Chronic kidney disease (CKD) is an important public health problem with a genetic component. We performed genome-wide association studies in up to 130,600 European ancestry participants overall, and stratified for key CKD risk factors. We uncovered 6 new loci in association with estimated glomerular filtration rate (eGFR), the primary clinical measure of CKD, in or near MPPED2, DDX1, SLC47A1, CDK12, CASP9, and INO80. Morpholino knockdown of mpped2 and casp9 in zebrafish embryos revealed podocyte and tubular abnormalities with altered dextran clearance, suggesting a role for these genes in renal function. By providing new insights into genes that regulate renal function, these results could further our understanding of the pathogenesis of CKD.
Identified more than 20 genetic loci associated with eGFR and prominently population-based cohorts, we and others have previously sized that GWAS in study populations stratified by four key CKD heterogeneous effects across these strata [11]. We thus hypothesized that additional 56,246 individuals, resulting in a total of 130,600 sample of 74,354 individuals with independent replication in the discovery approach extending our previous work [9] to a larger discovery population defined as eGFR<60 ml/min/1.73 m² in 2007-2013, ENGAGE platform, the research of Inga Prokopienko is funded in part through the European Community’s Seventh Framework Programme (FP7/2007-2013), ENGAGE project, grant agreement HEALTH-F4-2007-201413. R Machi acknowledges financial support from the European Commission under a Marie Curie Intra-European Fellowship. For the Rotterdam study and Rotterdam study II, the GWAS was funded by the Netherlands Organisation of Scientific Research NWO Investments (nr. 175.010.2005.011, 913-03-012), the Research Institute for Diseases in the Elderly (010-015, RIDE), the Netherlands Genomics Initiative (NGI)–Netherlands Consortium for Healthy Aged (NCHA) project nr. 050-060-810. The Rotterdam study is funded by Erasmus Medical Center and Erasmus University, Rotterdam, The Netherlands Organization for the Health Research and Development (ZonMW), the Research Institute for Diseases in the Elderly (RIDE), the Ministry of Education, Culture, and Science, the Ministry for Health, Welfare, and Sports, the European Commission (DG XII), and the Municipality of Rotterdam. The Erasmus Computing Grid, Rotterdam (The Netherlands) and the national German MedGRID and Services/MedGRID part of the German D-Grid were both funded by the German Bundesministerium fuer Forschung und Technologie under grants #01 AK 803-AH and #01 IG 00715 G, for access to their grid resources. A Dehghan is supported by NWO grant (vic), 91876-619. The Study of Health in Pomerania (SHIP) is part of the European Community Medicine Research network of the University of Greifswald, Germany, funded by the Federal Ministry of Education and Research (grant nos. 01Z29603, 01Z20103, and 01Z20403), the Ministry of Cultural Affairs as well as the Social Ministry of the Federal State of Mecklenburg-West Pomerania. Genome-wide data have been supported by the Federal Ministry of Education and Research (grant no. 03Z20012) and a grant from Siemens Healthcare, Erlangen, Germany, and the Federal State of Mecklenburg-West Pomerania. The University of Greifswald is a member of the ‘Center of Knowledge Interchange’ program of the Siemens AG. The Vis study was supported through the grants from the Medical Research Council UK to H Campbell, AF Wright, and I Rudan; and Ministry of Science, Education, and Sport of the Republic of Croatia to I Rudan (number 108-1080315-0302) and the European Union framework program 6 EUROSPLAN project (contract no. LSHTM-CR-2006-018947). The WGH is supported by HL 043851 and HL669757 from the National Heart, Lung, and Blood Institute and CA 047988 from the National Cancer Institute, the Donald W. Reynolds Foundation and the Foundation Leducq, with collaborative scientific support and funding for genotyping provided by Amgen. The 3 City study was supported by the National Foundation for Alzheimer’s disease and related disorders, the Institut Pasteur de Lille and the Centre National de Génotypage. The 3 City Study was performed as part of a collaboration between the Institut National de la Santé et de la Recherche Médicale (Inserm), the Victor Segalen Bordeaux II University and Sanofi-Synthelabo. The Fondation pour la Recherche Médicale funded the preparation and initiation of the study. The 3C Study was also funded by the Caisse Nationale Maladie des Travailleurs Salariés, Direction Générale de la Santé, MGEN, Institut de la Longévité, Agence Française de Sécurité Sanitaire des Produits de Santé, the Aquitaine and Bourgogne Regional Councils, Fondation de France and the joint French Ministry of Research/INSERM “Cocherettes et collectes de données biologiques” programme. Lille Génépiol received an unconditional grant from the Ligue Contre le cancer, Blue Mountains Eye Study (BMES) has been supported by a National Institute of Health grant (1R01-EY018891-01A1), the Italian RADGAC grant (407,000 Euro), and the National Health and Medical Research Council, Canberra Australia (Grant Nos: 974159, 211069, 991407, 457349). The GWAS studies of BMES population are supported by the Australian National Health and Medical Research Council (Grant Nos: 512423, 475604, 529912) and the Wellcome Trust, UK (2008), as part of Wellcome Trust Control Consortium 2 (A Viswanathan, P McGuffin, P Mitchell, F Topouzis, P Foster, Grant numbers 085475/B/08/Z and 085475/08/Z). EG Holliday and JJ Wang are funded by the Australian National Health and Medical Research Council (GNT 347825 and 333492). The CoLaus study received partially contributed by the Swiss Commission for funding research. GlaxoSmithKline, The Faculty of Biology and Medicine of Lausanne, and the Swiss National Science Foundation (33C5CO-122661). M Bochud is supported by the Swiss School of Public Health Plus (SSPH+). The Cardiovascular Risk in Young Finns study (YFS) is supported by the Academy of Finland (grant no. 117797, 121584, and 126925), the Social Insurance Institution of Finland, University Hospital Medical funds to Tampere and Turku University Hospitals, and the Finnish Foundation of Cardiovascular Research. The Emil Aaltonen Foundation (T H Lehtimaki, EGT) received targeted financing from Finnish Government SFS180142D08 and from the European Union through the European Regional Development Fund, in the frame of the Centre of Excellence in Genomics. The research of the Ham-fSIS was conducted in part using data and resources from the NHLBI Family Heart Study supported in part by NIH grant 5R01HL87000002. For the GoDARTS study, the Wellcome Trust provides support for Welcome Trust United Kingdom Type 2 Diabetes Case Control Consortium and the informatics support is provided by the Chief Scientist Office, and the Wellcome Trust funded Scottish Health Informatics Programme (ShIP). The INGI-Carantinino and INGI-FVG studies were supported by grants from Telethon, FVG region, and Fondo Trieste. The INGI-Clineto study was supported by grants from the EU (Vasoplus-037254), the Italian Ministry of Universities (FIRB - RBBIO64AYT), the Assessorato Ricerca Regione Campania, the Ente Parco Nazionale del Cilento e Vallo di Diano, and the Fondazione Banco di Napoli a M Ciullo. The INGI - Val Bondone study was supported from Compagnia di San Paolo, Torino, Italy, and Ministero della Salute, Grant No. 1005018. The JUPITER study was supported by grants from the Chief Scientist Office, and the Wellcome Trust. The JUPITER study was the genotyping were supported by AstraZeneca. The Ogliastro Genetic Park (OGP) - Replication Study and OGP - Talana study were supported by grants from the Italian Ministry of Education, University, and Research (MIUR) no. 5571/DSPAR/2002 and (FIRB) D M. No. 718/Ric/2005. The Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) study was supported by an investigator initiated grant from Bristol-Myers Squibb, USA. The study was conducted, analyzed, and reported independently by the company. The SAPALDIA study was supported by the Swiss National Science Foundation (grant no 33C5CO-108796, 3247BO-104283, 3247BO-104288, 3247BO-104284, 3247-065896, 3100-059302, 3200-052720, 3200-042532, 4026-028099), the Federal Office for Forest, Environment, and Landscape, the Federal Office of Public Health, the Federal Office of Roads and Transport, the canton’s government of Aargau, Basel-Stadt, Basel-Land, Geneva, Luzern, Ticino, Zurich, the Swiss Lung League, the canton’s Lung League of Basel Stadt/Basel Landschaft, Geneva’ Ticino, and Zurich. The SAPHIR-study was partially supported by a grant from the Camilla Eiser Stiftung to B Paulweber and by grants from the “Genomics of Lipid-associated Disorders – GOLD” of the “Austrian Research Programme GEN-AU” to F Kröenberg. eQTL analysis: HJ German received support from the AFAR/EMF postdoctoral fellowship and the Stanford Dean’s postdoctoral fellowship. HE Wheeler and SK Kim were supported from the grants from the NIA, NHGRI and NIGMS. Competing Interests: The authors have declared that no competing interests exist. *E-mail: foxca@nhlbi.nih.gov (CS Fox); wkao@jhsph.edu (WHL Kao) ‡ These authors contributed equally to this work. † These authors were joint senior authors on this work. Introduction

Chronic kidney disease (CKD) affects nearly 10% of the global population [1,2], and its prevalence continues to increase [3]. Reduced estimated glomerular filtration rate (eGFR), the primary measure used to define CKD (eGFR<60 ml/min/1.73 m²) [4], is associated with an increased risk of cardiovascular morbidity and mortality [5], acute kidney injury [6], and end stage renal disease (ESRD) [6,7].

Using genome-wide association studies (GWAS) in predominantly population-based cohorts, we and others have previously identified more than 20 genetic loci associated with eGFR and CKD [8–11]. Although most of these genetic effects seem largely robust across strata of diabetes or hypertension status [9], evidence suggests that some of the loci such as the UMOD locus may have heterogeneous effects across these strata [11]. We hypothesized that GWAS in study populations stratified by four key CKD risk factors - age, sex, diabetes or hypertension status - may permit the identification of novel eGFR and CKD loci. We carried this out by extending our previous work [9] to a larger discovery sample of 74,354 individuals with independent replication in additional 56,246 individuals, resulting in a total of 130,600 individuals of European ancestry. To assess for potential heterogeneity, we performed separate genome-wide association analyses across strata of CKD risk factors, as well as in more extreme CKD phenotype.

Results

Meta-analyses of GWAS on the 22 autosomes were performed for: 1) eGFR based on serum creatinine (eGFRCrea) and CKD (6,271 cases) in the overall sample, 2) eGFRCrea and CKD stratified by the four risk factors, and 3) CKD45, a more severe CKD phenotype defined as eGFRCrea <45 ml/min/1.73 m² in

GWAS Reveals New Loci for Kidney Function

Author Summary

Chronic kidney disease (CKD) is an important public health problem with a hereditary component. We performed a new genome-wide association study in up to 130,600 European ancestry individuals to identify genes that may influence kidney function, specifically genes that may influence kidney function differently depending on sex, age, hypertension, and diabetes status of individuals. We uncovered 6 new loci associated with estimated glomerular filtration rate (eGFR), the primary measure of renal function, in or near MPPED2, DDX1, SLCP47A1, CDK12, CASP9, and INO80. CDK12 effect was stronger in younger and absent in older individuals. MPPED2, DDX1, SLCP47A1, and CDK12 loci were associated with eGFR in African ancestry samples as well, highlighting the cross-ethnicity validity of our findings. Using the zebrafish model, we performed morpholino knockdown of mpped2 and casp9 in zebrafish embryos and revealed podocyte and tubular abnormalities with altered dextran clearance, suggesting a role for these genes in renal function. These results further our understanding of the pathogenesis of CKD and provide insights into potential novel mechanisms of disease.

SNPs are listed in the stratum where the smallest P value in the discovery analysis was observed. Sample size/number of studies in the discovery phase: 74,354/26 (overall, direction test), 66,931/24 (No Diabetes), 46,435/23 (age ≤ 65 years); replication phase: 56,246/19 (overall, direction test), 41,218/17 (No Diabetes), 28,631/16 (age ≤ 65 years); combined analysis: 130,600/45 (overall, direction test), 108,149/41 (No Diabetes), 75,066/39 (age ≤ 65 years).

Chr: chromosome; bp: base-pairs; Ref./Non-Ref. All.: reference/non-reference alleles; RAF: reference allele frequency; SE: standard error.

Genes nearby were based on RefSeq genes (build 36). The gene closest to the SNP is listed first and is in boldface if the SNP is located within the gene.

Effects on log(eGFRcrea); post GWAS meta-analysis genomic control correction applied to P values and SEs.

*While being uncovered in the younger samples, this locus showed consistent results in the non-diabetic group (combined-analysis P value 5.7 × 10⁻¹⁶) and in the overall population (P value 9.5 × 10⁻¹³) - see Tables S16 and S10 for additional details.

**The direction test was performed in the overall dataset; the genomic control corrected P value from the direction test for the SNP rs2928148 was 4.0 × 10⁻⁷. In the combined analysis, the largest effect size (0.0054 on log eGFR in ml/min/1.73 m²) and the smallest P value (3.7 × 10⁻⁵) were observed in the non-diabetic group.

†All results were confirmed by random-effect meta-analysis.

*Characteristics of the six lead SNPs in the EA individuals from the CKDGen consortium can be found in Table 1.

**S = number of independent, typed SNPs interrogated.

*The SNP rs11078903 was not present in the CARe consortium database.

Casp9 morphants displayed diminished clearance of 70,000 MW fluorescent dextran 48 hours after injection into the sinus venosus compared to controls, revealing significant functional consequences of casp9 knockdown (Figure 2Q–2V). No clearance abnormalities were observed in mpped2 morphants. The occurrence of abdominal edema is a non-specific finding that is frequently observed in zebrafish embryos with kidney defects. We examined the occurrence of edema in mpped2 and casp9 knockdown embryos at 4 and 6 days post fertilization (dpf), both in the absence and presence of dextran, and observed a significant increase in edema prevalence in casp9 with (P<0.0001) and without (P<0.0234) dextran challenge but not in mpped2 morphants (Figure 2W).

In order to further demonstrate differences in kidney function in response to knockdown of mpped2 and casp9, we injected the nephrotoxin gentamicin which predictably causes edema in a subset of embryos. Casp9 morphants were more susceptible to developing edema compared to both controls and mpped2 morphants (Figure 2X). In addition, edema developed earlier and was more severe, encompassing a greater area of the entire embryo (Figure S9). Together, these findings suggest that casp9 and mpped2 knockdowns result in altered kidney gene expression and function. Specifically, abnormal expression of pax2a and nephem in casp9 morphants in addition to dextran retention and edema formation suggest loss of casp9 impacts glomerular development and function.

The lead SNP at the MPPED2 locus is located approximately 100 kb upstream of the gene metallophosphoesterase domain containing 2 (MPPED2), which is highly evolutionary conserved and encodes a protein with metallophosphoesterase activity [18]. It has been recognized for a role in brain development and tumorigenesis [19] but thus far not for kidney function.

To determine whether the association at our newly identified eGFRcra loci was primarily due to creatinine metabolism or renal function, we compared the relative associations between eGFRcra and eGFR estimated using cystatin C (eGFRcys) (Figure S10, File S1). The new loci showed similar effect sizes and consistent effect directions for eGFRcra and eGFRcys, suggesting a relation to renal function rather than to creatinine metabolism. Placing the results of these 6 loci in context with our previously identified loci [8,9] [23 known and 6 novel], 18 were associated with CKD at a 0.05 significance level (odds ratio, OR, from 1.05 to 1.26; P values from 3.7 x 10^-16 to 0.01) and 11 with CKD45 (OR from 1.08 to 1.34; P values from 1.1 x 10^-5 to 0.047; Figure S11 and Table S15).

When we examined these 29 renal function loci by age group, sex, diabetes and hypertension status (Tables S16, S17, S18, and S19), we observed consistent associations with eGFRcra for most loci across all strata, with only two exceptions: UMOD had a stronger association in older individuals (P value for difference 3.4 x 10^-13) and in those with hypertension (P value for difference 0.002), and CDK12 was stronger in younger subjects (P value for difference 0.0008). We tested the interaction between age and rs11078903 in one of our largest studies, the ARIC study. The interaction was significant (P value = 0.0047) and direction consistent with the observed between-strata difference.

Finally, we tested for associations between our 6 new loci and CKD related traits. The new loci were not associated with urinary albumin-to-creatinine ratio (UACR) or microalbuminuria [20] (Tables S20 and S21), with blood pressure from the ICBP Consortium [21] (Table S22) or with myocardial infarction from the CARDioGRAM Consortium [22] (Table S23).

**Discussion**

We have extended prior knowledge of common genetic variants for kidney function [8–11,23] by performing genome-wide...
association tests within strata of key CKD risk factors, including age, sex, diabetes, and hypertension, thus uncovering 6 loci not previously known to be associated with renal function in population-based studies (MPPED2, DDX1, CASP9, SLC47A1, CDK12, INO80). In contrast to our prior genome-wide analysis [8,9], the majority of the new loci uncovered in the present analysis have little known prior associations with renal function. This highlights a continued benefit of the GWAS approach by using large sample sizes to infer new biology.

Despite our hypothesis that genetic effects are modified by CKD risk factors, most of the identified variants did not exhibit strong cross-strata differences. This highlights that many genetic associations with kidney function in African Americans underscores the generalizability of identified renal loci across ethnicities. Zebrafish knockdown of mped2 resulted in abnormal podocyte anatomy as assessed by expression of glomerular markers, and loss of casp9 led to altered podocyte and distal tubular marker expression, decreased dextran clearance, edema, and enhanced susceptibility to gentamicin-induced kidney damage. These findings demonstrate the potential importance of these genes with respect to renal function and illustrate that zebrafish are a useful in vivo model to explore the functional consequences of GWAS-identified genes.

Despite these strengths, there are some limitations of our study that warrant discussion. Although we used cystatin C to separate creatinine metabolism from true filtration loci, SNPs within the cystatin C gene cluster have been shown to be associated with cystatin C levels [8], which might result in some degree of misclassification in absolute levels. While we used standard definitions of diabetes and hypertension in the setting of population-based studies, these may differ from those definitions used in clinical practice. In addition, we were unable to differentiate the use of anti-hypertension medications from other clinical indications of these agents or type 1 from type 2 diabetes. The absence of association between our six newly discovered SNPs and the urinary albumin to creatinine ratio, blood pressure, and cardiovascular disease may have resulted from disparate genetic underpinnings of these traits, the overall small effect sizes, or the cross-sectional nature of our explorations; and we were unable to differentiate between these potential issues. Finally, power was modest to detect between-strata heterogeneity.

With increased sample size and stratified analyses, we have identified additional loci for kidney function that continue to have novel biological implications. Our primary findings suggest that there is substantial generalizability of SNPs associations across strata of important CKD risk factors, specifically with hypertension and diabetes.

Figure 2. Mpped2 and casp9 knockdowns result in defective kidney development. (A–E) Whole mount in situ hybridization in control embryos demonstrates normal expression of the global kidney marker pax2a (A: lateral view; B: dorsal view), the glomerular marker nephrin (C), and the tubular markers slc20a1a (proximal tubule, D), and slc12a3 (distal tubule, E) at 48 hours post fertilization (hpf). (F–J) Mpped2 morpholino (MO) knockdown embryos develop glomerular gene expression defects (F–H, arrowheads), but tubular marker expression is normal (I, J). (K–O) Casp9 MO knockdown embryos develop reduced glomerular gene expression (K–M, arrowheads) and shortened distal tubules (O). (P) Quantification of observed abnormalities per number of embryos reveal significant differences in expression of pax2a and nephrin in response to knockdown of both mpped2 and casp9 (Fisher’s exact test). (Q–V) Embryos were injected with control, mpped2, or casp9 MO at the one-cell stage and subsequently injected with 70,000 MW fluorescent rhodamine dextran at 80 hpf. Dextran fluorescence was monitored over the next 48 hours. All dextran-injected embryos show equal loading into the cardiac sinus venosus at 2 hours post-injection (2 hpi/82 hpf; Q, S, U). Compared to control MO-injected embryos (R) and mpped2 knockdown embryos (T), knockdown of casp9 resulted in reduced dextran clearance at 48 hpi as shown by increased trunk fluorescence (V). (W) Casp9 knockdown results in increased susceptibility to edema formation both spontaneously (−dex) (P value = 0.0234, Fisher’s exact test) and after dextran challenge (+dex) (P value < 0.0001). Embryos injected with both MO and dextran did not survive to 6 dpf (N/A). (X) Edema develops earlier and with higher frequency in casp9 morphants following injection of the nephrotoxin gentamicin.

Materials and Methods

Phenotype definition

Serum creatinine and cystatin C were measured as detailed in Tables S1 and S2. To account for between-laboratory variation, serum creatinine was calibrated to the US nationally representative National Health and Nutrition Examination Study (NHANES) standards in all discovery and replication studies as described previously [8,24,25]. GFR based on serum creatinine (eGFRcrea) was estimated using the four-variable MDRD Study equation [26]. GFR based on cystatin C (eGFRcys) was estimated as eGFRcrea = 76.7 × (serum cystatin C)−1.19 [27]. eGFRcrea and eGFRcys values <15 ml/min/1.73 m² were set to 15, and those >200 were set to 200 ml/min/1.73 m². CKD was defined as eGFRcrea <60 ml/min/1.73 m² according to the National Kidney Foundation guidelines [28]. A more severe CKD phenotype, CKD45, was defined as eGFRcrea <45 ml/min/1.73 m². Control individuals for both CKD and CKD45 analyses were defined as those with eGFRcrea >60 ml/min/1.73 m².

Covariate definitions

In discovery and replication cohorts, diabetes was defined as fasting glucose ≥126 mg/dl, pharmacologic treatment for diabetes, or by self-report. Hypertension was defined as systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg or pharmacologic treatment for hypertension.

Discovery analyses

Genotyping was conducted as specified in Table S4. After applying quality-control filters to exclude low-quality SNPs or samples, each study imputed up to ~2.5 million HapMap-II SNPs, based on the CEU reference samples. Imputed genotypes were coded as the estimated number of copies of a specified allele (allelic dosage). Additional, study-specific details can be found in Table S1.

Primary association analysis

A schematic view of our complete analysis workflow is presented in Figure S1. Using data from 26 population-based studies of individuals of European ancestry, we performed GWA analyses of the following phenotypes: 1) log(eGFRcrea), log(eGFRcys), CKD, and CKD45 overall and 2) log(eGFRcrea) and CKD stratified by diabetes status, hypertension status, age group (≤5/ >65 years), and sex. GWAS of log(eGFRcrea) and log(eGFRcys) were based on linear regression. GWAS of CKD and CKD45 were performed in studies with at least 25 cases (i.e. all 26 studies for CKD and 11 studies for CKD45) and were based on logistic regression. Additive genetic effects were assumed and models were adjusted for age and, where applicable, for sex, study site and principal components. Imputation uncertainty was accounted for by including allelic dosages in the model. Where necessary, relatedness was modeled with appropriate methods (see Table S1 for study-specific details). Before including in the meta-analysis, all GWA data files underwent to a careful quality control, performed using the GWAToolbox package in R (www.eurac.edu/GWA toolbox.html) [29].

Meta-analyses of study-specific SNP-association results, assuming fixed effects and using inverse-variance weighting, i.e.: the pooled effect $\hat{\theta}_{pooled}$ is estimated as $\sum_{i=1}^{K} w_i \hat{\theta}_i / \sum_{i=1}^{K} w_i$, where $\hat{\theta}_i$ is the effect of the SNP on the outcome in the $i$th study, $K$ is the number of studies, and $w_i = 1 / SE(\hat{\theta}_i)^2$ is the weight given to the $i$th study. The meta-analyses were performed using METAL [30], with genomic control correction applied across all imputed SNPs [31] if the inflation factor λ > 1 at both the individual study level and after the meta-analysis. SNPs with minor allele frequency (MAF) ≤ 1% were excluded. All SNPs with a meta-analysis $P$ value ≤ 5 × 10^{-8} for any trait or any stratum were deemed genome-wide significant [32].

In the eGFRcrea analyses, after excluding loci that were previously reported [8,9], we selected for replication all SNPs with $P$ value ≤ 5 × 10^{-8} in any trait or stratum that were independent (defined by pairwise $r^2 < 0.2$), in the primary association analysis. This yielded five SNPs in five independent loci. The same criterion was applied to the CKD analysis, where no SNPs passed the selection threshold. Given the smaller number of cases with severe CKD resulting in less statistical power, a different selection strategy was adopted for the CKD45 analysis: selected for replication were SNPs with discovery $P$ value ≤ 5 × 10^{-6}, MAF ≥ 5%, and homogeneous effect size across studies (I^2 ≤ 25%). Four additional SNPs were thereby selected for replication from the CKD45 analysis.

Direction test to identify SNPs for replication

In addition to identifying SNPs for replication based on the genome-wide significance threshold from a fixed effect model meta-analysis, we performed a “direction test” to identify additional SNPs for which between-study heterogeneity in effect size might have obscured the overall association that was nevertheless highly consistent in the direction of allelic effects. Under the null hypothesis of no association, the a priori probability that a given effect allele of a SNP has either a positive or negative association with eGFRcrea is 0.5. Because the meta-analysis includes independent studies, the number of concordant effect directions follows a binomial distribution. Therefore, we tested whether the number of discovery cohorts with the same sign of association (i.e. direction of effect) was greater than expected by chance given the binomial distribution and a null expectation of equal numbers of associations with positive and negative sign. The test was only applied for eGFRcrea in the overall analysis. Multiple testing was controlled by applying the same $P$ value...
threshold of $5 \times 10^{-8}$ as in the overall GWAS. Given that no SNP met this criterion, we selected for replication one novel SNP with the lowest $P$-value of $4.0 \times 10^{-7}$.

**Genome-wide between-strata difference test to identify SNPs for replication**

Based on the results of the stratified GWAS of eGFRcrea and CKD, for each SNP we tested the hypothesis whether the effect of a SNP on eGFRcrea or CKD was the same between strata (null hypothesis), i.e. diabetes versus non-diabetes subjects, hypertensive versus normotensive, younger versus older, females versus males. We used a two-sample test defined as $Z = (b_1 - b_2)/\sqrt{\text{SE}(b_1)^2 + \text{SE}(b_2)^2}$, with $b_1$ and $b_2$ indicating the effect estimates in the two strata and $\text{SE}(b_1)$ and $\text{SE}(b_2)$ their standard errors [33]. For large samples, the test statistic follows a standard normal distribution. SNPs were selected for replication if they had a between-stratum difference $P$-value $\leq 5 \times 10^{-5}$, an association $P$-value $\leq 5 \times 10^{-5}$ in one of the two strata, and MAF$\leq 10\%$. Independent loci were defined using the same criteria as described above. Eleven further SNPs, one per locus, were selected for replication from the between-strata difference test.

**Replication analysis**

Replication was performed for a total of 21 SNPs including 5 from the overall and stratified eGFRcrea analyses, 1 from the direction test on eGFRcrea, 4 from the overall CKD45 analysis, and 11 from the between-strata difference test. Replication studies used the same phenotype definition, and had available genotypes from imputed *in silico* genome-wide SNP data or de novo genotyping. The same association analyses including the identical stratifications were performed as in discovery studies. Details can be found in the Tables S2, S5 and S6. Study-specific replication results for the selected SNPs were combined using the same meta-analysis approach and software as in the discovery stage. One-sided $P$-values were derived with regard to the effect direction found in the discovery stage. Based on the $P$-value distribution of all SNPs submitted for replication (the 10 from eGFRcrea and CKD45 and the 11 from the between strata difference test), we estimated the False Discovery Rate as a q-value using the QVALUE [34] package in R. SNPs with q-value $< 0.05$ were called significantly replicating, thus specifying a list of associations expected to include not more than 5% false positives.

Finally, study-specific results from both the discovery and replication stage were combined in a joint inverse-variance weighted fixed-effect meta-analysis and the two-sided $P$-values were compared to the genome-wide significance threshold of $5 \times 10^{-8}$ to test whether a SNP was genome-wide significant. Between-study heterogeneity of replicated SNPs was quantified by the $I^2$ statistic [35].

**Replication genotyping**

For de novo genotyping in 10,446 samples from KORA F3, KORA F4, SAPHIR and SAPALDIA, the MassARRAY system at the Helmholtz Zentrum München, Germany was used, using Assay Design v3.1.2 and the iPLEX chemistry (Sequenom, San Diego, USA). Assay design failed for rs1322199 and genotyping was not performed. Ten percent of the spectra were checked by two independent, trained persons, and 100% concordance between investigators was obtained. SNPs with a $P$-value $< 0.001$ when testing for Hardy-Weinberg equilibrium (rs10490130, rs10068737, rs11078903), SNPs with call rate $< 90\%$ (rs300456 in KORA F4 only) or monomorphic SNPs (rs2928148) were excluded from analyses without attempting further genotyping.

The call rates of rs4149333 and rs752805 were near 0% on the MassARRAY system. These SNPs were thus genotyped on a 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, USA). Mean call rate across all studies and SNPs ranged from 96.8% (KORA F4) to 99% (SAPHIR). Duplicate genotyping was performed in at least 14% of the subjects in each study with a concordance of 95–100% (median 100%). In the Ogliastra Genetic Park Replication Study (n = 3000) de novo genotyping was conducted on a 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, USA), with a mean call rate of 99.4% and 100% concordance of SNPs genotyped in duplicate.

**Between-strata analyses for candidate SNPs in replication samples**

Twenty-nine SNPs, including the 6 novel loci reported in the current manuscript along with 23 previously confirmed to be associated with renal function [9], were tested for differential effects between the strata. The same $Z$ statistics as described for discovery (above) was used and the Bonferroni-adjusted significance level was set to $0.10/29 = 0.003$.

SNP-by-age interaction, for the one SNP showing significantly different effects between strata of age, was tested in the ARIC study by fitting a linear model on log(eGFRcrea) adjusted for sex, recruitment site, the first and the seventh genetic principal components (only these two were associated with the outcome at $P$-value $< 0.05$). Both the interaction term and the terms for the main effects of age and the SNP were included in the model.

**Power to assess between-strata effect difference**

To assess genome-wide between-strata differences, with alpha $= 5 \times 10^{-8}$ and power $= 80\%$, the maximum detectable difference was 0.025 when comparing nonDM versus DM and 0.015 when comparing nonHTN versus HTN. Similarly, when testing for between-strata differences the 29 known and new loci (Bonferroni-corrected alpha $= 0.003$) in the combined sample (n = ~125,000 in nonDM and n = ~13,000 in DM) we had 80% power to detect differences as large as 0.035.

**Look-up in African Americans (CARe)**

For each of the 6 lead SNPs identified in our European ancestry samples, we extracted eGFR association statistics from a genome-wide study in the CARe African ancestry consortium [12]. We further investigated potential allelic heterogeneity across ethnicities by examining the 250 kb flanking region surrounding each lead SNP to determine whether other SNPs with stronger associations exist in each region. A SNP with the smallest association $P$-value with MAF$> 0.03$ was considered the top SNP in the African ancestry sample. We defined statistical significance of the identified lead SNP in African ancestry individuals based on a region-specific Bonferroni correction. The number of independent SNPs was determined based on the variance inflation factor (VIF) with a recursive calculation within a sliding window of 50 SNPs and pairwise $r^2$ of 0.2. These analyses were performed using PLINK.

**Analyses of related phenotypes**

For each replicating SNP, we obtained association results for urinary albumin-to-creatinine ratio and microalbuminuria from our previous genome-wide association analysis [20], and for blood pressure and myocardial infarction from genome-wide association analysis from the ICBP [21] and CARDIoGRAM [22] consortia, respectively.
eSNP analysis

Significant renal SNPs were searched against a database of expression SNPs (eSNP) including the following tissues: fresh lymphocytes [36], fresh leukocytes [37], leukocyte samples in individuals with Celiac disease [33], lymphoblastoid cell lines (LCL) derived from asthmatic children [39], HapMap LCL from 3 populations [40], a separate study on HapMap CEU LCL [41], peripheral blood monocytes [42,43], adipose [44,45] and blood samples [44], 2 studies on brain cortex [42,46], 3 large studies of brain regions including prefrontal cortex, visual cortex and cerebellum (Emilsson, personal communication), liver [45,47], osteoblasts [48], skin [49] and additional fibroblasts, T cell and LCL samples [50]. The collected eSNP results met criteria for statistical significance for association with gene transcript levels as described in the original papers.

A second expression analysis of 81 biopores from normal kidney cortex samples was performed as described previously [51,52]. Genotyping was performed using Affymetrix 6.0 Genome-wide chip and with GTC Software (Affymetrix). For eQTL analyses, expression probes (Affymetrix U133set) were linked to SNP probes with >90% call-rate using ReSeq annotation (Affymetrix build a30). P values for eQTLs were calculated using linear multivariable regression in both cohorts and then combined using Fisher’s combined probability test (see also [52]). Pairwise LD was calculated using SNAP [53] on the CEU HapMap release 22.

Zebrafish functional experiments

Zebrafish were maintained according to established IACUC protocols. Briefly, we injected zebrafish embryos with newly designed (mpped2, ddx1) or previously validated (casp9 [54]) morpholino antisense oligonucleotides (MO, GeneTools, Philomath OR) at the one-cell stage at various doses. We fixed embryos in 4% PFA at the appropriate stages for in situ hybridization (http://zfin.org/ZFIN/Methods/ThisseProtocol.html). Different anatomic regions of the kidney were visualized using a panel of 4 established markers: pas2a (global kidney marker) [15], nephrin (podocyte marker) [16], slc20a1a (proximal tubule) [17], and slc12a3 (distal tubule marker) [17]. Abnormalities in gene expression were independently scored by two investigators. We compared the number of abnormal morphant embryos to control embryos, injected with a standard control MO designed by GeneTools, with the Fisher’s exact test, at the Bonferroni-based statistical significance level of 0.0125, i.e.: 0.05/4 markers. We fixed embryos, injected with control, mpped2, or casp9 MOs at the one-cell stage. At 48 hpf, embryos were manually dechorionated, anesthetized in a 1:20 dilution of 4 mg/ml Tricaine in embryo water, and oriented on a 1% agarose injection mold. As previously described [56], embryos were injected with equal volumes of 10 mg/ml gentamicin (Sigma) in the cardiac sinus venous, returned to fresh embryo water, and subsequently scored for edema (prevalence, time of onset) over the next 3 days.

Supporting Information

Figure S1 Flowchart of the project. (TIF)

Figure S2 Genome-wide $-\log_{10} P$ values plot from stage 1 discovery meta-analysis. Plots show the discovery analysis of eGFRcrea in the overall group, with known loci [8,9] highlighted in orange and novel loci highlighted in blue (A), and in strata of the main CKD risk factors (B, C, D, and E), with complementary groups being contrasted each other. The dotted line indicates the genome-wide significance threshold at $P$ value $= 5 \times 10^{-8}$. The unmarked locus is RNASEH2C on chromosome 11, colored in gray despite genome-wide significance. The $P$ value for the current stage 1 discovery for rs4014195 was $2.7 \times 10^{-7}$. This locus previously did not replicate [9]; when we additionally considered our prior non-overlapping in silico and de novo replication data, the current stage 2 $P$ value was 0.8832, yielding a combined stage 1+stage 2 $P$ value of $2.6 \times 10^{-7}$. Therefore, we did not submit this SNP for further replication. (PDF)

Figure S3 Quantile-quantile plots of observed versus expected $-\log_{10} P$ values from the discovery analysis of eGFRcrea overall (A) and by strata of the main CKD risk factors (B). The orange line and its 95% confidence interval (shaded area) represent the null hypothesis of no association. In panel (A), results are compared when considering all SNPs (black dots) and when removing SNPs from loci that were already reported in previous GWAS [8,9] (orange dots). The meta-analysis inflation factor $\lambda$ is reported along with the discovery sample size. Individual-study minimum, maximum and median $\lambda$s are also reported for comparison. Genomic-control correction was applied twice: on individual study results, before the meta-analysis, and on the meta-analysis results. (PDF)

Figure S4 Regional association plots for the six new loci in the European ancestry discovery samples: (A) MPPED2; (B) DDX1; (C) SLC47A1; (D) CASP9; (E) CDK12; (F) INO80. $-\log_{10} P$ values are plotted versus genomic position (build 36). The lead SNP in each region is labeled. Other SNPs in each region are color-coded based on their LD to the lead SNP (based on the HapMap YRI, see color legend). Gene annotations are based on UCSC Genome Browser (RefSeq Genes, build 36) and arrows indicate direction of transcription. Graphs were generated using the standalone version of LocusZoom [57], version 1.1. (PDF)

Figure S5 Forest plots of the six novel loci in the discovery phase. (TIF)

Figure S6 Results from discovery meta-analysis of eGFRcrea for the six new loci: overall sample and all strata are considered. Reported is the effect size on log(eGFRcrea) and its 95% confidence interval. The stratum where the SNP was discovered is marked with a triangle for discovery based on meta-analysis $P$ value or with a circle for discovery based on direction test. (TIF)

Figure S7 Regional association plots for the six new loci in the African ancestry CARe samples: (A) MPPED2; (B) DDX1; (C) SLC47A1; (D) CASP9; (E) CDK12; (F) INO80. $-\log_{10} P$ values are plotted versus genomic position (build 36). The lead SNP in each region is labeled and identified by a blue arrow and blue $P$ value. The SNP with the smallest $P$ value in the region is indicated by a red arrow. Other SNPs in each region are color-coded based on their LD to the lead SNP (based on the HapMap YRI, see color
GWAS Reveals New Loci for Kidney Function

Figure S8 Ddx1 knockdown does not affect kidney gene expression. (A–E) Uninjected control embryos show normal kidney development as demonstrated by in situ hybridization for the renal markers pax2a (A, B), nephrin (C), slc20a1a (D) and slc12a3 (E). (F–J) Ddx1 morpholino(MO)-injected embryos do not show significant changes in renal marker expression. (K) Number of observed abnormalities per number of embryos examined at 400 uM MO injection for renal gene expression analysis.

Figure S9 Casp9 and mpped2 knockdown embryos are more susceptible to gentamicin-induced kidney injury. Compared to control embryos (A), casp9 and mpped2 knockdown embryos develop edema at 103 hpf (C, E), suggestive of a renal defect. When injected with gentamicin, a nephrotoxin that reproducibly induces edema in control embryos (B), mpped2 and casp9 knockdown embryos develop edema earlier, more frequently, and in a more severe fashion (D, F). Whereas control embryos primarily develop cardiac edema, mpped2 and casp9 knockdown embryos display cardiac (arrowhead), ocular (black arrow), and visceral (white arrow) edema, demonstrating that mpped2 and casp9 knockdown predisposes embryos to kidney injury. (G) Quantification of edema prevalence in control, mpped2, and casp9 knockdown embryos 2, 22, and 55 hours post-injection (hpi) of gentamicin. These numbers are presented graphically in Figure 2X.

Figure S10 Comparison of the effect size on eGFRcrea and on eGFRcys for the lead SNPs of known and new loci. Results are based on the largest sample size available for each locus, i.e. the combined discovery and replication sample for the novel loci (N = 130,600), the discovery sample only for the known loci (N = 74,354). Sign of effect estimates has been changed to reflect the effects of the eGFRcrea lowering alleles. Original beta values.
