Abstract

The remarkable increase in chondrocyte volume is a major determinant in the longitudinal growth of mammalian bones. To permit a detailed morphological study of hypertrophic chondrocytes using standard histological techniques, the preservation of normal chondrocyte morphology is essential. We noticed that during fixation of growth plates with conventional fixative solutions, there was a marked morphological (shrinkage) artifact, and we postulated that this arose from the hyper-osmotic nature of these solutions. To test this, we fixed proximal tibia growth plates of 7-day-old rat bones in either (a) paraformaldehyde (PFA; 4%), (b) glutaraldehyde (GA; 2%) with PFA (2%) with ruthenium hexamine trichloride (RHT; 0.7%), (c) GA (2%) with RHT (0.7%), or (d) GA (1.3%) with RHT (0.5%) and osmolarity adjusted to a ‘physiological’ level of ~280mOsm. Using conventional histological methods, confocal microscopy, and image analysis on fluorescently-labelled fixed and living chondrocytes, we then quantified the extent of cell shrinkage and volume change. Our data showed that the high osmolarity of conventional fixatives caused a shrinkage artefact to chondrocytes. This was particularly evident when whole bones were fixed, but could be markedly reduced if bones were sagittally bisected prior to fixation. The shrinkage artefact could be avoided by adjusting the osmolarity of the fixatives to the osmotic pressure of normal extracellular fluids (~280mOsm). These results emphasize the importance of fixative osmolarity, in order to accurately preserve the normal volume/morphology of cells within tissues.

Keywords: Shrinkage, artefact, osmolarity, glutaraldehyde, para-formaldehyde, growth plate.

Introduction

The accurate study of the morphology of living cells as they appear within tissues is difficult but fundamental for an understanding of normal cell biology, and the changes that occur in disease states. Accordingly a vast amount of research has been performed on chemically-fixed cells and tissues. The intention has been to retain the fine morphology and constituents of living in situ cells so that they can be studied without the complications of deleterious changes to cell metabolism and loss of viability during the investigation (see Hopwood, 1985). In addition, tissue fixation should protect against cell autolysis, attack by bacteria, and changes to cell volume and shape especially during subsequent preparative treatment (Baker, 1960) when tissue dehydration is frequently performed. Thus, fixative solutions should serve to stabilize the specimen and protect it from rigorous physical tissue processing and staining as required for study (Hopwood, 1969). Our particular research emphasis has been on the cellular mechanisms underlying the structure and function of the mammalian growth plate. There has been extensive study on chemically-fixed growth plates, and particular interest in the remarkable increase in chondrocyte volume which is a major determinant of bone growth (Breur et al., 1991). The large volumes of growth plate chondrocytes (typically ranging from 1,000 to 10,000μm³; Bush et al., 2008) potentially makes them extremely sensitive to osmotic artefacts during fixation.

Para-formaldehyde (PFA) and glutaraldehyde (GA) and their combinations have long been used as fixative solutions (Fox et al., 1985; Hopwood, 1969) to retain the properties of cells and tissues (Kiernan, 1999; Renshaw, 2007). Perhaps the most widely used fixative for histology and histopathology is 10% neutral buffered formalin however this is not usually used for studies on the growth plate. Examples of more conventional aldehyde preparations used for this tissue are (a) 4% (w/v) PFA (Fox et al., 1985; Hosoya et al., 2005; solution A, Table 1) which has the same formaldehyde concentration (4%) as 10% Formalin (Kiernan, 1999), (b) 2% (w/v) GA & RHT (ruthenium hexamine trichloride) combined with 2% (w/v) PFA (Farnum et al., 2002; solution B, Table 1) and (c) 2% GA (w/v) with 0.7% (w/v) RHT (Hunziker et al., 1983; solution C see Table 1). Although the fixative properties have been widely known, less appreciated is the fact that the osmolarity of these solutions is markedly greater than that of typical physiological extracellular...
solutions (Table 1). The osmolarity of the fixative solutions and their effects on cell and tissue morphology have received relatively little attention recently – indeed often appear ignored – despite the fact that there are studies in the literature highlighting this issue. For example, Schultz and Karlsson (1965) observed that hypertonic fixative solutions perfused into the central nervous system caused cellular shrinkage and increased extracellular spaces, whereas isotonic (300-320mOsm) and hypotonic fixatives could result in cell swelling. Mathieu et al. (1978) have reported the importance of both the % of GA and the molarity of the vehicle used for the fixative solution for the preservation of lung tissue. Even with these early studies, there are recent examples of investigators using hyper-osmolar fixative solutions (Farnum et al., 2002; Hosoya et al., 2005) but little if any comment on the morphology of the fixed cells which frequently appear shrunken/distorted (Erben, 1997; Kouri et al., 1996; Ross and Reith, 1985; Sanchez et al., 2000; Van der Eerden et al., 2000) and little or no attempt at quantification of the shrinkage artefact. We wished therefore (a) to re-visit this issue and emphasize the importance of osmotic correction to fixative solutions in order to retain cell morphology and (b) provide quantitative data on the extent of cell shrinkage and specifically report on the influence of fixative osmolarity on connective tissue cells.

During preliminary experiments attempting to optimize the fixation protocols for mammalian growth plates, we noticed that for the same standard fixative, the appearance of hypertrophic zone cells in histological sections from whole bones were markedly different compared to those from sagitally sectioned bones. The morphology of the cells in the whole bone fixed samples appeared considerably mis-shapen and shrunken, whereas in the bisected bone, morphology was relatively normal. From our previous studies on the shape/volume of chondrocytes exposed to osmotic challenge (Bush and Hall, 2001) we suspected that an artefact of the relatively high osmotic pressure of the fixative solutions might account for the suspected that an artefact of the relatively high osmotic exposure to osmotic challenge (Bush and Hall, 2001) we bisected bone, morphology was relatively normal. From sagittally sectioned bones. The morphology of the hypertrophic zone cells in histological sections from other experiments following U.K. Home Office guidelines. The tibia of each hind limb with intact proximal growth plate cartilage was dissected and temporarily placed in medium (phosphate buffered saline; PBS; approx. 293mOsm) containing alpha modified essential medium (α-MEM; 7.5% v/v; Invitrogen) and bovine serum albumin V (1mM), prior to fixation.

For the preparation of samples for histology, 2 tibia from each animal were used and placed in fixative solutions of differing composition as follows: (a) conventional fixative solutions (Table 1), (b) fixatives with GA concentration maintained constant, but with various osmolarities similar to those used for conventional fixative solutions (Table 2), and (c) fixatives with various concentrations of GA but with osmolarity maintained at approx. 550mOsm (Table 3). The growth plates were fixed for 24hrs at room temperature for subsequent paraffin-
embedding for histological sectioning. For group (a) three intact tibias and 3 bisected tibias were fixed in each fixative solution, whereas in group (b) and (c), three and five intact tibias were used in each fixative solution respectively.

For the preparation of growth plates for the analysis of in situ growth plate chondrocyte (GPC) volume, tibias from eight P7 rat pups were grouped into: (i) five bones maintained intact, and (ii) ten bones that were bisected sagittally. Bones were incubated with either CMFDA-green or NaCl.

Histology of the growth plate

Bones were embedded in paraffin wax using a standard procedure (Kiernan, 1999) and tissue sections (10μm) cut using a microtome (Reichert-Jung Microtome 2050 Supercut, Arnsberg, Germany). The sections were then mounted on poly-l-lysine-coated microscope slides (Polyline™, VWR International, Leicestershire, UK) and dried overnight. After de-paraffinisation with xylene and rehydration with a series of ethanol solutions (100%, 90%, 75%), the sections were stained with 0.1% (w/v) Toluidine blue O in PBS buffer (pH 5.5; 30 secs at room temperature) using the technique adapted from Bancroft and Cook (1994). The sections were then rinsed briefly in distilled water and allowed to air dry prior to mounting in FluorSave™ with cover slips.

Measurement of growth plate chondrocyte shrinkage

Histological sections of fixed hypertrophic GPC stained with 0.1% Toluidine blue O were observed under an x63 (oil-immersion) objective lens. Several histological views of chondrocytes within sections S5 and S6 of the hypertrophic zone (see details in the section ‘In situ volume measurement’ below), and Figure 1(A) were randomly selected and the images recorded using a mounted digital camera (Coolpix 4500, Nikon, Tokyo, Japan) with Coolpix MDC2 Relay lens (MXA 2900, Nikon). The captured images were then transferred to a computer for further image analysis. Java-based scientific image processing software (ImageJ, NIH, Bethesda, MD, U.S.A.) was then used to measure the cell shrinkage from the images of the histological sections.

In order to determine the extent of chondrocyte shrinkage it was necessary to identify the area of individual chondrocytes and that of their lacuna – i.e., the ‘cavity’ in which the cell resided. It was in fact relatively straightforward to do this as the outermost edge of the cell area stained distinctly with Toluidine blue O, and the perimeter of the corresponding lacuna was identified as the edge of the extracellular matrix that demarcated the border between the stained area of the matrix and the ‘space’ of the lacuna which was relatively unstained. It was noted that the area of the lacuna could only be observed if there was cell shrinkage. For each group of treatments, 4 fields of view from each growth plate section were selected and up to 11 cells and their corresponding lacunae randomly taken for area measurement. The area of each

Table 3. Modified fixative solutions with varying GA concentration, but with similar final osmolarity.
cell and that of its associated lacuna were selected by outlining their perimeters using the freehand selection tool (see Fig. 2A, panel a). The total area of the cell and its lacuna were then determined using the ‘analyze’ and ‘measure’ toolbar in the software. Cell shrinkage was calculated as \( \{100 - \frac{\text{cell area}}{\text{lacuna area}} \times 100\} \) and expressed as a percentage of the initial volume (see Fig. 2A, panel a). When the cell and its corresponding lacuna shared the same perimeter, the value of cell shrinkage was zero as defined above.

**Confocal laser scanning microscopy (CLSM)**

An upright Zeiss Axioskop LSM 510 (Carl Zeiss Ltd., Welwyn Garden City, Herts., U.K.) CLSM was used to acquire fluorescent images of in situ hypertrophic growth plate chondrocytes. Cells were visualized using a Plan-
Fig. 2A. Conventional fixatives cause considerable shrinkage of hypertrophic growth plate chondrocytes when applied to whole (intact) bones. Intact proximal tibias of 7-day-old rat pups were fixed using various standard fixative solutions (Table 1) and sections prepared and stained with 0.1% Toluidine blue O (see Materials and Methods). The method used to calculate the extent of chondrocyte shrinkage was illustrated in Panel (a). The thick white line was drawn free-hand around the perimeter of the lacuna and the black broken line drawn around the membrane edge of its resident chondrocyte (see details in Materials and Methods). The gap between the cells and the border of the lacuna is illustrated by double headed arrows. Cell shrinkage was observed in all conventional fixatives (panels a - c) but not when the osmolarity of the fixative was adjusted to a ‘physiological’ osmolarity (panel d). For pooled data see Figure 3. The scale bar of 20μm in this and the following Figure applied to all panels.

Neofluar x10/0.3 numerical aperture (NA) dry objective for a low power overview and an Achroplan x 63/0.95 NA ceramic water-dipping lens for high power views. Intracellular CMFDA was excited using an Argon laser (Ex = 488nm) and emitted fluorescence (Em = 517nm) detected using a 500-550nm band pass filter. The confocal detection pinhole was set at 1.00 Airy Unit. Laser power and detector sensitivity were adjusted to provide optimum image quality. The scanning speed was typically 0.6Hz with 2 frame integration of a 512 x 512 pixel image, with serial 1 μm z-step optical sections (see Bush and Hall, 2001; Bush et al., 2007 for further details).

In situ volume measurement
Whole growth plates imaged from the proliferative to hypertrophic zones were divided into eight equal parts and labeled S1 to S8 (Fig. 1A). This was done so that a comparative analysis could be made between corresponding sections from different individuals irrespective of variations in section cutting angle (Bush et al., 2008). Since the greatest number of hypertrophic cells that was consistently found to be intact was in S5 and S6, the in situ growth plate cell volume analysis was performed only at these sections. Chondrocytes in S7-S8 often appeared to be in poor condition, possibly as a result of...
Volume and morphology of rat growth plate chondrocytes (GPC)

Initially, to determine live cell volumes and the morphology of in situ unfixed chondrocytes, we labelled in situ growth plate chondrocytes with calcein as shown (Fig. 1). Imaging of the fluorescently-labelled in situ living growth plate chondrocytes demonstrated a clear increase in the size of GPC from the proliferative through to hypertrophic zones (Fig. 1a). Chondrocytes within the proliferative zone (between the reserve and hypertrophic zone) appeared
ellipsoidal and usually arranged in columns of at least three to eight cells. In the hypertrophic zone (between the proliferative zone and the zone of calcification) the cells were larger and frequently more rounded although there were cells with a height greater than the cell’s width (Buckwalter et al., 1985; Farnum and Wilsman, 1986).

In accordance with the visual appearance of chondrocytes along the growth plate, the quantified volume of in situ cells increased although it was clearly not a linear process as there was a relatively poor fit to a linear regression (correlation coefficient \( r^2 = 0.793 \)). The volume increase was initially gradual through to S5, but then became more rapid from S5-S8 similar to an exponential growth relationship (Fig. 1b). When the volume data were transformed to \( \log_{10} \) and plotted semi-logarithmically (see inset to Fig. 1b) there was a much better fit to the data (\( r^2 = 0.955 \)) supporting the notion of a logarithmic increase in chondrocyte volume associated with hypertrophy. In the present study we focused on chondrocytes within these latter sections of the growth plate. Although the shrinkage artefact was apparent in the smaller cells, it was very difficult to quantify the phenomenon using our imaging methods (see Materials and Methods). This was because the distinction between the perimeter of the lacuna and the cell edges of smaller (shrunken) cells was difficult to determine accurately, resulting in large variations.

Therefore, we decided to study the phenomenon only on chondrocytes in the hypertrophic zone to ensure accurate measurements, and the cells within S5-S6 were chosen because an adequate number of intact cells from these segments could consistently be observed.

**Measurement of cell shrinkage**

The accuracy of the method used for assessing chondrocyte shrinkage in histological sections as described in Materials & Methods (Fig. 2A panel a) was initially determined by measuring the area of GPC cells that had distinct and well-defined perimeters. The cell measurement was made independently using the free-hand selection tool on the same cell twice and the difference between the two readings compared. The mean difference between the two measurements was 2.7±1.9 % (mean ± standard deviation (S.D.), for 11 cells) indicating the measurement method had an appropriate level of accuracy.

**Morphology of growth plate chondrocytes fixed using conventional solutions**

An ideal fixative should successfully preserve tissue for subsequent staining procedures, but it is important to accurately retain the original morphology of the living cells in the tissue, free from artefacts occurring during the fixation process. To demonstrate the morphology of GPC...
fixed with conventional fixatives (Farnum et al., 2002; Hosoya et al., 2005; Hunziker et al., 1983), we used three standard and widely-used solutions (Table 1). These fixative solutions were all hyper-osmotic (Table 1), and therefore for comparison an iso-osmotic fixative with osmolarity adjusted to close to that of typical extracellular physiological solutions (280mOsm; Table 1), was also included.

In whole (non-bisected) bone samples, fixed and processed as described for histology (see Materials and Methods), there was a clear cell shrinkage artefact observed in tissue fixed with the three conventional fixatives (solutions A, B & C; Table 1; Fig. 2A panels a-c). Among the three fixatives, chondrocyte shrinkage assessed visually was most marked for solutions A and B and least for solution C (Fig. 2A(c)). When osmotically corrected solution D (~280mOsm) was used, we observed no apparent cell shrinkage (Fig. 2A panel d). Quantitatively, solution A caused the highest cell shrinkage (44 ± 3% (3[44])), followed by solution B (31 ± 4% (3[44]), then cells in solution C 17 ± 5% (3[44]) and finally for the osmotically-corrected fixative solution D, there was no significant change in cell volume (5.5 ± 0.8% (3[44])). When analysing the extent of the shrinkage from solutions A to D (lowering osmolarity, Table 1), there was a significantly decreasing trend (one-way ANOVA test; P=0.010) however only the shrinkage for cells in solutions A and B were significantly different (unpaired Student’s t-test, P<0.05) from the osmotically-corrected fixative solution D. Note that although shrunken cells were routinely observed microscopically in cells fixed in solution C (Fig. 2A panel c) the pooled data did not show a significant difference and this was mainly because of the range in the magnitude of the shrinkage effect.

In bisected bones (Fig. 2B), microscopic inspection showed clearly that the extent of the chondrocyte shrinking artefact was considerably reduced with the four fixatives when compared to the cells within fixed whole bones (Fig. 2A panels a-d). When the shrinkage was quantified (Fig. 3B), the same decreasing trend in cell shrinkage with the four fixatives was also observed and the trend significant over the whole range (one-way ANOVA test; P=0.024). The absolute level of shrinkage and the trend with decreasing osmolarity, was less compared to the data for intact bones (Fig. 3A). When the data sets for intact and bisected bones over the range of fixatives were compared using a two-way ANOVA, the difference was significant (P=0.004). In solution A cell shrinkage in bisected bones was 22 ± 2.6%, which was significantly less than the shrinkage of chondrocytes fixed in intact tibias (P=0.030). Fixative solution B caused 17 ± 1.4% (3[44]) shrinkage whereas solution C caused 9 ± 0.4% (3[44]) cell shrinkage.
Shrinkage artifact with conventional fixatives

MY Loqman et al.

and these values were less than for intact bones but did not reach the level of significance ($P>0.05$). Cell shrinkage in the iso-osmotic fixative solution D for GPC in bisected bones was only $4 \pm 0.4\%$ (Fig. 3) and this was not significantly different from the data in intact bones (see above). These results showed that the shrinkage artefact was considerably reduced if the bones were bisected prior to fixation, and with osmotic correction, there was no significant shrinkage artefact of GPC in either intact or bisected bones.

As noted in Table 1, the pH of the fixatives varied over the range 5.67 to 7.11, which was the result of different types and concentration of fixative agents and buffer concentration. We conducted a further experiment to examine whether pH contributed significantly to the quality of tissue preservation.

We tested two pH values (i.e., 5.6 and 7.2) using the same fixative solution (solution D) to fix two groups of growth plate tissue from proximal tibia of P7 rats ($n=3$). Using the same method to quantify the cell shrinkage as described previously, the result showed that at pH 5.7 there was $8 \pm 0.6\%$ (mean $\pm$ S.E.M.) cell shrinkage, whereas at pH 7.2 there was $7 \pm 1.5\%$ of cell shrinkage. These were not significantly different ($P<0.05$) and so we concluded that pH over this range had a

Fig. 5. Reduced volume and altered morphology of in situ GPC fixed within intact bone compared to those within bisected bones. Panels (a-c) showed the typical appearance of fluorescently (CMFDA-green)-labelled chondrocytes within intact (panel a) or bisected (panels b, c) bones, and fixed under the various conditions indicated. The shrinkage of some cells was observed in the fixed in situ cells (examples indicated with white arrows, panels a, b) but not in the osmotically-corrected fixative solution D (panel c). Panel (d) shows the appearance of unfixed (i.e., living) in situ hypertrophic GPCs labelled with calcein. All images were taken by CLSM using a x63 water-dipping objective. Cell volume measurements were performed as described (see Materials and Methods) with pooled data given in Table 4. Details of the composition of fixative solutions are given in Table 1. Scale bar = 20mm.
negligible effect on cell shrinkage compared to the osmolarity of the fixative solutions.

**Fixation of GPC using different concentrations and osmolarities of glutaraldehyde (GA) solution**

To test whether the osmolarity or concentration of fixative was responsible for the shrinkage artefact, whole bones were immersed in solutions with varying osmolarity (273-1141 mOsm) and standard fixative concentrations (GA 1%, RHT 0.7%; Table 2), or in solutions varying fixative concentration (GA 0.5-4%) whilst maintaining osmolarity relatively constant (555± 8 mOsm; Table 3). At the lowest osmolarity (273 ± 13 mOsm), cell shrinkage was minimal (13 ± 0.6% (3[44])), but as it was raised, there was a progressive and significant increase (ANOVA, P<0.001) in the extent of cell shrinkage (Fig. 4(A)). At the highest osmolarity studied (1141 mOsm) cell shrinkage was 52 ± 1.6% (3[44]) and significantly greater (unpaired Student’s t-test, P<0.001 for both) than the shrinkage observed in 273 and 467 mOsm solutions. When the GA concentration was varied over the range 0.5 to 4%, but with the osmolarity of all solutions maintained constant, the shrinkage of GPC fixed in intact bones with 1%, 2% and 4% GA was 15 ± 2.4%, 12 ± 0.5%, and 16 ± 2.1% respectively, and not significantly different (P>0.05; data from at least (5[44]); Fig. 4B). It was notable that GA at 0.5% showed an apparent slightly higher cell shrinkage (25 ± 4.1% (5[44]) compared to 1% GA, but this was not significantly different from the lowest cell shrinkage produced by GA at 2% (P>0.05). The morphology of a noticeable number of these cells was abnormal, suggesting that they were not properly fixed, and thus it was possible that the cells were susceptible to the post-fixation dehydration protocols (Mohamad Yusof Loqman, unpublished observations). Taken together, these data suggest that the shrinkage and morphological changes of GPC fixed using standard solutions could be accounted for by the osmolarity of the fixative solutions and not by the concentration of the fixative.

**In situ growth plate chondrocyte volume following fixation with solution A in intact and bisected bones**

The volume of in situ GPC within intact or sagittally-bisected bones and fixed under various conditions was also assessed using another method. Solution A was chosen as it had the highest osmolarity among the different conventional fixative solutions used in the present study, resulted in the greatest shrinkage artefact (which was easily measured), and has been used previously in the study of growth plate chondrocytes (see Table 1). Images of fluorescently-labelled in situ chondrocytes taken by CLSM showed the majority of cells with abnormal shrunken morphology in intact bone fixed with this solution (Fig. 5a). When the bone was sagittally bisected and then fixed using the same solution, the proportion of shrunken chondrocytes was markedly less (Fig. 5b), and similarly when these bones were fixed in the osmotically-corrected solution (solution D, Table 1) there were almost no shrunken cells observed (Fig. 5c) with the cells appearing morphologically normal. The volume of GPC fixed in the intact bone had a significantly reduced cell volume of almost two and half-fold less compared to the cells in the bisected bone (Table 4; unpaired t-test: P = 0.016, n=5). For comparison, GPC volume of living non-fixed bone and of bisected bones fixed in solution D were not significantly different from the GPC volume of bisected bone fixed in solution A (unpaired t-tests, P>0.05). However, the volume of GPC fixed in solution A showed no significant decrease compared to the volume of GPCs fixed in solution D and non-fixed GPC as expected due to cell shrinkage, as shown previously (Figure 3B). The reason for this was not immediately obvious, although it should be noted that the errors associated with the measurement of in situ GPC volume were relatively large (Table 4). In summary, the reduction in cell volume was significantly greater for GPC within intact bones compared to bisected bones when fixed in a conventional fixative solution (Table 4).

**Discussion**

This study demonstrated that the osmolarity of fixative solutions was of critical importance for maintaining the normal morphology of in situ hypertrophic chondrocytes within the mammalian growth plate following chemical fixation. The shrinkage artefact evident when using conventional fixatives, was abolished when the osmolarity of the medium was reduced close to that of normal physiological solutions or markedly reduced when the bones were sagittally bisected prior to fixation. These results raise important issues in relation to the accurate preservation of cell morphology by these widely-used chemical fixative solutions.

The first point to consider is the identification of a fixative concentration that ensured proper fixation of the

CMFDA-labelled in situ chondrocytes were fixed under the conditions shown (see Figure 5), their volume determined as described (see Materials and Methods) and the pooled data presented. Data (as means ± S.E.M.) are from n = 5 animals with 5-29 chondrocytes measured from each animal. *Denotes a significant difference (P<0.05; Student’s unpaired t-test) between the data for the intact bone and each of the data sets for the bisected bone sections.
cells/tissue without the osmolarity being too high to cause a shrinkage artefact and our data suggest that solution D was optimal (Table 1; Fig. 3). This osmolarity would be close to that normally present in physiological extracellular solutions meaning that the osmolarity of the cells within the extracellular matrix of the growth plate would similarly be optimal for normal chondrocyte morphology. (Note however that the exact extracellular osmolarity around the GPC will most likely be higher due to the presence of glycosaminoglycans present in the extracellular matrix (Urban et al., 1993)). A lower concentration of GA (0.5%) produced what appeared to be a shrinkage artefact (Fig. 4B) but although individual shrunken cells were present on visual examination, statistical analysis of pooled data showed this was not significant. However we would caution against using such a low concentration as the fine appearance of the cells suggested that there were cells that were not properly fixed, resulting in morphological changes/distortions during post-fixation protocols (Mohamad Yusof Loqman, unpublished observations). Previous studies have, however, successfully utilized low fixative concentrations. For example Maunsbach (1966) investigating the kidney and Hopwood (1967) studying the brain noted that GA was an effective fixative down to 0.25% (Hopwood, 1967; Maunsbach, 1966). It is possible that low fixative concentrations could be used successfully in these studies because of the different physical nature of hard tissues compared to soft tissues, as in the latter the diffusion rate and thus penetration of the fixative would be expected to be considerably greater. Our findings were in general agreement with a previous report that identified the importance of fixative osmolarity to produce correct soft tissue preservation. Mathieu et al., (1978) reported both the GA percentage and molarity of the fixative vehicle were of importance for the preservation of lung tissue. In this study, they noted the shrinkage was induced by the osmolarity of buffer and fixative combined, as evidenced by shape changes of erythrocytes in capillaries and small vessels of the trachea, and a reduction in the air-blood tissue barrier of the trachea with different fixative osmolalities. Higher fixative concentrations (e.g. 2-4% GA) could of course be used for some applications where cell shrinkage is not a concern (e.g. for tissue perfusion fixation (Santoreneos et al., 1998) or biomaterial fixation (Nuss et al., 2006)), but clearly the results from the present study emphasize the importance of researchers being aware of the potential for an osmotic shrinkage artefact to cell shape.

In the present study we included RHT (ruthenium hexamine trichloride) in most of the fixative solutions (Table 1). Hunziker et al., (1982) have proposed that this cationic dye stabilized the GPC plasma membrane within the lacuna by establishing electrostatic cross-linkage between anionic components within the plasma membrane and the proteoglycans of the pericellular matrix which surrounds chondrocytes. They suggested that this could prevent the rupture or detachment of the plasma membrane from the pericellular matrix when conventional aldehyde solutions were used simultaneously (Hunziker et al., 1982, 1992) (Fixative solutions B and C; Table 1). In our hands however, the presence of RHT could not prevent the shrinkage artefact (see Fig. 3). Thus, although the % shrinkage was not significantly different from the osmotically-corrected fixative solution (solution D) it was still clearly greater than the solution B & C. In addition, we routinely observed abnormal/shrunken cells (Fig. 2A panels b and c) as also observed in the original Hunziker et al. (1983) study. Therefore, although it is possible that RHT does protect against the shrinkage effect to some extent by stabilizing the cell membrane against the pericellular matrix, we feel that osmotic correction is the preferred procedure to eliminate the artefact (Fig. 3) and the presence of any abnormal cells (Fig. 2A panel d).

The nature of the chemical fixative is also an issue of importance as there is not one fixative suitable for all applications. For example, GA has been associated with antigen masking due to its excessive and aggressive cross-linking of proteins, and is therefore normally considered unsuitable for tissues intended for immunohistochemical staining (Renshaw, 2007). GA is usually used as a mixture with PFA termed Karnovsky’s fixative (Karnovsky, 1965) so as to take advantage of the latter which has rapid tissue penetration although the fixation rate is not as rapid as that of GA (Kiernan, 1999). Our view is that PFA (4%) alone, probably gives the best compromise between good cytological preservation and immunolocalization, while at the same time maintaining antigen masking to a minimum. However, as it is a fixative solution with high osmolarity (Table 1), tissues should be bisected beforehand to maximize rapid fixative access to limit undesirable cell shrinkage artefacts although it should be noted that they were still clearly apparent (Fig. 2B panel a) and still significant (~20% shrinkage, Fig. 3). We note that although 10% neutral buffered formalin is rarely used in growth plate studies, it is a widely used fixative for routine histology and histopathology (Renshaw, 2007). However it should be noted that its osmolarity (measured at approx. 1700mOsm; Mohamad Yusof Loqman, unpublished observations) is even higher than the fixatives used here and thus we would expect that the artefactual shrinkage would be even more marked than reported for solution A (4% PFA).

The finding that the shrinkage artefact was significantly reduced in bisected compared to whole bones, strongly suggested that the rate of penetration of the fixative compared to the osmotic changes to chondrocytes resulting from the high osmolarity of the fixative solutions are important. In the whole bone, the large shrinkage artefact suggested that osmotically-induced cell shrinkage occurred before the tissue was fixed. Thus when the bone was placed in the fixative solution, water movement out of the bones to the hyper-osmolar fixative solution occurred rapidly, and before the fixative fully penetrated the bone/cartilage matrix to fix the cells throughout the sample. Dempster (1960) has shown that fixatives obeyed the diffusion laws, that is, the depth penetrated (d) was proportional to the square root of time and the coefficient of diffusibility of the fixative, which was specific for each fixative. As the diffusion is directly proportional to the concentration gradient based on Fick’s Law (Mehrer, 2007), the diffusibility of the fixative molecules (PFA, FA, GA) through the extracellular matrix of the tissue will undoubtedly be less than that for water molecules because
of their different molecular shape and molecular weight. Thus, the diffusibility of the fixatives will be markedly less than that of water, leading to a greater shrinkage effect in thicker and denser tissues such as bone/cartilage, compared to ‘soft’ tissues such as brain and kidney. For thick tissues where preservation of cell morphology deep in the tissue is of importance, osmotic adjustment with lower fixation concentrations and longer fixation times would be advisable. Most workers set the fixation period using conventional fixatives of between 1-4 hrs, or even longer (Hopwood, 1969). The optimum time will depend on several factors including the physical properties of the tissue (e.g. bone/cartilage vs. brain) concentration of the fixative and thickness of tissue sections. Higher fixative concentration requires shorter fixation times (Monis et al., 1965) whereas thicker blocks and harder tissues will necessitate longer fixation times as the penetration of the fixative will be slower.

Our results demonstrated that the shrinkage artefact could also be significantly reduced – although not abolished – when the bone was bisected before being fixed in standard (high osmolarity) fixative solutions (Fig. 3). Bone bisection would markedly reduce the physical obstacles and diffusional distances thereby providing a more direct and far more rapid exposure of the GPC that were being visualized to the fixative solutions. The rate of fixation would thus be much more rapid compared to GPC within intact bone, although the fact that the shrinkage artefact was still present indicated that despite the increased access provided to the fixative, significant cell shrinkage still occurred before the tissue was effectively fixed (Fig. 3). However, the drawback with bone bisection as a manoeuvre to reduce the fixation artefact would be that it could cause physical trauma/death to the cells at the cut edge (Huntley et al., 2005) and unless care was taken with imaging protocols by optically sectioning deeper into the tissue, the damaged surface cells would be the ones that are visualized. Bone bisection would also release internal (physiological) pressures within the bone and result in the loss/damage to matrix constituents (loss of proteoglycans, damage to the collagenous network, altered ionic/osmotic environment) potentially leading to changes to the in vivo properties (volume/morphology) of chondrocytes prior to fixation (Guilak and Mow, 2000).

Our measurements of cell shrinkage by a histological method (Fig. 2A,B; Fig. 3) were supported to some extent by volume analysis of fluorescently-labelled living in situ GPC images taken by CLSM (Fig. 5 and Table 4). Although the latter technique was more time-consuming, it served as a useful additional and direct measure of cell volume to confirm the cell shrinkage due to hyper-osmolar fixatives. The results from this method clearly showed the reduction in the cell volume of chondrocytes fixed with PFA (4%) in intact bone compared to bisected bone (Table 4). We would have expected that in parallel with the histological shrinkage measurements (Fig. 3A, B), the volume of cells within the bisected bone samples would not have been reduced in the PFA solution to the same extent as cells fixed with the osmotically-corrected fixative solution. At present we do not have an explanation for this finding, but note that we did not find the volume method was as sensitive for detecting the chondrocyte shrinkage compared to the histological method.

Both of these approaches provided us with more accurate quantitative measurements of the cell shrinkage artefact, compared to previous indirect methods e.g. counting the number of cell nuclei per unit area of tissue (Fox et al., 1985). Previous studies had suggested fixation artefacts arose from subsequent steps in tissue processing e.g. during ethanol-induced dehydration and embedding (Hopwood, 1969). However our data suggested that before it was possible to determine these secondary artefacts resulting from further preparation of tissue for histological analysis, it was essential that as far as possible the fixed tissue was close to its native state by abolishing the osmotic shrinkage artefact reported here.

In summary, our study demonstrated that the high osmolarity of conventional fixatives caused a shrinkage artefact to chondrocytes within the hypertrophic zone of the mammalian growth plate. This was particularly noticeable when whole bones were fixed, but was still present when the bones were bisected prior to fixation. This problem could be avoided by adjusting the osmolarity of the fixatives to the osmotic pressure of normal extracellular fluids (~280mOsm). In conclusion, in order to preserve the normal volume/morphology of cells within tissue samples, careful consideration should be given to the osmotic pressure of the fixative solution.

Discussion with Reviewer

Reviewer I: 10% Neutral Buffered Formalin is probably the most widely used fixative for routine histology and histopathology. Was this fixative tested at all? Did the authors simply concentrate on fixatives considered specific for growth plates?

Authors: While 10% Neutral Buffered Formalin (also referred to as 4% formaldehyde (Renshaw, 2007)) is widely used for processing tissues for routine histology, its use in growth plate tissue fixation is rather uncommon compared to other conventional fixatives as tested in the present study. Accordingly we have not focussed on this fixative. We note that the osmolarity of the 10% neutral phosphate buffered formaldehyde solution measured in our laboratory was ~1700mOsm, and thus much higher than the osmolarity of the fixatives used in the present investigation. We would expect that the artefactual shrinkage produced by this fixative would be much more marked, and have included a comment on the use of this commonly used fixative compared to the other fixatives used in our study.
