Abstract

Tuning hardwired compiler optimizations for rapidly evolving hardware makes porting an optimizing compiler for each new platform extremely challenging. Our radical approach is to develop a modular, extensible, self-optimizing compiler that automatically learns the best optimization heuristics based on the behavior of the platform. In this paper we describe MILEPOSTGCC, a machine-learning-based compiler that automatically adjusts its optimization heuristics to improve the execution time, code size, or compilation time of specific programs on different architectures. Our preliminary experimental results show that it is possible to considerably reduce execution time of the MiBench benchmark suite on a range of platforms entirely automatically.

1 Introduction

Current architectures and compilers continue to evolve bringing higher performance, lower power and smaller size while attempting to keep time to market as short as possible. Typical systems may now have multiple heterogeneous reconfigurable cores and a great number of compiler optimizations available, making manual compiler tuning increasingly infeasible. Furthermore, static compilers often fail to produce high-quality code due to a simplistic model of the underlying hardware.

The difficulty of achieving portable compiler performance has led to iterative compilation [11, 16, 15, 26, 33, 19, 30, 24, 25, 18, 20, 22] being proposed as a means of overcoming the fundamental problem of static modeling. The compiler’s static model is replaced by a search of the space of compilation strategies to find the one which, when executed, best improves the program. Little or no knowledge of the current platform is needed so programs can be adapted to different architectures. It is currently used in library generators and by some existing adaptive tools [36, 28, 31, 8, 1, 3]. However it is largely limited to searching for combinations of global compiler optimization flags and tweaking a few fine-grain transformations within relatively narrow search spaces. The main barrier to its wider use is the currently excessive compilation and execution time needed in order to optimize each program. This prevents its wider adoption in general purpose compilers.

Our approach is to use machine learning which has the potential to reuse knowledge across iterative compilation runs, gaining the benefits of iterative compilation while reducing the number of executions needed.

The MILEPOST project’s [4] objective is to develop compiler technology that can automatically learn how to best optimize programs for configurable heterogeneous embedded processors using machine learning. It aims to dramatically reduce the time to market of configurable systems. Rather than developing a specialised compiler by hand for each configuration, MILEPOST aims to produce optimizing compilers automatically.
A key goal of the project is to make machine learning-based compilation a realistic technology for general-purpose compilation. Current approaches [29, 32, 10, 14] are highly preliminary; limited to global compiler flags or simple transformations considered in isolation. GCC was selected as the compiler infrastructure for MILEPOST as it is currently the most stable and robust open-source compiler. It supports multiple architectures and has multiple aggressive optimizations making it a natural vehicle for our research. In addition, each new version usually features new transformations demonstrating the need for a system to automatically re-tune its optimization heuristics.

In this paper we present early experimental results showing that it is possible to improve the performance of the well-known MiBench [23] benchmark suite on a range of platforms including x86 and IA64. We ported our tools to the new ARC GCC 4.2.1 that targets ARC International’s configurable core family. Using MILEPOST GCC, after a few weeks training, we were able to learn a model that automatically improves the execution time of MiBench benchmark by 11% demonstrating the use of our machine learning based compiler.

This paper is organized as follows: the next section describes the overall MILEPOST framework and is, itself, followed by a section detailing our implementation of the Interactive Compilation Interface for GCC that enables dynamic manipulation of optimization passes. Section 4 describes machine learning techniques used to predict good optimization strategies for a given set of program features and is built as a plugin so that it can be re-inserted into MILEPOST GCC. On encountering a new program the plugin determines the program’s features, passing them to the model which determines the optimizations to be applied.

In order to learn a good strategy, machine learning tools need a large number of compilations and executions as training examples. These training examples are generated by a tool, the Continuous Collective Compilation Framework[2] (CCC), which evaluates different compilation optimizations, storing execution time, code size and other metrics in a database. The features of the program are extracted from MILEPOST GCC via a plugin and are also stored in the database. Plugins allow fine grained control and examination of the compiler, driven externally through shared libraries.

**Deployment** Once sufficient training data is gathered, a model is created using machine learning modeling. The model is able to predict good optimization strategies for a given set of program features and is built as a plugin so that it can be re-inserted into MILEPOST GCC. On encountering a new program the plugin determines the program’s features, passing them to the model which determines the optimizations to be applied.

**Framework** In this paper we use a new version of the Interactive Compilation Interface (ICI) for GCC which controls the internal optimization decisions and their parameters using external plugins. It now allows the complete substitution of default internal optimization heuristics as well as the order of transformations.

We use the Continuous Collective Compilation Framework [2] to produce a training set for machine learning models to learn how to optimize programs for the best performance, code size, power consumption and any other objective function needed by the end-user. This framework allows knowledge of the optimization space to be reused among different programs, architectures and data sets.

Together with additional routines needed for machine learning, such as program feature extraction, this forms the MILEPOST GCC. MILEPOST GCC transforms the compiler suite into a powerful research tool suitable for adaptive computing.

The next section describes the new ICI structure and explains how program features can be extracted for later machine learning in Section 4.

2 MILEPOST Framework

The MILEPOST project uses a number of components, at the heart of which is the machine learning enabled MILEPOST GCC, shown in Figure 1. MILEPOST GCC currently proceeds in two distinct phases, in accordance with typical machine learning practice: training and deployment.

**Training** During the training phase we need to gather information about the structure of programs and record how they behave when compiled under different optimization settings. Such information allows machine learning tools to correlate aspects of program structure, or features, with optimizations, building a strategy that predicts a good combination of optimizations.
3 Interactive Compilation Interface

This section describes the Interactive Compilation Interface (ICI). The ICI provides opportunities for external control and examination of the compiler. Optimization settings at a fine-grained level, beyond the capabilities of command line options or pragmas, can be managed through external shared libraries, leaving the compiler uncluttered.

The first version of ICI [21] was reactive and required minimal changes to GCC. It was, however, unable to modify the order of optimization passes within the compiler and so large opportunities for speedup were closed to it. The new version of ICI [9] expands on the capabilities of its predecessor permitting the pass order to be modified. This version of ICI is used in the MILEPOST GCC to automatically learn good sequences of optimization passes. In replacing default optimization heuristics, execution time, code size and compilation time can be improved.

3.1 Internal structure

To avoid the drawbacks of the first version of the ICI, we designed a new version, as shown in Figure 2. This version can now transparently monitor execution of passes or replace the GCC Controller (Pass Manager), if desired. Passes can be selected by an external plugin which may choose to drive them in a very different order to that currently used in GCC, even choosing different pass orderings for each and every function in program being compiled. Furthermore, the plugin can provide its own passes, implemented entirely outside of GCC.

In an additional set of enhancements, a coherent event and data passing mechanism enables external plugins to discover the state of the compiler and to be informed as it changes. At various points in the compilation process events (IC Event) are raised indicating decisions about transformations. Auxiliary data (IC Data) is registered if needed.

Since plugins now extend GCC through external shared libraries, experiments can be built with no further modifications to the underlying compiler. Modifications for
different analysis, optimization and monitoring scenarios proceed in a tight engineering environment. These plugins communicate with external drivers and can allow both high-level scripting and communication with machine learning frameworks such as MILEPOST GCC.

Note that it is not the goal of this project to develop fully fledged plugin system. Rather, we show the utility of such approaches for iterative compilation and machine learning in compilers. We may later utilize GCC plugin systems currently in development, for example [7] and [13].

Figure 3 shows some of the modifications needed to enable ICI in GCC with an example of a passive plugin to monitor executed passes. The plugin is invoked by the new -fici GCC flag or by setting ICI_USE environment variable to 1 (to enable non-intrusive optimizations without changes to Makefiles). When GCC detects these options, it loads a plugin (dynamic library) with a name specified by ICI_PLUGIN environment variable and checks for two functions start and stop as shown in Figure 3a.

The start function of the example plugin registers an event handler function executed_pass on an IC-Event called pass_execution.

Figure 3c shows simple modifications in GCC Controller (Pass Manager) to enable monitoring of executed passes. When the GCC Controller function execute_one_pass is invoked, we register an IC-Parameter called pass_name giving the real name of the executed pass and trigger an IC-Event pass_execution. This in turn invokes the plugin function executed_pass where we can obtain the current name of the compiled function using ici_get_feature("function_name") and the pass name using ici_get_parameter("pass_name").

IC-Features provide read only data about the compilation state. IC-Parameters, on the other hand, can be dynamically changed by plugins to change the subsequent behavior of the compiler. Such behavior modification is demonstrated in the next subsection using an example with an avoid_gate parameter needed for dynamic pass manipulation.

Since we use the name field from the GCC pass structure to identify passes, we have had to ensure that each pass has a unique name. Previously, some passes have had no name at all and we suggest that in the future a good development practice of always having unique names would be sensible.
Before we attempt to learn good optimization settings

Previous research shows a great potential to improve

3.2 Dynamic Manipulation of GCC Passes

Figure 3: Some GCC modifications to enable ICI and an example of a plugin to monitor executed passes: a) IC Framework within GCC, b) IC Plugin to monitor executed passes, c) GCC Controller (pass manager) modification

performance to be gained within GCC from such actions
otherwise there is no point in trying to learn. By using
the Continuous Collective Compilation Framework [2]
to random search though the optimization flag space
(50% probability of selecting each optimization flag)
and MILEPOST GCC 4.2.2 on AMD Athlon64 3700+
and Intel Xeon 2800MHz we could improve execution
time of s
corners by around 16%, compile time by
22% and code size by 13% using Pareto optimal points
as described in the previous work [24, 25]. Note, that
the same combination of flags degrade execution time
of this benchmark on Itanium-2 1.3GHz by 80% thus
demonstrating the importance of adapting compilers to
each new architecture. Figure 4a shows the combina-
tion of flags found for this benchmark on AMD platform
while Figures 4b,c show the passes invoked and moni-
tored by MILEPOST GCC for the default -O3 level and
for the best combination of flags respectively.

Given that there is good performance to be gained
by searching for good compiler flags, we now wish
to automatically select good optimization passes and
transformation parameters. These should enable fine-
grained program and compiler tuning as well as non-
intrusive continuous program optimizations without
of compiler flags found using CCC Framework with uniform random search strategy that so that we can set

execute_one_pass

pass orders using ICI, we recompiled the same bench-

tures are typically a summary of the internal program fine-grain transformation parameters and influence code

modifications to Makefiles, etc. The current version of ICI allows passes to be called directly using the ici_run_pass function that in turn invokes GCC function execute_one_pass. Therefore, we can circumvent the default GCC Pass Manager and execute good sequences of passes previously found by the CCC Framework as shown in Figure 2b or search for new good orders of optimizations. However, we leave the determination of their interaction and dependencies for future work.

To verify that we can change the default optimization pass orders using ICI, we recompiled the same benchmark with the -O3 flag but selecting passes shown in Figure 4c. However, note that the GCC internal function execute_one_pass shown in Figure 4c has gate control (pass->gate()) to execute the pass only if the associate optimization flags is selected. To avoid this gate control we use IC-Parameter "gate_status" and IC-Event "avoid_gate" so that we can set gate_status to TRUE within plugins and thus force its execution. The execution of the generated binary shows that we improve its execution time by 13% instead of 16% and the reason is that some compiler flags not only invoke associated pass such as -funroll-loops but also select specific fine-grain transformation parameters and influence code generation in other passes. Thus, at this point we recom-pile programs with such flags always enabled, and in the future plan to add support for such cases explicitly.

3.3 Adding program feature extractor pass

Our machine learnt model predicts the best GCC optimization to apply to an input program based on its program structure or program features. The program features are typically a summary of the internal program representation and characterize the essential aspects of a program needed by the model to distinguish between
good and bad optimizations.

The current version of ICI allows invoking auxiliary passes that are not a part of default GCC compiler. These passes can monitor and profile the compilation process or extract data structures needed to generate program features.

During the compilation, the program is represented by several data structures, implementing the intermediate representation (tree-SSA, RTL etc), control flow graph (CFG), def-use chains, the loop hierarchy, etc. The data structures available depend on the compilation pass currently being performed. For statistical machine learning, the information about these data structures is encoded as a vector of constant size of numbers (i.e. features) - this process is called feature extraction and is needed to enable optimization knowledge reuse among different programs.

Therefore, we implemented an additional GCC pass ml-feat to extract static program features. This pass is not invoked during default compilation but can be called using a extract_program_static_features plugin after any arbitrary pass starting from FRE when all the GCC data necessary to produce features is ready.

In the MILEPOST GCC, the feature extraction is performed in two stages. In the first stage, a relational representation of the program is extracted; in the second stage, the vector of features is computed from this representation.

In the first stage, the program is considered to be characterized by a number of entities and relations over these entities. The entities are a direct mapping of similar entities defined by the language reference, or generated during the compilation. Such examples of entities are variables, types, instructions, basic blocks, temporary variables, etc.

A relation over a set of entities is a subset of their Cartesian product. The relations specify properties of the entities or the connections between them. For describing the relations we used a notation based on logic - Datalog is a Prolog-like language but with a simpler semantics, suitable for expressing relations and operations between them [35, 34]

For extracting the relational representation of the program, we used a simple method based on the examination of the include files. The compiler main data structures are struct data types, having a number of fields. Each such struct data type may introduce an entity, and its fields may introduce relations over the entity representing the including struct data type and the entity representing the data type of the field. This data is collected using ml-feat pass.

In the second stage, we provide a Prolog program defining the features to be computed from the Datalog relational extracted from the compiler internal data structures in the first stage. The extract_program_static_features plugin invokes a Prolog compiler to execute this program, the result being the vector of features shown in Table 1 that can later be used by the Continuous Collective Compilation Framework to build machine learning models and predict best sequences of passes for new programs. This example shows the flexibility and capabilities of the new version of ICI.

4 Using Machine Learning to Select Good Optimization Passes

The previous sections have described the infrastructure necessary to build a learning compiler. In this section we describe how this infrastructure is used in building a model.

Our approach to selecting good passes for programs is based upon the construction of a probabilistic model on a set of M training programs and the use of this model in order to make predictions of “good” optimization passes on unseen programs.

Our specific machine learning method is similar to that of [10] where a probability distribution over “good” solutions (i.e. optimization passes or compiler flags) is learnt across different programs. This approach has been referred in the literature to as Predictive Search Distributions (PSD) [12]. However, unlike [10, 12] where such a distribution is used to focus the search of compiler optimizations on a new program, we use the distribution learned to make one-shot predictions on unseen programs. Thus we do not search for the best optimization, we automatically predict it.

4.1 The Machine Learning Model

Given a set of training programs \( T^1, \ldots, T^M \), which can be described by (vectors of) features \( t^1, \ldots, t^M \), and for which we have evaluated different sequences of optimization passes \( x \) and their corresponding execution
times (or speed-ups y) so that we have for each program $M_j$ an associated dataset $D_j = \{(x_i^j, y_i^j)\}_{i=1}^{N_j}$, with $j = 1, \ldots, M$, our goal is to predict a good sequence of optimization passes $x^*$ when a new program $T^*$ is presented.

We approach this problem by learning the mapping from the features of a program $t$ to a distribution over good solutions $q(x|t, \theta)$, where $\theta$ are the parameters of the distribution. Once this distribution has been learnt, predictions on a new program $T^*$ is straightforward and it is achieved by sampling at the mode of the distribution. In other words, we obtain the predicted sequence of passes by computing:

$$x^* = \arg\max_x q(x|t, \theta).$$

(1)

### 4.2 Continuous Collective Compilation Framework

We used Continuous Collective Compilation Framework [2] and MILEPOST GCC shown in Figure 1 to generate a training set of programs together with compiler flags selected uniformly at random, associated sequences of passes, program features and speedups (code size, compilation time) that is stored in the externally accessible Global Optimization Database. We use this training set to build machine learning model described in the next section which in turn is used to predict the best sequence of passes for a new program given its feature vector. Current version of CCC Framework requires minimal changes to the Makefile to pass optimization flags or sequences of passes and has a support to verify the correctness of the binary by comparing program output with the reference one to avoid illegal combinations of optimizations.

### 4.3 Learning and Predicting

In order to learn the model it is necessary to fit a distribution over good solutions to each training program beforehand. These solutions can be obtained, for example, by using uniform sampling or by running an estimation of distribution algorithm (EDA, see [27] for an overview) on each of the training programs. In our experiments we use uniform sampling and we choose the set of good solutions to be those optimization settings that achieve at least 98% of the maximum speed-up available in the corresponding program-dependent dataset.

Let us denote the distribution over good solutions on each training program by $P(x|T^j)$ with $j = 1, \ldots, M$. In principle, these distributions can belong to any parametric family. However, in our experiments we use an IID model where each of the elements of the sequence are considered independently. In other words, the probability of a “good” sequence of passes is simply the product of each of the individual probabilities corresponding to how likely each pass is to belong to a good solution:

$$P(x|T^j) = \prod_{\ell=1}^{L} P(x_\ell|T^j),$$

(2)

As proposed in [12], once the individual training distributions $P(x|T^j)$ have been obtained, the predictive distribution $q(x|t, \theta)$ can be learnt by maximization of the conditional likelihood or by using $k$-nearest neighbor methods. In our experiments we use a 1-nearest neighbor approach. In other words, we set the predictive distribution $q(x|t, \theta)$ to be the distribution corresponding to the training program that is closest in feature space to the new (test) program.

Note that we currently predict “good” sequences of optimization passes that are associated to the best combination of compiler flags. We will investigate in future work the application of our models to the general problem of determining “optimal” order of optimization passes for programs.

### 5 Experiments

We performed our experiments on four different platforms:

- **AMD** – a cluster with 16 AMD Athlon 64 3700+ processors running at 2.4GHz
- **IA32** – a cluster with 4 Intel Xeon processors running at 2.8GHz
- **IA64** – a server with Itanium2 processor running at 1.3GHz
- **ARC** – FPGA implementation of the ARC 725D processor running GNU/Linux with a 2.4.29 kernel.
In all case the compiler used is MILEPOST GCC 4.2.x with the ICI version 0.9.6. We decided to use open-source MiBench benchmark with MiDataSets [20, 6] (dataset No1 in all cases) due to its applicability to both general purpose and embedded domains.

5.1 Generating Training Data

In order to build a machine learning model, we need training data. This was generated by a random exploration of a vast optimization search space using the CCC Framework. It generated 500 random sequences of flags either turned on or off. These flag settings can be readily associated with different sequences of optimization passes. Although such a number of runs is very small in respect to the optimisation space, we have shown that sufficient information can be gleaned from this to allow significant speedup. Indeed, the size of the space left unexplored serves to highlight our lack of knowledge in this area, and the need for further work.

Firstly, features for each benchmark were extracted from programs using the new pass within MILEPOST GCC, and these features then sent to the Global Optimization Database within CCC Framework. An ML model for each benchmark was built, using the execution time gathered from 500 separate runs using different random sequences of passes, and a fixed data set. Each run was repeated 5 times so speedups were not caused by cache priming, etc. After each run, the experimental results including execution time, compilation time, code size and program features are sent to the
database where they are stored for future reference.

Figure 5a shows that considerable speedups can be already obtained after iterative compilation on all platforms. However, this is a time-consuming process and different speedups across different platforms motivates the use of machine learning to automatically build specialized compilers and predict the best optimization flags or sequences of passes for different architectures.

5.2 Evaluating Model Performance

Once a model has been built for each of our benchmarks, we can evaluate the results by introducing a new program to the system, and measuring how well the prediction provided by our model performs. In this work we did not use a separate testing benchmark suite due to time constraints, so instead leave-one-out-cross-validation was used. Using this method, all training data relating to the benchmark being tested is excluded from the training process, and the models rebuilt. When a second benchmark is tested, the training data pertaining to the first benchmark is returned to the training set, that of the second benchmark excluded, and so on. In this way we ensure that each benchmark is tested as a new program entering the system for the first time—of course, in real-world usage, this process is unnecessary.

When a new program is compiled, features are first generated using MILEPOST GCC. These features are then sent to our ML model within CCC Framework (implemented as a MATLAB server), which processes them and returns a predicted sequence of passes which should either improve execution time or reduce code size or both. We then evaluate the prediction by compiling the program with the suggested sequence of passes, measure the execution time and compare with the original time for the default `-O3` optimization level. It is important to note that only one compilation occurs at evaluation—there is no search involved. Figure 5b shows these results for the ARC725D. It demonstrates that except a few pathological cases where predicted flags degraded performance and which analysis we leave for future work, using CCC Framework, MILEPOST GCC and Machine Learning Models we can improve original ARC GCC by around 11%.

This suggests that our techniques and tools can be efficient to build future iterative adaptive specialized compilers.

6 Conclusions and Future Work

In this paper we have shown that MILEPOST GCC has significant potential in the automatic tuning of GCC optimization. We plan to use these techniques and tools to further investigate the automatic selection of optimal orders of optimization passes and fine-grain tuning of transformation parameters. The overall framework will also allow the analysis of interactions between optimizations and investigation of the influence of program inputs and run-time state on program optimizations. Future work will also include fine-grain runtime adaptation for multiple program inputs on heterogeneous multi-core architectures.

7 Acknowledgments

The authors would like to thank Sebastian Pop for the help with modifying and debugging GCC and John W.Lockhart for the help with editing this paper. This research is supported by the European Project MILEPOST (MachIne Learning for Embedded PrOgramS opTimization) [4] and by the HiPEAC European Network of Excellence (High-Performance Embedded Architecture and Compilation) [5].
