and have a distinct experimental advantage in that CENP-A\textsuperscript{Cnp1} nucleosomes and kinetochores are assembled over specific central domains of ~10 kb that are flanked by H3K9me heterochromatin repeats [49, 50]. The unique central CENP-A domain of cen2 allows detailed analyses unhampered by problematic repetitive centromere DNA [19, 51]. Initial microscopic and genetic analyses indicated that cell-cycle loading of fluorescently tagged CENP-A at the S. pombe centromere cluster is either biphasic, occurring both in S phase and G2 [52], or mid-late G2 [53]. However, the dynamics of CENP-A, H3, and RNA polymerase (RNAP)II association have not been examined throughout the cell cycle at an individual specific centromere sequence in any system.

Here we demonstrate that histone H3 is incorporated at S. pombe centromeres during S phase, where it serves as an interim placeholder prior to its replacement by new CENP-A during G2. This cell-cycle-regulated program occurs independent of CENP-A and kinetochore assembly, because H3 exhibits similar cell-cycle dynamics on ectopically located centromere DNA, devoid of CENP-A. Moreover, ectopic centromere DNA exhibits intrinsically low H3 nucleosome occupancy and rapid nucleosome turnover. Thus, H3 nucleosomes assembled on centromere DNA are intrinsically unstable. Elongating RNAPII transiently accumulates on this centromere DNA during G2, coincident with the time of H3 eviction. We propose that centromeric DNA drives a program of cell-cycle-coupled events ensuring the sequential and temporally regulated deposition of H3, followed by its replacement with CENP-A resulting in its replenishment. Similar RNAPII transcription-coupled events may contribute to the replacement of H3 with CENP-A on centromeric DNA in other eukaryotes.

**RESULTS**

**New CENP-A\textsuperscript{Cnp1} Is Deposited at Centromeres during G2**

Previous single-cell analyses indicated that CENP-A\textsuperscript{Cnp1} levels at S. pombe centromeres decline during replication and are replenished during G2 [53], whereas genetic analyses suggested that incorporation occurs during both S and G2 phases [52]. S. pombe CENP-A\textsuperscript{Cnp1} transcript and protein levels increase prior to replication, in advance of general histone gene induction (Figures S2A and S2B) [54]. To accurately distinguish between newly synthesized and pre-existing old CENP-A\textsuperscript{Cnp1} protein, we used recombination-induced tag exchange (RITE) [55]. All pre-existing “old” CENP-A\textsuperscript{Cnp1} was tagged with the hemagglutinin (HA) epitope. Following β-estradiol-induced nuclear import of Cre-EBD in cdc25-22/G2-arrested cells, recombination between Lox sites resulted in “new” T7 epitope-tagged CENP-A\textsuperscript{Cnp1} being expressed in the following G1/S (Figures 1A and S1). After release from G2 (36°C → 25°C shift), the majority of the cell population underwent synchronous cell division as indicated by a peak in separated cell frequency (cytokinesis; 71%) after ~65 min (Figure 1B). G1 is very short in S. pombe and S phase coincides with cytokinesis, which is followed immediately by the next G2 [56].

Quantitative chromatin immunoprecipitation (qChIP) analyses at several positions across the central domains (cc1, cc2) at centromeres 1 and 2 (cen1, cen2) revealed a drop in old CENP-A\textsuperscript{Cnp1},HA levels during S phase, consistent with its dilution by distribution to both sister centromeres (Figures 1A, 1B, and S2E). Association of new CENP-A\textsuperscript{Cnp1},T7 with cc1/cc2 rose to a maximum during the subsequent G2 (time point [T] 190), indicating that most new CENP-A\textsuperscript{Cnp1} is incorporated during G2 (Figures 1B and S2E). Old CENP-A\textsuperscript{Cnp1},HA and new CENP-A\textsuperscript{Cnp1},T7 then decline as cells enter the next S phase (T215) as both are distributed to new chromatids. Microscopic analyses showed that following release from the cdc25-22/G2 block, old CENP-A\textsuperscript{Cnp1},HA was detectable at centromeres throughout the time course. In contrast, and in agreement with qChIP, new CENP-A\textsuperscript{Cnp1},T7 centromere localization was only detected during the next G2 (T100; Figures 1C and 1D).
Thus, both qChIP and microscopic analyses show that pre-existing CENP-A Cnp1 declines at *S. pombe* centromeres during replication, after which new CENP-A Cnp1 is primarily incorporated in G2. Fission yeast centromeres therefore undergo mitosis with a full complement of CENP-A Cnp1 chromatin that is halved during their replication. The net loss of CENP-A Cnp1 from sister centromeres may result in an increase in the size or numbers of inter-nucleosomal gaps between CENP-A Cnp1 nucleosomes. Alternatively, H3-containing nucleosomes may be assembled as temporary placeholders at centromeres during S phase by replication-coupled mechanisms.

**CENP-A Profiles Reveal Widespread Deposition and Distinct States during the Cell Cycle**

We next performed ChIP sequencing (ChIP-seq) to qualitatively assess the distribution of old HA- and new T7-tagged CENP-A Cnp1 across centromeres and the genome, throughout the cell cycle in *cdc25-22* synchronized cells. Following release from G2 and RITE tag swap, samples were collected every 25 min. At T25, old CENP-A Cnp1, HA was detected across cc2 in a series of ~20 peaks with relatively shallow intervening troughs, but no significant new CENP-A Cnp1-T7 was detected within centromeres (Figure 2A). As cells proceeded through replication (peak septation/T100), both old CENP-A Cnp1-HA and new CENP-A Cnp1-T7 peaks within cc2 appeared more distinct with deeper troughs, suggesting that the positioning of CENP-A Cnp1-containing particles becomes more confined (Figure 2A). Most new CENP-A Cnp1-T7 was deposited in G2, when the distinctive “shark-tooth” S phase pattern (T100) became less prominent (T125). Subsequently, a series of peaks gradually returned with intervening shallow troughs, suggesting restoration of mature CENP-A Cnp1 chromatin prior to the next mitosis (T200; Figure 2B). Similar dynamics were observed at all centromeres (Figure S3). These qualitative data are generally consistent with qChIP and microscopic analyses, which detect only low levels of new CENP-A Cnp1 at centromeres in S phase, whereas most new CENP-A Cnp1 incorporation occurs in G2 (Figure 1).

Unexpectedly, ChIP-seq revealed transient widespread low-level incorporation of new CENP-A Cnp1-T7 across the genome prior to S phase, mainly within gene bodies (T50; Figures 3A and 3B). New genic CENP-A Cnp1 deposition was most obvious when
the profile was compared with that of old CENP-ACnp1-HA over specific genes (Figure 3C). This widespread new CENP-ACnp1 rapidly disappeared as cells enter S phase (T75), and coincided with some new CENP-ACnp1-T7 accumulation within centromeres (Figure 3A). This non-centromeric signal was exclusive to T50 and did not represent background or an artifact introduced by our analysis. Indeed, in an independent approach, transient incorporation of GFP-CENP-ACnp1 was detected by qChIP prior to two sequential S phases (T20 and T180) within three genes (septation/S phase starts at T60 and T210; Figure 3D).

Histone H3 Is Deposited at Centromeres in S Phase and Evicted during G2
In many eukaryotes, CENP-A incorporation is temporally separated from replication. A placeholder model predicts that H3 should increase at S. pombe centromeres during S phase (T75), and subsequently declines in G2. In contrast, H3 association with gene bodies (i.e., open reading frames; ORFs), intergenic regions, and RNAPII promoter-associated nucleosome-depleted regions (NDRs) was unaltered by cell-cycle phase, and H4 levels were similar at centromeres and elsewhere at all cell-cycle phases.

To verify the timing of H3 deposition, we RITE-tagged one (hht2+/H3.2) of the three genes encoding identical canonical histone H3 proteins. All three S. pombe histone H3 proteins (H3.1, H3.2, H3.3) assemble into chromatin during replication; there is no exclusively replication-independent H3 equivalent to the metazoan H3.3 variant [57]. Thus, H3.2-RITE provides a tracer for the dynamics of all H3. In cdc25-22/G2-blocked cells all pre-existing old histone H3.2 will be T7 tagged and, following cell-cycle phases are consistent. Furthermore, comprehensive ChIP-nexus analyses of histones H3 and H4 for representative G1-M, S, and G2 phase samples (Figures 4F and S4) confirmed that H3 association across the central domain of all three centromeres (cc1, cc2, cc3) increases in S phase and subsequently declines in G2. In contrast, H3 association with gene bodies (i.e., open reading frames; ORFs), intergenic regions, and RNAPII promoter-associated nucleosome-depleted regions (NDRs) was unaltered by cell-cycle phase, and H4 levels were similar at centromeres and elsewhere at all cell-cycle phases.

To verify the timing of H3 deposition, we RITE-tagged one (hht2+/H3.2) of the three genes encoding identical canonical histone H3 proteins. Thus, H3.2-RITE provides a tracer for the dynamics of all H3. In cdc25-22/G2-blocked cells all pre-existing old histone H3.2 will be T7 tagged and, following cell-cycle phases are consistent. Furthermore, comprehensive ChIP-nexus analyses of histones H3 and H4 for representative G1-M, S, and G2 phase samples (Figures 4F and S4) confirmed that H3 association across the central domain of all three centromeres (cc1, cc2, cc3) increases in S phase and subsequently declines in G2. In contrast, H3 association with gene bodies (i.e., open reading frames; ORFs), intergenic regions, and RNAPII promoter-associated nucleosome-depleted regions (NDRs) was unaltered by cell-cycle phase, and H4 levels were similar at centromeres and elsewhere at all cell-cycle phases.

To verify the timing of H3 deposition, we RITE-tagged one (hht2+/H3.2) of the three genes encoding identical canonical histone H3 proteins. All three S. pombe histone H3 proteins (H3.1, H3.2, H3.3) assemble into chromatin during replication; there is no exclusively replication-independent H3 equivalent to the metazoan H3.3 variant [57]. Thus, H3.2-RITE provides a tracer for the dynamics of all H3. In cdc25-22/G2-blocked cells all pre-existing old histone H3.2 will be T7 tagged and, following
T7 → HA tag swap induction during the G2 block, all new H3.2 will be HA tagged (Figure 4G).

By the end of S phase (T150, after septation peak), qChIP revealed that old H3.2-T7 levels drop within centromeres and on the constitutively expressed act1+ gene (Figure 4H). This decline must represent the distribution of parental H3.2-T7 nucleosomes to sister chromatids. New H3.2-HA accumulated within centromeric cc2 during S/early G2 (T90–T150) but declined during mid-late G2 (Figure 4H). The loss of this new H3.2-HA coincided with the time when most new CENP-ACnp1 deposition was detected within centromeres (Figure 1) and when total centromere-associated GFP-CENP-Acnp1 was found to increase (Figure 4D). No such reduction in H3.3-HA levels was observed on the act1+ gene during G2; instead, new H3.2-HA was incorporated during replication and remained in place throughout the following G2 (Figure 4H). ChIP for H3 on the same samples confirmed that total H3 increased on centromeric cc2 during S phase but subsequently declined in G2, whereas little overall cell-cycle change occurred on act1+ (Figure 4H).

Together, these analyses show that H3 accumulates within the CENP-A<sup>Cnp1</sup>-containing regions of centromeres during S phase but is later removed during G2. New CENP-A<sup>Cnp1</sup> is incorporated within these centromeric regions during G2, coincident with H3 removal. We conclude that H3 nucleosomes assembled within centromeres during S phase serve as temporary placeholders that are replaced by CENP-A<sup>Cnp1</sup> nucleosomes during G2.

**Centromere DNA Alone Drives Histone H3 Cell-Cycle Dynamics**

The above dynamics of H3 and CENP-A<sup>Cnp1</sup> at centromeres may be entirely dictated by kinetochore-associated CENP-A<sup>Cnp1</sup> loading factors (e.g., HJURP<sup>Scm3</sup>, Mis18 [33, 58, 59]), or central domain sequences themselves might enforce processes that promote such dynamics. To determine whether centromere DNA itself programs H3 cell-cycle dynamics, we utilized cells carrying 8.5 kb of cc2 DNA at the non-centromeric <i>ura4</i> locus and with endogenous cen2-cc2 replaced with cenT central...
core DNA (cc1) so that ectopic cc2 (ura4:cc2) is the only copy of this element (Figure 5A [37, 38]). qChIP on asynchronous cells confirmed that ectopic ura4:cc2 was completely devoid of CENP-A\textsuperscript{Cnp1} and assembled in H3 chromatin, albeit at low levels relative to act1 (Figure 5B). Remarkably, qChIP on cdc25-22 synchronized cells revealed that, as at endogenous centromeres (cc1), H3 accumulated on ectopic ura4:cc2 DNA (cc2) during S phase (T60–T100) but subsequently decreased during G2 (T90–T150; Figure 5C). H3 levels rose again during the next S phase (T210). We conclude that innate properties of central domain DNA promote H3 nucleosome assembly during S phase and their later removal during G2.

**H3 Nucleosomes Exhibit Low Occupancy and High Turnover on Ectopically Located Centromere DNA**

The cell-cycle dynamics of H3 gain and loss on ectopic central domain DNA suggest that H3 nucleosomes assembled on these sequences may be inherently unstable. We next compared the steady-state levels of H3 and H4 associated with native cen2-cc2, ectopic ura4:cc2, and with gene bodies, intergenic regions, and promoter-associated NDRs using ChIP-nexus [60]. As expected, only low levels of H3 were detected over the central domains of endogenous centromeres (cc1, cc2, cc3), where most H3 is replaced by CENP-ACnp1 (Figure 5D). In contrast, H4 (a component of H3 and CENP-ACnp1 nucleosomes) levels throughout centromeric central domains and gene bodies were equivalent. Remarkably, significantly lower levels of H3 and H4 were detected at ectopic ura4:cc2 DNA, similar to those within intergenic regions and NDRs. These analyses suggest that H3 nucleosome assembly is strongly disfavored on ectopic ura4:cc2, whereas CENP-A\textsuperscript{Cnp1} nucleosomes exhibit greater stability on cc2 DNA within a functional centromere.

We next utilized H3.2-RITE to measure H3 turnover on ectopic ura4:cc2 in comparison to heterochromatic repeats and highly transcribed genes in G2-arrested cells. The H3.2-HA→T7 tag swap was induced in cdc25-22/G2-arrested cells

**Figure 4. Histone H3 Acts as an Interim Placeholder for CENP-A\textsuperscript{Cnp1} during S Phase**

(A) Illustrative graph showing the expected behavior of CENP-A\textsuperscript{Cnp1} and histones H3 and H4 at centromeres as a result of placeholder or gap-filling models.

(B) Schematic of S. pombe centromere 1 and 2 organization. Positions of primers used for qChIP are as indicated. A schematic of cdc25-22 block-release cell-cycle synchronization to assess cell-cycle histone dynamics at centromeres is shown.

(C–E) Representative qChIP experiment measuring histone H3 (C), GFP-CENP-ACnp1 (D), and histone H4 (E) levels at the indicated positions at cen1/ cen2 (B), and on act1 (F), in the same samples throughout the cell cycle. For H3 and H4 (C and E), % IP levels were normalized first using ChIP levels at Schizosaccharomyces octosporus act1 from spiked-in chromatin and then to T0 values for each series of samples. Green rectangle: time of H3→CENP-A\textsuperscript{Cnp1} exchange.

(F) Quantitation of H3 and H4 occupancy by ChIP-nexus in cell-cycle phases. Boxplot of H3 (left panel) and H4 occupancy (right panel) over central domains (cc1, cc2, cc3 together), gene bodies, intergenic regions, and NDRs. y axis: log2 RPKM (reads per kilo-base per million mapped reads) values.

(G) Diagram of H3.2-RITE T7→HA swap. The RITE cassette was integrated in-frame downstream of hht2. Cell-cycle block release and tag swap induction are as described in Figure 1A.

(H) qChIP for old H3-T7, new H3-HA, and total H3 levels on endogenous cc2 at cen2 (top panel) and act1 (bottom panel) throughout the cell cycle. y axis: % IP levels were normalized to T0 values for each series of samples. See also Figure S4.
and new histone H3.2-T7 incorporation was monitored (Figure 5E). As expected, only low levels of new H3-T7 were incorporated into heterochromatin, where histone turnover is low [61, 62]. Similarly, the turnover of H3 nucleosomes within cc1 at endogenous cen1 was also low, presumably because most H3 nucleosomes were replaced by CENP-A Cnp1 during G2. Consistent with transcription-coupled nucleosome exchange, high levels of new H3-T7 were incorporated into chromatin associated with the highly expressed act1+, pyk1+, and spd1+ genes after 1 and 2 hr. Intriguingly, high levels of new H3-T7 were detected on ectopic ura4:cc2 after just 1 hr, indicating extensive H3 turnover. These data suggest that central domain DNA may render assembled H3 nucleosomes unstable so that they are continually displaced, resulting in low nucleosome occupancy.

RNAPII Accumulates on Centromere DNA Coincident with H3 Removal

Transcription has been implicated in the deposition of CENP-A at centromeres [44, 45], and defective RNAPII elongation is known to enhance CENP-A Cnp1 deposition on naive cc2 DNA in S. pombe [37, 38]. Indeed, western analysis indicates that elongating RNAPII-S2P (serine 2 phosphorylated) is present in affinity-selected GFP-CENP-ACnp1 chromatin (Figure 6A). To determine whether transcription, H3 turnover, and CENP-A Cnp1 deposition on cc2 DNA might be coupled, we performed ChIP-seq for elongating RNAPII on synchronized cells carrying ectopic ura4:cc2. The cyclical association of RNAPII-S2P with known cell-cycle-regulated genes in synchronized cultures confirmed that we detect the cell-cycle-regulated engagement of RNAPII-S2P (Figure S5A).

In G2-blocked cells (T0), relatively high levels of elongating RNAPII were detected on ectopic ura4:cc2 (Figures 6B, S5B, and S5C). However, upon release into the cell cycle, associated RNAPII-S2P rapidly declined to a minimum (T40) prior to S phase and accumulated again during G2 (T100–T140; Figure 6C). RNAPII-S2P qChIP at several locations across ura4:cc2 confirmed that elongating RNAPII occupancy falls in advance of S phase (T40), increases during G2 (T100–T140), and again decreases to a minimum before the next S phase (T160–T180; Figure 6D). Thus, elongating RNAPII reaches maximal levels on ectopic ura4:cc2 during G2 when H3 is removed (Figure 5C).
suggesting that transcriptional elongation may be involved in H3 removal.

At endogenous CENP-A<sup>Cnp1</sup>-coated cc1 and cc2, RNAPII-S2P also rises during G2 (T120–T140; Figures 6F and S5D), coincident with loss of H3 (Figures 6G and S5E). The cell-cycle RNAPII-S2P association profile on centromeric cc1 and cc2 is confounded by a more dominant RNAPII-S2P peak during mitosis (Figure 6F). The mitotic recruitment of RNAPII appears to be conserved but is likely to be functionally distinct from the RNAPII-S2P that is coupled to CENP-A dynamics [41, 63]. This M phase RNAPII-S2P peak is probably kinetochore imposed, as it was not detected on ectopic ura4:cc2. The increase in RNAPII-S2P at endogenous centromeres during G2 is clearly less conspicuous than that detected at ectopic cc2 (see Discussion). Regardless, RNAPII-S2P recruitment appears to increase at both endogenous centromeres and ectopic cc2 during G2, when H3 levels decline but CENP-A levels increase.

Marker genes inserted in central domains of <i>S. pombe</i> centromeres become assembled in CENP-A<sup>Cnp1</sup> chromatin [64]. To determine whether marker genes also acquire other central domain properties, RNAPII-S2P and H3 levels associated with a promoter-attenuated <i>arg3+</i> gene inserted in cc1 of cen1 (cc1:<i>arg3+</i>) were analyzed throughout the cell cycle (Figure 6E [65]). Whereas <i>arg3+</i> at its endogenous location showed a relatively flat H3 cell-cycle profile and an RNAPII peak in M-G1 consistent with its known cell-cycle regulation (Figures 6H and 6I [66]), cc1:<i>arg3+</i> displayed distinctly different H3 and RNAPII-S2P profiles, mirroring that of flanking cc1 centromeric chromatin. This normal arg3+ gene H3 chromatin dynamics appear to be overridden by a program imposed by surrounding central domain chromatin: the unremarkable H3 cell-cycle pattern on <i>arg3+</i> is converted to a “placeholder” pattern, where H3 incorporation rises in S phase and falls dramatically in G2, accompanied by a distinctive RNAPII-S2P profile.
Our analysis suggests that central domain DNA from S. pombe centromeres may program transcription-coupled H3 nucleosome destabilization during G2, resulting in their replacement with CENP-A Cnp1-containing nucleosomes when a sufficient route of CENP-A Cnp1 supply is available.

**DISCUSSION**

To understand more fully how CENP-A Cnp1 chromatin domains are established and propagated on particular sequences across multiple generations, we focused on the cell-cycle dynamics of S. pombe centromere-associated chromatin. RITE tag swap experiments allowed us to determine that most new CENP-A Cnp1 is incorporated at S. pombe centromeres during G2. Our analyses also conclusively demonstrate that histone H3 is deposited as a temporary placeholder during S phase. Importantly, these measurements pinpoint a specific window in G2 where H3 → CENP-A Cnp1 nucleosome exchange occurs. In addition, we show that the CENP-A Cnp1 chromatin profile is highly dynamic, exhibiting stage-specific patterns throughout the cell cycle. Strikingly, we find that ectopically located centromere DNA assembles inherently unstable H3 nucleosomes that exhibit high turnover rates, and during replication this DNA also directs elevated incorporation of H3 nucleosomes that are evicted in the following G2 when elongating RNAPII is recruited. Because the ectopic cc2 insert is 8.5 kb in length, it thus seems unlikely that the observed dynamics are influenced by flanking non-centromeric chromatin. Together, our analyses support a model in which centromere DNA possesses inherent properties that may drive a sequence-directed cell-cycle-regulated program that promotes H3 nucleosome assembly in S phase and subsequent eviction in G2 allowing the incorporation of new CENP-A Cnp1 nucleosomes (Figure 7).

The cell-cycle timing of new CENP-A loading at centromeres varies between organisms; however, a conserved feature is that new CENP-A incorporation is uncoupled from replication, when most new H3 chromatin assembly occurs [23–27]. Key components required for CENP-A chromatin maintenance at human centromeres (Mis18 complex, Mis18BP1, HJURP) are recruited to centromeres in a temporally restricted manner prior to, or coincident with, new CENP-A deposition [5, 67, 68]. However, Mis18 and Scm3 HJURP remain associated with S. pombe centromeres throughout most of the cell cycle, apart from a brief period in mitosis [33, 58]. Thus, S. pombe centromeres might be more generally competent for new CENP-A Cnp1 deposition throughout the cell cycle. It was therefore critical to specifically distinguish old parental CENP-A Cnp1 from newly synthesized CENP-A Cnp1 at individual centromeres. Previous studies have suggested either biphasic (both S and G2) or G2-specific replenishment of S. pombe CENP-A Cnp1 and relied on microscopic measurement at the centromere cluster rather than association with chromatin [52, 53]. RITE tagging allowed detailed examination of the behavior of both old and new CENP-A Cnp1 at specific centromeres. Our data show that in S. pombe the majority of the new CENP-A Cnp1 deposition occurs during G2, with only low-level new CENP-A Cnp1 deposition during replication. These analyses refine previous studies of CENP-A Cnp1 replenishment and suggest that other mechanisms, apart from the temporally regulated recruitment of CENP-A loading factors to centromeres, can influence the cell-cycle stage-specific restriction of new CENP-A Cnp1 incorporation.

An unexpected finding was that new CENP-A Cnp1 is transiently incorporated within genomic regions along chromosome arms prior to replication. In S. pombe, the gene encoding CENP-A Cnp1 (cnp1) is known to be expressed prior to the peak of canonical histone gene expression in advance of S phase (Figure S2B [54]). As a consequence of this earlier CENP-A Cnp1 expression, there is a brief window during the cell cycle where the ratio of soluble CENP-A Cnp1 versus canonical histone H3 may be skewed. This could account for the transient widespread incorporation of CENP-A Cnp1 within genes that may be mediated by transcription-coupled nucleosome turnover. In essence, this portion of the cell cycle exhibits similarity to cells overexpressing CENP-A Cnp1 [69]. Conversely, histone H3 can replace CENP-A Cnp1 within S. pombe centromeres when the H3:CENP-A Cnp1 ratio is perturbed [64]. The CENP-A Cnp1 incorporation that we detect along S. pombe chromosome arms is rapidly removed. In other organisms, CENP-A can also be incorporated throughout the genome, with or without overexpression [14, 15, 37, 70]. This “sampling” by genome-wide CENP-A Cnp1 incorporation every cell cycle could potentially contribute to the formation of neocentromeres when conditions demand.

Our comparison of the relative levels of CENP-A Cnp1, H3, and H4 within the CENP-A domain of centromeres revealed that...
canonical histone H3 is transiently deposited as a placeholder during S phase and later exchanged for new CENP-A\(^{\text{Cnp1}}\) in G2. At human centromeres, chromatin fiber analysis suggests that the replication-independent H3.3 variant acts as an interim placeholder for CENP-A [30], and thus H3 placeholder function may be conserved across eukaryotes where new CENP-A deposition is separated from replication. The use of H3 as a transient placeholder in S. pombe is important, because it identifies a cell-cycle period when specific H3 \(\rightarrow\) CENP-A replacement events must take place and involve factors that mediate histone exchange or complete nucleosome turnover.

Where tested, centromere DNA sequences are clearly a preferred substrate for de novo CENP-A assembly [51, 71]. The embedded features that identify centromere assembly for efficient CENP-A assembly involve DNA-binding factors such as CENP-B and processes such as transcription [20, 35, 36, 39–45]. Transcription is a potent chromatin remodeling mechanism and is coupled to histone exchange; new histone H3.3 is deposited within transcribed genes and H2A is exchanged for the variant H2A.Z in the highly dynamic NDR promoter-proximal nucleosomes of many organisms [72]. Our finding that elongating RNAPII-S2P increases on S. pombe centromere DNA simultaneously with H3 eviction and CENP-A\(^{\text{Cnp1}}\) incorporation is compatible with a model where transcription-coupled remodeling events define this centromeric DNA by driving H3 \(\rightarrow\) CENP-A exchange. Indeed, RNAPII is known to be an excellent nucleosome disassembly and remodeling machine [73, 74]. Consistent with a role in transcription in facilitating CENP-A\(^{\text{Cnp1}}\) incorporation, there is a high density of transcriptional start sites within centromere DNA that may promote pervasive low-quality transcription [38].

Elongating RNAPII was found to increase at both endogenous centromeres and on ectopically located central domain DNA (ura4+cc2) during G2. Ectopic cc2 DNA lacks CENP-A\(^{\text{Cnp1}}\), so that all associated nucleosomes contain H3. In contrast, at centromeres, when this same cc2 DNA enters G2, it is assembled in chromatin in which approximately half the nucleosomes are placeholder H3 and the other half are CENP-A. The CENP-A N-terminal tail is distinct from that of H3 and lacks key lysine residues (K4, K36) whose modification in H3 aids transcription. Indeed, CENP-A nucleosomes inhibit transcription in vitro [75]. Therefore, the lower elongating RNAPII levels on centromeric cc2 compared to ectopic cc2 may be a consequence of CENP-A nucleosomes impeding transcription. The more easily detected elongating RNAPII on H3 chromatin-coated ectopic cc2 centromere DNA during G2 may represent an extreme version of the G2 events that normally occur on centromere-located cc2. It seems likely that limited RNAPII transcription-coupled turnover also contributes to H3 \(\rightarrow\) CENP-A exchange at endogenous centromeres.

Several studies indicate that centromeric DNA is transcribed and linked with CENP-A deposition [44, 45]. It remains unclear whether the act of transcription, the resultant non-coding RNAs, or both are involved in promoting CENP-A assembly. Recent analysis indicates that human \(\alpha\) satellite transcripts participate in CENP-A incorporation at centromeres and RNAPII-mediated transcription promotes CENP-A incorporation at D. melanogaster centromeres. Fission yeast central domain transcripts are exosome degraded, and consequently they are short lived and undetectable in wild-type cells [36]. However, we show that elongating RNAPII is clearly recruited to centromere DNA in G2 at the time of H3 \(\rightarrow\) CENP-A exchange. As at promoter-associated NDRs, fission yeast centromeric DNA has an intrinsic ability to recruit elongating RNAPII and destabilize H3 nucleosomes in a cell-cycle-regulated manner. Such embedded features may earmark these sequences for CENP-A\(^{\text{Cnp1}}\) incorporation.

Redundant processes are likely to mediate de novo assembly and maintenance of CENP-A on centromere DNA in order to ensure efficient and robust kinetochore formation. Different organisms may place more emphasis on different component processes involved in ensuring CENP-A chromatin assembly, but it seems likely that the inherent properties we have uncovered within fission yeast centromere DNA are also shared with transcribed centromeric DNA of other organisms. Despite the challenge of precisely assessing RNAPII engagement and histone dynamics at centromeres composed of highly repetitive DNA, it is now important to determine whether centromere DNA from other organisms also has an innate capacity to drive H3 eviction.

**STAR+ METHODS**

Detailed methods are provided in the online version of this paper and include the following:

- **KEY RESOURCES TABLE**
- **CONTACT FOR REAGENT AND RESOURCE SHARING**
- **EXPERIMENTAL MODEL AND SUBJECT DETAILS**
  - Fission Yeast Methods
- **METHOD DETAILS**
  - Cytology
  - ChiP-qPCR
  - ChiP-Seq and ChiP-Nexus
  - Immunoprecipitation and Western analyses
  - RNA preparation and Reverse Transcriptase qPCR analysis
- **QUANTIFICATION AND STATISTICAL ANALYSIS**
- **DATA AND SOFTWARE AVAILABILITY**

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes five figures and two tables and can be found with this article online at https://doi.org/10.1016/j.cub.2018.10.049.

**ACKNOWLEDGMENTS**

We are grateful to Fred van Leeuwen for RITE system constructs and the LoxP peptide antibody. We thank Nick Toda, Pauline Audergon, Jesus Torres-Garcia, Ryan Ard, Daniel Robertson, and David Kelly for their useful suggestions and technical input. M.S. was partly supported by an EMBO Long-Term Fellowship (ALTF 664-2011). P.T. was partly supported by funding from the European Commission Network of Excellence EpiGeneSys (HEALTH-F4-2010-257082) and a Wellcome Enhancement grant (095021) to R.C.A. S.C. was supported by a Wellcome PhD Studentship (086574). R.C.A. is a Wellcome Principal Research Fellow (200885); the Wellcome Centre for Cell Biology is supported by core funding from Wellcome (203149).

**AUTHOR CONTRIBUTIONS**

M.S. and R.C.A. jointly conceived the study. M.S., P.T., S.A.W., P.P.S., A.M.R., and S.C. performed experiments. M.S., P.T., and A.L.P. analyzed data. M.S. and R.C.A. wrote the manuscript with input from other authors.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Fission Yeast Methods
Standard genetic and molecular techniques were followed. Fission yeast methods were as described [80]. YES (Yeast Extract with Supplements) was used as a rich medium or PMG (Pombe Minimal Glutamate) for growth of cells in liquid cultures. 4X YES was used for experiments where higher cell numbers were required. CENP-AΔnp1 and H3.2 RITE strains were constructed by PCR amplifying HA/T7 or T7/HA RITE cassettes described in [55] and integration at the endogenous gene locus. Cre-EBD open reading frame was PCR amplified from pTW040 [55] and cloned in pRAD11, 13, 15 vectors containing different strengths of ADH promoters (Gift from Y. Watanabe). The Cre-EBD plasmids were integrated at the $ars1$ locus by transformation of the plasmid DNAs linearized by $MluI$ digestion. Strains are described in Table S1.

METHOD DETAILS

Cytology
Cells were fixed with 3.7% formaldehyde for 7 min at room temperature. Immuno-localization staining was performed as described [81]. The following antibodies were used at 1:100 dilution: Anti HA (Abcam, ab9110), anti-T7 (Merck, 69522); Alexa 594 and 488 labeled secondary antibodies at 1:1000 dilution (Life Technologies). Single images were acquired with a Zeiss LSM 880 confocal microscope equipped with Airyscan superresolution imaging module, using a 100X/1.40 NA Plan-Apochromat Oil DIC M27 objective lens. Images were processed using ZEN Black image acquisition and processing software (Zeiss MicroImaging). Images were analyzed using ImageJ as follows: the region of interest was selected by the user (CENP-AΔnp1 nuclear spot) in both HA and T7 channels by manually intensity thresholding the image. The pixel intensities from the thresholded area were then calculated to give mean intensities. For each time point, (except T5 where n = 94), 100 cells were analyzed and intensity for each signal either HA (old CENP-A) or T7 (new CENP-A) is presented as a boxplot.
ChIP-qPCR
Cells were fixed with 1% formaldehyde for 15 min followed by quenching with 250 mM Glycine for 5 min at room temperature. ChIP was essentially performed as described [64] using antibodies against CENP-A<sup>Cnp1</sup> (Sheep in-house; 10 μl), H3 (ab1791, Abcam; 2 μl), H4 (Merck, 05-858; 2 μl), HA (12CA5, in-house preparation; 2 μl), T7 (Abcam, ab9138; 2 μl), GFP (ThermoFisher Scientific, A11122; 2 μl) and Phopho serine 2 RNA polymerase II (Abcam, ab5095; 2 μl). 2.5×10<sup>6</sup> cells were used per ChIP sample. Where indicated, formaldehyde fixed Schizosaccharomyces octosporus cells were added at the cell lysis stage for spiked-in control. Quantitative PCR reactions were performed in 10 μl volume with Light Cycler 480 SybrGreen Master Mix (Roche, 04887352001). The data were analyzed using Light Cycler 480 Software 1.5 (Roche). q-PCR primers are listed in Table S2. Percentage immunoprecipitation values were calculated using the equation: \((2^{\Delta\Delta Ct})\)×100. \(\Delta Ct\) values were adjusted for the amount of lysate and dilution used in qPCR. Where mentioned, normalized percentage IP values were obtained by dividing all the % IP values in the respective time point series with the % IP value obtained from the indicated time point (specified in the figure legend).

ChIP-Seq and ChIP-Nexus
Due to higher number of cells required, for ChIP-Seq from synchronized cell cultures, cells were grown in 4X-YES and ChIP protocol was modified. Briefly, cell pellets corresponding to 7.5×10<sup>8</sup> cells were lysed by four 1-minute cycles of bead beating in 500 μl of lysis buffer (50 mM HEPES-KOH, pH 7.5, 140 mM NaCl, 1 mM EDTA, 1% Triton X-100, 0.1% sodium deoxycholate). Insoluble chromatin fraction was isolated by centrifugation at 6000 g. The pellet was washed with 1 ml lysis buffer. This washed pellet was gently resuspended in 300 μl lysis buffer containing 0.2% SDS and sheared by sonication with Bioruptor (Diagenode) for 30 min (30 s On, 30 s off at high setting). 900 μl of lysis buffer (without SDS) was added and samples were clarified by centrifugation at 17000 g for 20 min. Supernatants were used for ChIP. Respective antibody and protein G-dynabeads (ThermoFisher Scientific) amounts were scaled up according to the cell number. Immunoprecipitated DNA was recovered using QIAGEN PCR purification kit. ChIP-Seq libraries were prepared with 1-5 ng of ChIP or 10 ng of input DNA. DNA was end-repaired using NEB Quick blunt kit (E1201L). The blunt, phosphorylated ends were treated with Klenow exo- (NEB, M0212S) and dATP to yield a protruding 3−A base for ligation of NEXTflex adapters (Bioo Scientific) which have a single ‘T’ base overhang at the 3’ end. After adaptor ligation DNA was PCR amplified with Illumina primers for 13-15 cycles and library fragments of ~300 bp (insert plus adaptor sequences) were selected using Ampure XP beads.

ChIP-Nexus libraries were prepared essentially as described [60]. Briefly, protein G-dynabeads bound DNA-protein-complexes were affinity selected using antibodies. DNA was end repaired using T4 DNA polymerase (NEB, M0203S), DNA polymerase I large fragment (NEB, M0210S) and T4 polynucleotide kinase (NEB, M0201S). A single 3′-A overhang was added using Klenow exo- polymerase. Adapters were ligated and blunted again by Klenow exo+ polymerase to fill in the 5′ overhang first and then by T4 DNA polymerase to trim possible 3′ overhangs. Blunted DNA was then sequentially digested by lambda exonuclease (NEB, M0262S) and RecJF (NEB, M0264L). Digested single strand DNA was then eluted, reverse cross-linked and phenol-chloroform extracted. Fragments were then self-circularized by Circligase (Epigenet, CL4111K). An oligonucleotide was hybridized to circularize single DNA for subsequent BamHI digestion in order to linearize the DNA. This linearized single strand DNA was then PCR-amplified using adaptor sequences and libraries were purified and size selected using Ampure XP beads. The libraries were sequenced following Illumina HiSeq2500 work flow.

Next generation sequencing libraries were aligned to S. pombe build ASM294v2.20 using Bowtie2 [76]. ChIP-Seq reads with mapping qualities lower than 30, and read pairs mapped over 500-nt apart or less than 100-nt, were discarded. All the ChIP-Seq data were normalized with respect to their input data (Enrichment = IPRPKM/InputRPKM). ChIP peaks were identified from the alignments using DeepTools [78] was used to generate genome wide enrichment profiles using a 50 bp window size and the data visualized using the IGV genome browser. ChIP-Nexus data were analyzed using MACE [79]. ChIP-Nexus data described in Figures 4F and S4 were normalized with their input data.

Immunoprecipitation and Western analyses
Cell were grown in 4X-YES and 5x10<sup>9</sup> cells were used per IP. Briefly, cells were harvested by centrifugation at 3500g, washed twice with water and flash frozen in liquid nitrogen. Frozen cell pellets were ground using Retsch MM400 mill. The grindate was resuspended in 10 mM Tris pH7.4, 5 mM CaCl<sub>2</sub>, 5 mM MgCl<sub>2</sub>, 50 mM NaCl, 0.1% IGEPAL-CA630 and supplemented with Halt protease and phosphatase inhibitor (ThermoFisher Scientific, 1861281) and 2 mM PMSF. Chromatin was solubilized by incubation with 2 units of Micrococcal nuclease (Sigma, N3755) for 10 min at 37°C. MNase digestion was stopped by adding EDTA to 20 mM and lysate were rotated at 4°C for 1 hr to ensure chromatin solubilization. Lysates were clarified by centrifugation at 20,000g for 10 min and supernatants were used for immunoprecipitation. Cleared lysates were incubated with 10 μg of anti-GFP antibody (Roche, 11814460001) and 25 μl of protein G-dynabeads (ThermoFisher Scientific), which were already crosslinked with DMP (dimethyl pimelimidate) (ThermoFisher Scientific, 21666), for 1 hr at 4°C with gentle rotation. Bead-bound affinity-selected chromatin was washed three times with lysis buffer and eluted with LDS loading buffer (ThermoFisher Scientific, 84788). Western blotting detection was performed using anti-GFP (Roche, 11814460001), anti-H3 (Abcam, ab1791) and anti-phospho-Serine2-RNA polymerase II (Abcam, ab5095) and secondary IRDye 680RD anti-Rabbit (Li-Cor, 926-68073) and IRDye 800CW anti-Mouse antibodies (Li-Cor, 926-32210).

CENP-A<sup>Cnp1</sup> RITE strain (T7 to HA) Cell population were synchronized using cdc25-22 block release. Tag switch was induced during the block by addition of β-estradiol to 1 μM for the last 2 hr of the block. Cell populations were synchronously released from the G2
block by lowering the culture temperature to 25 °C and culture samples were collected at indicated time intervals. 7.5x10^8 cells were used for each immunoprecipitation sample. Cells were washed twice with water and frozen. Cell pellets were lysed by bead beating in 1.5 mL lysis buffer (50 mM HEPES-KOH, pH 7.5, 140 mM NaCl, 1 mM EDTA, 1% Triton X-100, 0.1% Sodium Deoxycholate) containing 1 mM PMSF and protease inhibitors (Roche). Cell lysates were sonicated for 12 cycles (30 s on, 30 s off) using a Bioruptor (Diagenode), rotated for 1 hr at 4 °C and clarified by centrifugation at 17000 g for 20 min. Cleared lysates were incubated overnight with 10 µL CENP-A antibody and 50 µL of protein-G agarose beads (Roche). Beads were washed 3 times with the lysis buffer and immunoprecipitated material was eluted by incubating the beads in 1X LDS loading buffer (ThermoFisher Scientific). Western analysis was performed using anti-HA (Sigma, 11867423001, clone 3F10), anti-LoxP (gift from Fred van Leeuwen), secondary anti-Rat IgG HRP (Sigma, A9037) and anti-Rabbit IgG HRP (Sigma, A6154).

RNA preparation and Reverse Transcriptase qPCR analysis
RNA was extracted from 2x10^7 synchronized CENP-A/crep1 RITE strain (HA to T7) at indicated time points using RNeasy Mini kit (QIAGEN, 74104) according to manufacturer’s instruction. 2 µg of RNA was converted to cDNAs using SuperScript IV First-Strand Synthesis System (ThermoFisher Scientific, 18091050). Quantitative PCR reactions were performed in 10 µL volume with Light Cycler 480 SybrGreen Master Mix (Roche, 04887352001). The data were analyzed using Light Cycler 480 Software 1.5 (Roche). q-PCR primers are listed in Table S2.

QUANTIFICATION AND STATISTICAL ANALYSIS
Statistical parameters are described in the relevant figure legends. Where indicated, the value of n represents the number of independent replicates. Histograms and line plots shown in the study represent mean values from indicated number of replicates. Error bars represent the calculated standard deviation.

In Figures 1D, 4F, 5D, and S4, standardized box-plots are shown. The box includes data in the interquartile range, IQR: 25th-75th. The middle lines represent the calculated medians. Whisker lengths represent the lowest and highest data range within 1.5 IQR from the box. Outlier values are shown as circles. In Figures 6C and S5B, violin plots are used to visualize the distribution of the data: black bars in the center represents the IQR, white circles represent the calculated median values. The thin black line shows the 95% confidence intervals. A Pearson’s correlation test was performed on H3 and H4 ChIP-Nexus experimental replicates (r value > 0.98).

DATA AND SOFTWARE AVAILABILITY
The accession number for the sequencing data reported in this paper is GEO: GSE106494.
