Abstract

Wilms’ tumour (WT) is a pediatric tumor of the kidney that arises via failure of the fetal developmental program. The absence of identifiable mutations in the majority of WTs suggests the frequent involvement of epigenetic aberrations in WT. We therefore conducted a genome-wide analysis of promoter hypermethylation in WTs and identified hypermethylation at chromosome 5q31 spanning 800 kilobases (kb) and more than 50 genes. The methylated genes all belong to a, b, and c protocadherin (PCDH) gene clusters (Human Genome Organization nomenclature PCDHA, PCDHB, and PCDHG, respectively). This demonstrates that long-range epigenetic silencing (LRES) occurs in developmental tumors as well as in adult tumors. Bisulfite polymerase chain reaction analysis showed that PCDH hypermethylation is a frequent event found in all Wilms’ tumor subtypes. Hypermethylation is concordant with reduced PCDH expression in tumors. WT precursor lesions showed no PCDH hypermethylation, suggesting that de novo PCDH hypermethylation occurs during malignant progression. Discrete boundaries of the PCDH domain are delimited by abrupt changes in histone modifications; unmethylated genes flanking the LRES are associated with permissive marks which are absent from methylated genes within the domain. Silenced genes are marked with non-permissive histone 3 lysine 9 dimethylation. Expression analysis of embryonic murine kidney and differentiating rat metanephric mesenchymal cells demonstrates that Pcdh expression is developmentally regulated and that Pcdhg genes are expressed in blastemal cells. Importantly, we show that PCDHs negatively regulate canonical Wnt signalling, as short-interfering RNA–induced reduction of PCDH-encoded proteins leads to elevated b-catenin protein, increased b-catenin/T-cell factor (TCF) reporter activity, and induction of Wnt target genes. Conversely, over-expression of PCDHs suppresses b-catenin/TCF-reporter activity and also inhibits colony formation and growth of cancer cells in soft agar. Thus PCDHs are candidate tumor suppressors that modulate regulatory pathways critical in development and disease, such as canonical Wnt signaling.

Introduction

Wilms’ tumour (WT) represents a paradigm for cancer arising from disrupted development. Failure of the metanephric blastemal cells to undergo mesenchymal to epithelial transition, together with proliferation of these undifferentiated cells, is intrinsic to the development of Wilms’ tumours [1]. Thus WT predisposing genes are often critical in normal nephrogenesis. As the aetiology of WTs cannot be explained solely by the known genetic changes, we have evaluated epigenetic changes in WTs. Several epigenetic lesions have previously been identified in Wilms’ tumour, in particular loss of imprinting at chromosome 11p13 [2,3] and 11p15 [4], which we have shown to be early and independent events [5]. In common with other cancers, WTs also show tumour suppressor gene silencing which includes genes such as HACE1 (73% of tumours analysed) [6], RASSF1 (56%) [7], CASP9 (43%), MGMT (30%), RASSF5/NORE1 (15%), and CDKN2A (10–15%) [8]. In addition, we have recently shown over-expression of the GLIIPR1 gene resulting from promoter hypomethylation (87%) [9].
Author Summary

The development of tissues and organs in the human body requires carefully regulated production of proteins by cells. Proteins permit the growth and development of the many varied structures required for a healthy body. In many diseases, including some cancers, tissues and organs fail to develop as they should due to the normal production of proteins being changed. The work presented here shows that in Wilms’ tumor, a childhood cancer of the kidney, a large group of related proteins that are likely necessary for growth and development of a normal kidney are not produced properly. This is due to the production being switched off within the cancer cells. We show how these proteins, known as protocadherins, can themselves alter the function of other proteins already known to be important in normal growth and cancer. Thus our study increases our understanding of how protocadherins are important in normal growth and of how altering protocadherins may lead to disease, such as cancer.

In order to identify candidate genes involved in Wilms’ tumorigenesis, we undertook genome-wide analysis of promoter methylation. We have identified pronounced tumour-specific hypermethylation in a region spanning ~800 kb of chromosome 5q31. This region contains members of the PCDH superfamily in 3 multi-gene clusters (PCDHA@, PCDHB@ and PCDHG@) [10]. Hypermethylation of this locus is an example of long range epigenetic silencing, which has previously been reported in colorectal cancer at chromosome 2q14.2 [11], the MLH1 locus on 3p22 [12], and for the HOXA gene cluster on chromosome 7p15 in breast and lung cancers [13,14]. We demonstrate that silencing of gene expression is concomitant with DNA hypermethylation and repressive histone modifications. Although little is known about the functions of these clustered PCDHs, other members of the PCDH superfamily have been shown to have tumour suppressor activity, such as PCDH10 in various carcinomas [15,16] and PCDH8 in breast cancer [17]. Functional data presented here suggest that proteins encoded by the chromosome 5q31 PCDHs modulate the Wnt pathway and are candidate Wilms’ tumour suppressor genes.

Results

A large hypermethylated domain at 5q31 in Wilms’ tumor

Following methylated DNA immunoprecipitation (MeDIP, Figure S1A), the efficacy and specificity of the MeDIP protocol was verified using quantitative real-time polymerase chain reaction (PCR) of a constitutively methylated CpG island (CGI) at the H19 imprinting control region, demonstrating successful enrichment relative to input DNA. Specificity for methylated CGIs was shown by PCR of the RASSF1 5’ CGI. Amplification of a non-CGI sequence (an intragenic region of the TBP gene), was used as a negative control for methylated DNA enrichment (Figure S1B). Validated MeDIP DNA samples from human fetal kidney and Wilms’ tumours were then hybridised to Nimblegen HG18 Refseq promoter microarrays (MeDip-chip) to detect tumour-specific alterations in methylation.

Microarray data from 5 sporadic WTs were examined to identify promoters displaying tumour-specific hypermethylation (P<0.05, t-test). Overall we found 2043 hypermethylated genes. Significantly, a large subset of these targets were found in 2 or more tumours; pairwise comparisons showed that each individual tumour had between 12.0% and 33.7% (mean 23.8%) of hypermethylated targets in common with the other tumours analysed. The genomic distribution of recurrently hypermethylated genes was non-random (P<0.001, chi square test), with many being located together or within gene clusters (Table S1). Contiguous hypermethylated genes were more likely to be found in several tumours (13 out of 17 loci).

Strikingly, of 146 annotated genes hypermethylated in 3 or more tumours, 25 were PCDHs located at chromosome 5q31 and MeDIP-chip data revealed enriched tumour/normal ratios across 50 closely-linked CGIs spanning 800 kb on chromosome 5q31.3 (Figure 1A and Figure S1C). Hypermethylation at this locus was identified in all tumours examined (Table S2) and hypermethylated CGIs localise to PCDHA@, PCDHB@ and PCDHG@. Each PCDHB@ gene is encoded by a single, unspliced exon, while the PCDHA@ and PCDHG@ genes have unique 5’ exons splicing into cluster-specific constant region exons encoding invariant cytoplasmic domains [10]. Proximal and distal boundaries to the hypermethylated domain were apparent (Figure 1A) and, remarkably, tumour MeDIP signal was enriched at virtually all of the PCDH CGIs across the locus (Figure 1B). As a complementary screening approach, we also conducted enrichment of methylated DNA from the WiT49 Wilms’ tumour cell-line [18] using recombinant methyl-CpG binding domain (MBD) protein, which permitted microarray methylation profiling without probe DNA amplification. This analysis also showed hypermethylation of multiple PCDHs across the region (data not shown). Both genome-wide analyses identified genes previously known to be hypermethylated in Wilms’ tumour, such as RASSF1 (Table S2). Thus our genome-wide promoter analysis identifies a novel region of long-range epigenetic silencing in WTs on chromosome 5q31.3.

Long-range epigenetic modifications at 5q31 are common in Wilms’ tumour but not in preneoplastic lesions

We used combined bisulfite and restriction analysis (COBRA) to validate and characterise methylation in normal and tumour DNAs. Methylation profiles were consistent with the microarray data, and locus-wide hypermethylation was observed in all tumours and WT49 cells (Figure 1C and 1D). We also analysed an additional thirteen PCDHs that were identified as hypermethylated by MeDIP-chip, demonstrating that hypermethylation varied between individual tumours (Figure 1C and 1D). Of 19 PCDHG@ genes, 15 were hypermethylated according to COBRA and array analysis, together with 15/16 PCDHB@ genes and 13/15 PCDHA@ genes. Bisulfite sequencing data was consistent with COBRA and MeDIP-chip data (Figure 1E). In total, we analysed 38 WTs (Table S2) and all display hypermethylation of multiple PCDHs, with many PCDHs showing a very high frequency of hypermethylation in tumours. These include PCDHG4, hypermethylated in 24/27 tumours (89%), PCDHB8 (23/25, 92%), PCDHG2 (11/13, 85%) and PCDHB9 (21/33, 64%), COBRA analyses of PCDHAC1, PCDHAC2, PCDHB1, PCDHG3 and PCDHG5 showed no evidence of hypermethylation, consistent with MeDIP-chip data (Figure 1B and 1C and Table S2).

Analysis of PCDH methylation in microdissected perilobar nephrogenic rests, presumptive WT precursor lesions, revealed no PCDH hypermethylation (Figure S3) but hypermethylation was evident at the PCDHG4 and PCDHB4 genes in a set of stromal-predominant tumours (Figure S4). Taken together our data show that hypermethylation occurs at high frequencies in all WT subtypes, and strongly suggests that de novo methylation arises
during neoplastic progression from nephrogenic rest to Wilms’
tumour.

There was no tumour-specific hypermethylation apparent at
upstream and downstream CGIs within 100 kb (eight promoter
CGIs in total) of the PCDH clusters. A non-clustered proto-
cadherin gene on chromosome 5q31, PCDH1, 300 kb telomeric to
PCDHG8, was also unmethylated. Two non-PCDH genes are
situated within the methylated domain; SLC25A2 was constitu-
tively methylated in both normal tissues and tumours and TAF7
was constitutively unmethylated (Figure 1C and Figure S2). Thus,
their methylation is unaffected by the surrounding epigenetic
defect, and tumour-specific hypermethylation is specific to
clustered PCDHs.

Silencing of PCDH expression in Wilms’ tumour

Quantitative RT-PCR showed negligible PCDHA@ expression
in kidney. However, PCDHB@ and PCDHG@ transcripts were
readily detectable in fetal kidney, and consistent suppression of
methylated PCDHG@ transcripts was apparent in tumours relative
to kidney. Of 11 hypermethylated PCDHG@ genes analysed in our
tumour panel, 9 showed greater than 90% repression, with the
remaining 2 showing very low basal expression in fetal kidney. For
many PCDHs, expression in tumours was decreased over 100-fold
or below the limits of detection (Figure 2A). PCDHGC3 was
consistently unmethylated in WTs (Figure 1C), but PCDHGC3
expression was lowered in WTs relative to normal kidney
(Figure 2C). Interestingly, WT49 PCDH methylation and
expression reflects the general silencing pattern observed with
WTs (Figure 2B), but in addition to PCDHGC3, PCDHGA6 is also
unmethylated in WT49 cells. Despite the absence of hypermethy-
lation, reduced expression of both PCDHGA6 and PCDHGC3
transcripts relative to fetal kidney was apparent in WT49 cells.
Expression of PCDHGA6 was, however, further suppressed in WTs
with PCDHGA6 hypermethylation (Figure 2C).
Expression of PCDHB genes in tumours was more variable than the PCDHG genes. PCDHB8 and PCDHB15 exhibited strong methylation associated silencing but PCDHB12 was not consistently down-regulated in tumours, despite hypermethylation (Figure 2A). All seven methylated PCDHB genes analysed were, however, concordantly silenced in WT49 cells (Figure 2B). Unmethylated genes outside the LRES boundary, such as HARS2 and HDAC3, were not suppressed (Figure 2A and 2C).

To further establish the relationship between methylation and expression, we treated WT49 cells with 5-azacytidine, which induced the expression of epigenetically silenced PCDHB and PCDHG genes (Figure S5); in contrast, genes located outside the hypermethylated domain, which showed unaltered expression in tumours (Figure 2), were unaffected (Figure 2A and 2C).

In summary, our expression analyses demonstrate that PCDHB and PCDHG expression occurs in human kidney, and that epigenetic silencing of gene expression occurs in WT.

Figure 2. Silencing of PCDH expression in Wilms' tumour. (A) Expression levels of genes across the locus in 9 tumours (Texp), relative to the mean of 4 normal fetal kidney samples (N exp). Grey bars are used for genes showing tumour-specific hypermethylation, white bars for unmethylated genes and black bars for the constitutively methylated SLC25A2 gene. Expression of unmethylated genes (white bars), constitutively methylated genes (black bar) and hypermethylated PCDHs (grey bars) are shown. (B) Expression levels of 5q31 transcripts correspond with DNA methylation status in WT49 cells. Expression of unmethylated genes (white bars), constitutively methylated genes (black bar) and hypermethylated PCDHs (grey bars) are shown. (C) Suppression of methylated and unmethylated PCDHs within the chromosome 5q31 LRES. Gene expression levels relative to the house-keeping gene TBP are shown. Horizontal black line, median value; box, interquartile range; whiskers, data range excluding outliers; black dots, outliers (defined as those data points greater than range multiplied by inter-quartile range beyond the box). Grey boxes give samples shown to be hypermethylated, open boxes represent unmethylated samples.

Profiling of histone modifications at active and silenced genes within the 5q31 LRES

We compared permissive (histone 3 dimethyl lysine 4, H3K4me2; histone 3 acetyl lysine, H3Ac) and repressive (histone 3 dimethyl lysine 9, H3K9me2) histone modifications at gene loci across the PCDH domain (Figure 3) by chromatin immunoprecipitation analysis (ChIP). Genes located outside the PCDH domain were enriched for H3K4me2 and H3Ac. Conversely, methylated PCDHs were enriched for H3K9me2. Hypermethylated PCDH6, PCDH8 and PCDH10 genes all showed repressive histone modifications. As expected, the SLC25A2 (constitutively methylated) and TAF7 (unmethylated) genes were associated with repressive and permissive modifications, respectively. The PCDH6, PCDH10 and PCDH13 genes, which were not hypermethylated in the WT49 cell line, all had an active chromatin profile.

Comparison of gene expression levels, DNA methylation and histone marks (Figure 3, right panels) shows that DNA hypermethylation and silencing correlate with diminished H3Ac and
H3K4me2, whereas “active” promoters have high H3Ac and H3K4me2 levels (Spearman rank order correlation coefficient, $r = 0.67$, $P = 0.003$, and $r = 0.63$, $P = 0.006$ respectively). H3K9me2 shows an opposite pattern, that is high levels at methylated/silenced genes (Spearman rank order correlation coefficient, $r = 0.83$, $P = 0.0002$). The degree of H3K9me2 enrichment displays proportionality to gene silencing (Pearson correlation coefficient, $r = 0.88$). Thus tumour-specific DNA hypermethylation is strongly linked with specific, repressive chromatin modifications, whereas unmethylated genes within, and flanking the region maintain an active chromatin configuration.

PCDH expression in renal development and differentiation

Previous studies have indicated that PCDH expression is largely restricted to neuronal tissues [10]. As we found abundant expression of PCDH@ and PCDHG@ genes in human fetal kidney (Figure 2), we examined Pcdh@ and Pcdhg@ expression during murine kidney development. Similar to humans, Pcdh@ genes were expressed predominantly in brain, with negligible levels in kidney. In contrast, Pcdh@ and Pcdhg@ expression was abundant in kidney, with expression comparable to brain and exceeding placenta, liver and spleen. Transcript levels followed similar temporal profiles to Wt1, a mediator of mesenchymal-epithelial transition (Figure 4A). Postnatally, Pdhd expression decreases, in contrast to E-cadherin (Cdh1), where high expression levels are maintained in the mature organ. As our human expression analysis was restricted to comparing transcript levels in fetal kidney and Wilms’ tumours (Figure 2), we also assessed other human fetal tissues for PCDH@ encoded proteins by immuno-blotting in order to confirm abundant expression in fetal kidney. High expression was also evident in lung and brain, compared with moderate expression in gut. On longer exposure, low expression was also apparent in liver and spleen (Figure 4B).

In order to gain further insight on cell-type specific expression, we analysed Pcdh@ and Pcdhg@ transcript levels during epithelial differentiation of rat mesenchymal cells in organ culture. Freshly isolated metanephric mesenchymal cells were found to express high Pcdh@ levels, and epithelial differentiation induced by growth factors was accompanied by down-regulation of Pdhd6, Pdhd12 and Wt1. Pdhd2 and Pdhd3 were also decreased upon differentiation, but to a lesser extent (Figure 4C). As expected, a sharp rise in Cdh1 expression was observed, consistent with increasing epithelialisation.

Figure 3. Hypermethylation across the chromosome 5q31 LRES is associated with specific histone modifications. Bar charts (left) show ChIP–quantitative PCR measuring relative levels of specific histone modifications at individual gene loci across the 5q31 locus in WiT49 cells. (A) H3Ac ChIP, (B) H3K4me2 ChIP, (C) H3K9me2 ChIP, all expressed relative to input DNA. Scatter plots (right) show the relationship between relative gene expression levels and histone modifications at each gene. The x-axis shows specific histone levels relative to input DNA, and the y-axis shows mRNA expression in WiT49 cells (Texp) relative to average mRNA expression in 4 fetal kidney samples (Nexp). Grey bars/datapoints signify genes hypermethylated in WiT49, open bars/datapoints show unmethylated genes, and the black bar/datapoint shows constitutively methylated SLC25A2.

doi:10.1371/journal.pgen.1000745.g003
Figure 4. Developmental expression patterns of PCDHs. (A) PCDH transcript levels in mouse developmental tissues. Quantitative real-time expression analysis, relative to Tbp, in placenta (P), and E17.5 mouse fetal liver (Li), spleen (S), brain (B), and kidney (K) (E17.5, postnatal 0.5 week, 1 week, and 3 week) using assays specific for the constant region exons of Pcdha@ and Pcdhg@, and individual Pcdh transcripts. Expression of Wt1 and Cdh1 are also shown (black bars). (B) Immunoblotting of human fetal tissue proteins with pan γ-PCDH antibody or actin for loading control. Samples are kidney (K), liver (Li), lung (Lu), spleen (S), brain (B), and gut (G). (C) Gene expression changes accompanying epithelial differentiation of rat metanephric mesenchyme following Lif, Fgf2, and Tgfα treatment. Quantitative real-time expression analysis, relative to Tbp, is shown for freshly dissected rat metanephric mesenchyme (MM) and differentiating mesenchyme (DM). (D) Immunohistochemical analysis of 1-day postnatal murine kidney with antibodies towards Wt1 and γ-PCDHs. Blastema (b), primitive glomeruli (pg), and ureteric buds (u) are labelled. The control panel shows a section where the primary antibody has been omitted. Bar = 50 μm.

doi:10.1371/journal.pgen.1000745.g004
Comparison of expression levels in murine developmental samples and rat mesenchymal cells suggests that the mesenchyme may be the principal cellular component expressing PCDHs in developing kidney. We therefore assessed expression of *PcdhG* encoded proteins (γ-PCDHs) immunohistochemically in postnatal day 1 murine kidney (Figure 4D). High expression was evident in the blastemal cells, with decreasing and more variable expression apparent in tubules and parietal epithelia. Subcellular staining was variable and included nuclear staining, which is consistent with a role for the γ-PCDH intracellular domain in gene regulation [20,21]. Expression in the ureteric bud and visceral epithelia was low or absent. Thus γ-PCDH proteins are evident in the murine equivalent of the presumptive multipotent cell of origin for WT. This is consistent with PCDHs having a role in kidney development and Wilms’ tumorigenesis.

Modulation of canonical Wnt signalling by PCDHs

Little is known about PCDH cellular functions, but a member of the PCDH superfamily, PCDH-PC, was previously shown to positively regulate β-catenin/TCF signalling [22]. The Wnt signalling pathway, which utilises the β-catenin/TCF transcriptional complex to programme developmental gene expression, is essential for nephrogenesis [23]. Constitutive Wnt signalling brought about by compromised β-catenin function is also involved in several cancers including WT [24]. We therefore assessed the possible effects of γ-PCDH knockdown on β-catenin/TCF mediated transcription using luciferase reporter plasmids which contain a minimal promoter adjacent to 7 tandem TCF binding sites (Super8xTOPFLASH, [25]). Short-interfering RNAs (siRNAs) were designed to target the constant region sequences of *PCDHG* and transfected into WiT49 cells. Although WiT49 cells show extensive hypermethylation across the PCDH locus, specific PCDHs (for example, *PCDHG6* and *PCDHG12*) escape hypermethylation and are expressed, albeit at lower levels relative to fetal kidney (Figure 2C); WiT49 cells also exhibit intermediate Wnt signalling activity in the absence of β-catenin mutations, and are therefore suitable for investigating PCDH effects on the Wnt pathway.

The activity of the β-catenin/TCF reporter was increased by knockdown of γ-PCDHs, suggesting that γ-PCDHs negatively influence the canonical Wnt pathway. A second siRNA targeting a different sequence within the *PCDHG* constant region gave similar results, negating the possibility of off-target effects (data not shown). Reporter upregulation was abolished by *CTNNB1* siRNA co-transfection, demonstrating that enhanced TCF-mediated activation was β-catenin-dependent (Figure 5A). This was further supported by immunoblot analysis which showed that knockdown of γ-PCDHs was accompanied by elevated β-catenin protein levels (Figure 5A, inset), although *CTNNB1* transcript levels were unchanged (data not shown). Knockdown of γ-PCDHs also induced expression of known β-catenin/TCF target genes *CCND1*, *CMYC* and *PAX8*, as well as repression expression of *WT1* (Figure 5B). We also individually over-expressed *PCDHG2*, *PCDHG6* and *PCDHG12* in WiT49 cells, human embryonic kidney 293 cells (HEK293) treated with Wnt3a conditioned medium (CM) cells. A plasmid containing a cDNA encoding dominant-negative TCF4 (TCF4-DN) is also shown as a positive control. Cells were co-transfected with PCDH containing a cDNA encoding dominant-negative TCF4 (TCF4-DN) is also shown as a positive control. Cells were co-transfected with PCDH and transfected into WiT49 cells. Although WiT49 cells positively regulate β-catenin/TCF signalling [22]. The Wnt activity (Figure 5C). The latter cell-line is derived from a colorectal cancer with an activating β-catenin mutation [26,27] and also demonstrates increased cellular β-catenin accompanying γ-PCDH knockdown. As our epigenetic and functional analyses allude to a tumour suppressor function for PCDHs, we evaluated the effect of ectopic PCDH expression on tumour-related phenotype using cell-culture based assays commonly used for assessing tumour suppressor gene function, that is inhibition of colony formation and growth in soft agar [15]. Transfection of WiT49 cells with *PCDHG42*, *PCDHG6* or *PCDHG12* resulted in moderate PCDH protein expression leading to approximately 30–85% suppression of colony formation activity. Taken together, our data implicate *PCDHG* encoded proteins in negative modulation of canonical Wnt signalling.

As our epigenetic and functional analyses allude to a tumour suppressor function for PCDHs, we evaluated the effect of ectopic PCDH expression on tumour-related phenotype using cell-culture based assays commonly used for assessing tumour suppressor gene function, that is inhibition of colony formation and growth in soft agar [15]. Transfection of WiT49 cells with *PCDHG42*, *PCDHG6* or *PCDHG12* resulted in moderate PCDH protein expression leading to approximately 30–85% suppression of colony formation...
Similarly, transfection of HCT116 cells resulted in approximately 70% suppression of colony formation \((P<0.01)\), and transfection of HEK293 cells led to 60–85% suppression \((P<0.005)\) (Figure 6A). Suppression of colony formation was not a non-specific side-effect of gene overexpression, as transfection of HEK293 cells with \(CTNNB1\) cDNA encoding a degradation-resistant mutant of \(\beta\)-catenin failed to suppress colony formation (Figure S7).

We also assessed the effect of PCDH expression on anchorage-independent growth in soft agar using HCT116 cells (Figure 6B). Colony forming efficiency was markedly reduced by PCDHGA2, PCDHGA6 and PCDHGA12 relative to cells transfected with expression vector only (approximately 85%–95% suppression relative to the vector control).

Collectively, therefore, our experiments demonstrate that PCDHs regulate critical transduction and transcription pathways and have growth regulatory properties consistent with tumour suppressor activity.

**Discussion**

By conducting genome-wide promoter methylation analysis, we have identified a large cluster of paralogous PCDH genes on chromosome 5q31 which undergo hypermethylation in Wilms' tumours. Transcriptional silencing of PCDHs was prevalent in WTs, and PCDH hypermethylation constitutes the most frequent epigenetic silencing event in WT. This putative WT suppressor domain is the first report of LRES in childhood tumours. Our data also suggests roles for PCDHs in normal nephrogenesis, including modulation of key regulatory pathways such as canonical Wnt signalling.

LRES regions have been identified in several adult cancers including, breast [13], colon [11,12], head, neck and lung [14,28,29]. A recent genome-wide analysis of methylation in breast cancers showed that multiple agglomerative epigenetic aberrations occur, including regions undergoing hypermethylation and hypomethylation. Interestingly, the \(PCDH\) locus on chromosome 5q31 was one of several hypermethylated domains shown in breast cancer, together with others such as \(HOXD0\) on chromosome 2 and \(HIST1\) on chromosome 6 [30]. Such regions were also identified in our analysis (Table S1). Thus, in addition to gene-specific epigenetic lesions, our study shows that some, but not all, LRES domains are conserved between embryonal and adult cancers. Also individual genes within an LRES region can show tumour-type specific changes, illustrated by \(PCDHGC3\) which is frequently hypermethylated in breast cancer but which escapes methylation in WTs. The contribution of LRES to tumour pathology is not well characterised, but transcriptional suppression of multiple genes across a chromosomal region can be considered to be functionally analogous to cytogenetic loss.

Silencing of individual genes within the LRES domains on chromosome 2q and 3p in colorectal cancer appears to be dependent on a domain-wide non-permissive chromatin configuration, rather than the methylation status, as unmethylated genes within these domains and up to 1000 kb away are also suppressed.

**Figure 6. Growth inhibition by PCDHs.** (A) Suppression of WiT49, HCT116, and HEK293 cell colony formation following ectopic expression of PCDH cDNAs. After selection and staining, plates were photographed and colony counts determined for each transfection. Representative plates (left) and mean colony counts (right) are shown. Verification of PCDH protein expression after transfection, together with tubulin as a loading control is shown below the histograms. (B) Inhibition of anchorage-independent growth of HCT116 cells by PCDHs, cells were plated in triplicate and colonies formed after 10–14 days were photographed and counted within 10 random fields. Representative fields are shown (left) together with colony forming efficiency (CFE), expressed as percentage of colonies >50 \(\mu\)m diameter (right). Cell-based assays were repeated at least twice, and representative data are shown.

doi:10.1371/journal.pgen.1000745.g006
Expression of the Pdhs peaks in the last week of nephrogenesis; thereafter, expression decreases, in contrast to Cadh1, which encodes the epithelial cadherin, E-cadherin. Epithelial differentiation of rat metanephric mesenchyme cells in organ culture was also accompanied by decreasing levels of Pdha1 expression. A recent microarray analysis of gene expression with laser captured kidney components showed expression of Pdha13 and Pdha12 expression attenuating between the cap mesenchyme and renal vesicle [40]. Together with our expression analyses, this suggests that the Pdhs expression peak in murine nephrogenesis likely reflects the expansion of nephrogenic progenitors as kidney development nears completion [41]. Our Pdhs expression analyses in human fetal kidney, during murine nephrogenesis and in rat metanephric mesenchyme suggest that Pdhs may have hitherto uncharacterised roles in renal development. Although Pdha14 mutant mice, which undergo neurodegeneration and neonatal death in less than 12 hours, did not show a gross kidney phenotype, kidney defects were not explored in detail [42] (Wang & Sanes, personal communication). The early postnatal lethality observed with homozygous Pdha14 mutant mice would also preclude full assessment of effects on nephrogenesis, as murine kidney development continues in the first week following birth. Therefore we were unable to assess renal defects in Pdha14 null mice, we did examine postnatal kidney from heterozygous Pdha14 mutant mice (see Text S1), as heterozygous mutations of developmental genes such as Wt1 have been shown to result in end-stage renal disease [43]. Histological examination of kidneys from 3 month old heterozygotes showed no evidence of overt kidney malformations (Figure S8). However, it will clearly be of great interest to analyse a larger heterozygous cohort together with embryonic kidney from homozygous Pdha14 mutants in future studies.

The canonical Wnt signalling pathway is a prerequisite for initiating and maintaining mesenchymal to epithelial transitions during kidney development, and it is also known that mesenchyme with high β-catenin activity fails to form epithelial structures [44]. Thus attenuation of Wnt signalling is necessary during nephrogenesis. Importantly, our functional analysis shows that γ-Pdhs repress β-catenin/Tcf mediated transcription, with lowered Pcdh15 leading to elevated β-catenin protein, high β-catenin/Tcf reporter activity and induced expression of Wnt target genes. Conversely, ectopic expression of Pdhs was able to suppress β-catenin/Tcf reporter activity in heterologous cell systems. In contrast to Wnt target genes, Wt1 expression levels were reduced by Pcdh15 knockdown, demonstrating that Wnt target gene induction is not reflecting a generalised increase in transcription and that other regulatory networks are also influenced by cellular Pcdhs levels. The significance of these results is underlined by our findings of epigenetic silencing of Pcdhs in WT, as this would be predicted to lead to elevated β-catenin/Tcf activity. In this regard, it is notable that enhanced β-catenin signalling in WTs is observed more frequently than Ctnnb1 and Wtx mutations in WTs [45,46] and that Ctnnb1 mutation is, like Pcdh15 silencing, a late event in Wilms’ tumorigenesis. Although our analysis of Pcdhs on Wnt signalling can only approximate the permutational silencing in WTs, our results prompt the hypothesis that the canonical Wnt pathway is modulated by Pcdhs, and that in normal nephrogenesis, elevated Pcdhs serve to downregulate β-catenin activity, thereby permitting completion of epithelial differentiation. Epigenetic silencing of Pcdhs might contribute to deregulation of Wnt signalling, and a failure of mesenchymal to epithelial transition resulting in persistence of a progenitor cell pool and consequent Wilms’ tumorigenesis. Pcdhs may also have a role in the aetiology of other cancers, such as breast cancer,
where PCDH hypermethylation is prevalent [30] and activation of Wnt/β-catenin signalling occurs, despite mutations of Wnt pathway components being rare [47].

Although the mechanisms by which PCDHs influence pathways such as Wnt signalling require delineation, we note that, as well as encoding a nuclear moity capable of regulating gene expression directly [20,21], z- and γ-PCDHs have recently been reported to negatively regulate proline-rich tyrosine kinase 2 PYK2 [48] which was previously shown to phosphorylate β-catenin [49]. As phospho-regulation of β-catenin can promote interactions with transcriptional co-activators [50], we speculate that elevated PYK2 activity may arise as a consequence of PCDH silencing and thereby lead to a shift of the β-catenin adhesion/signalling balance. This and other downstream consequences of PCDH silencing warrant intensive future study.

Materials and Methods

Ethical statement

All human tissues were acquired with appropriate local research ethics committee approval and all animal procedures were conducted in accordance with regulations (UK Home Office) and international standards on animal welfare.

Patient samples

All tissues were obtained as snap frozen samples from the Bristol Children’s Hospital, the Royal Marsden Hospital and the University of Heidelberg Children’s Hospital. Human fetal tissue samples were from 19 to 31 weeks of gestation. Details of clinical samples are given in Table S3.

Cell culture, transfections, and reporter assays

WI3T19 [18], HCT116 [9] and HEK293 cell-lines (adenovirus transformed human embryonic kidney cells [51]) were cultured using standard methods in Dulbecco’s modified Eagle’s medium (DMEM) supplemented with 10% fetal calf serum, 2 mmol/l L-glutamine, 0.1 mg/ml penicillin/streptomycin, at 37°C under 5% CO2. L/Wnt5a fibroblast cell lines (ATCC, Manassas, VA) were grown in DMEM supplemented with 10% fetal calf serum, and Wnt5a conditioned medium was prepared according to the protocol provided by ATCC (http://www.atcc.org).

For knockdown analyses, cells were transfected with DharmaFECT DUO (Dharmacon, Inc.) with 50 nM total of ON-TARGETplus short interfering RNA (siRNA) duplexes. For β-catenin/TCF reporter activity assays, 105 cells/well were seeded in 24-well plates and 100 ng of Super 8xTOPFLASH or Super 8xFOPFLASH reporter plasmids were co-transfected with siRNAs and 24-well plates and transfected with 400 ng of expression plasmids in 6-well plates and plated in triplicate in 10 cm dishes 48 hours after transfection. Selection was performed with 200 μg/ml (HCT116) or 100 μg/ml (WI3T19) of zeocin (Invitrogen) for 2 weeks after which colonies were methylene blue stained and counted using ImageJ software (http://rshop.nih.gov/ij/). Colony formation assays were repeated at least twice.

Growth in soft agar was assessed essentially as previously described [15]. Briefly, 2.5×103 transfected HCT116 cells were suspended in DMEM medium containing 10% fetal calf serum, 0.35% agar, and 200 μg/ml zeocin. The suspension was then layered on 6 cm plates containing DMEM medium containing 10% fetal calf serum, 0.7% agar, and 200 μg/ml zeocin. Plating was carried out in triplicate and repeated at least twice. Cells were fed every 4–5 days, and after 10–14 days growth, colonies of greater than approximately 50 μm within 10 microscopic fields were counted under a phase contrast microscope. Colony forming efficiency is presented as percentage of colonies larger than 50 μm within total cells.

Methylated–DNA immunoprecipitation (MeDIP) and chromatin immunoprecipitation (ChIP)

High molecular weight genomic DNAs were extracted from tissues using standard phenol-chloroform techniques and fragmented to a size range of 200–500 base pairs using a Diagnode Bioruptor. Four micrograms of sonicated genomic DNA and 20 μg anti-5-methyl cytidine monoclonal antibody (Eurogentec, Liege, Belgium) were incubated at 4°C overnight in immunoprecipitation buffer, and then for a further 2 hours with goat anti-mouse IgG magnetic beads (N.E. Biolabs). After purification, MeDIP DNA was blunt-ended with T4 DNA polymerase (N.E. Biolabs) and ligation-mediated PCR (LM-PCR) was carried out as described [52,53]. DNAs were then sent to Nimblegen for labelling and hybridization to Nimblegen HG18 ReSeq promoter arrays. Data was analysed using ChipMonk v1.2.1 tiling array analysis software (Dr Simon Andrews, Babraham Institute, Cambridge UK, http://www.bioinformatics.bbsrc.ac.uk/projects/chipmonk). To identify hypermethylated CGIs, a log2ratio cut-off of 1.5 and a window of 500 bp was used to carry out the replicate t-test (P<0.05) on probes within 200 bp of predicted CpG islands (http://genome.ucsc.edu). Additional statistical analysis was carried out using R (http://www.r-project.org/). The array data reported in this paper have been deposited in the Gene Expression Omnibus (GEO) database, (http://www.ncbi.nlm.nih.gov/geo) under accession number GSE15027.

For PCDH over-expression studies, cDNAs were obtained by RT-PCR from fetal kidney RNA and cloned into pCDNA3.1/Zeo (Invitrogen). For β-catenin/TCF reporter assays, 105 cells/well were seeded in 24-well plates and transfected with 400 ng of expression constructs together with 100 μg Super 8xTOPFLASH or Super 8xFOPFLASH using Fugene 6 (Roche), and assayed for luciferase as described above. For colony formation assays, 2.5×103 HCT116 and WI3T19 cells were transfected with 1 μg of expression plasmids in 6-well plates and plated in triplicate in 10 cm dishes 48 hours after transfection. Selection was performed with 200 μg/ml (HCT116) or 100 μg/ml (WI3T19) of zeocin (Invitrogen) for 2 weeks after which colonies were methylene blue stained and counted using ImageJ software (http://rshop.nih.gov/ij/). Colony formation assays were repeated at least twice.

WI3T19 chromatin marks were assessed using a ChiP Kit (Upstate Biotechnology) with antibodies for histone 3 dimethyl lysine 4 (H3K4me2, Upstate Technology), histone 3 dimethyl lysine 9 (H3K9me2, Abcam), and histone 3 acetyl lysine (H3Ac, Upstate). Quantification using real-time PCR was carried out using the Stratagene MX3005P QPCR System (La Jolla, CA) along with the PlatinumSYBR green qPCR SuperMix-UDG (Invitrogen). Reactions volumes of 20 μl contained 10 μl of Platinum SYBRgreen qPCR SuperMix-UDG (Invitrogen, Paisley, UK), 30 nM ROX reference dye, 0.2 μM forward primer, 0.2 μM reverse primer, and 1.5 μl of ChiP DNA template. Primer sequences are available in Table S4.
Methylation and expression analysis

Up to 1 µg DNA was sodium bisulfite converted using the EZ DNA Methylation-Gold Kit (Zymo Research, CA). Amplicons for combined bisulfite restriction analysis (COBRA) and bisulfite sequencing were made using the Hot Start Red Taq PCR system (Sigma). Primers and restriction enzymes are available in Table S4. For bisulfite sequencing, PCR products were cloned into the pGEM-T-easy cloning vector (Promega), and fluorescently sequenced using standard M13 primer sequences.

For comparative quantitative Real-Time RT-PCR, 1 µg of DNase-treated (TURBO DNA-free, Ambion Inc, TX) total RNA was reverse-transcribed with oligo(dT)20 at 50°C for 1 h using the ThermoScript RT-PCR System (Invitrogen), Real-time PCR was performed using the Stratagene MX3005P QPCR System (La Jolla, CA) along with the Platinum SYBR green qPCR SuperMix-UDG (Invitrogen). Reactions volumes of 20 µl contained 10 µl of Platinum SYBR green qPCR SuperMix-UDG (Invitrogen, Paisley, UK), 50 nM ROX reference dye, 0.2 µM forward primer, 0.2 µM reverse primer, and 2.5 µl of 1:10 diluted cDNA template. Primer sequences are available in Table S4. Thermal cycling consisted of an initial incubation step of 50°C for 2 minutes and a denaturation step of 95°C for 10 minutes. This was followed by 40 cycles of 95°C/15 seconds, 58°C/30 seconds, 72°C/30 seconds. Gene expression was quantified by comparative Ct method, normalizing values to the housekeeping gene TBP. All assays were performed in duplicate.

Immunoblotting and immunohistochemistry

Protein extraction and immunoblotting were carried out essentially as previously described [2] with primary antibodies to β-catenin (Cell signalling), α-tubulin (Sigma) and the γ-PCDH constant region (Greg Phillips, Mount Sinai School of Medicine, USA). This pan-γ-PCDH antibody is a characterised afffinity-purified rabbit polyclonal against a GST-fusion protein containing the constant cytoplasmic domain encoded by purified rabbit polyclonal against a GST-fusion protein containing the constant cytoplasmic domain encoded by

 amplification using ligation-mediated PCR (LM-PCR), labelled and hybridised with promoter microarrays (B) Real-time RT-PCR of MeDIP-enriched tumour DNAs (upper). Enrichment was validated using primers specific to a non-CGI sequence within the TBP gene (grey bars), the constitutively methylated H19 imprinting control region (black bars), and selective enrichment of the methylated RASSF1 5′-CGI in a methylated and unmethylated tumour (open bars). MeDIP DNA was quantified relative to input DNA. The lower panel shows COBRA confirmation of H19 imprinting control region and the RASSF1 5′-CGI methylation status. Arrowheads show methylated (M) and unmethylated (UM) DNA fragments; presence or absence of restriction enzyme is indicated (+/−). (C) The Tumour (T) versus normal fetal kidney (N) signal ratio (y-axis) from 17,777 promoter-associated probes are plotted according to their physical location on chromosome 5 (x-axis) for 5 WT. Hypermethylation at 5q31 is indicated by the vertical arrow.

Figure S2 Methylation analysis of genes neighbouring the chromosome 5q31 PCDH cluster. Arrowheads show methylated (M) and unmethylated (UM) DNA fragments; presence or absence of restriction enzyme is indicated (+/−). M1+, in vitro methylated DNA (A) Distal neighbours of the clustered PCDHs in normal and tumour tissues. COBRA analysis of C141, TMC06, NDUFA2 and WDR55 5′-CGIs (located −153, −147, −139, and −119 kb upstream of the PCDH clusters, respectively), FK, 22-week fetal kidney; WT, five pooled WT DNAs. (B) 5′-CGI methylation analysis of the non-clustered PCDH1 gene (located 366 kb downstream of the PCDH clusters) was carried out on eleven WT using COBRA. 22-week foetal kidney, FK; FK2, 16-week foetal kidney.

Found at: doi:10.1371/journal.pgen.1000745.s002 (1.85 MB TIF)

Figure S3 Methylation analysis of PCDHB6 in WT precursor lesions. (A) COBRA analysis of PCDHB6 in DNA extracted from fetal kidney (FK), WT, and associated perilobar nephrogenic rests (NR). T, Wilms’ tumours. Arrowheads show methylated (M) and unmethylated (UM) DNA fragments; presence or absence of restriction enzyme is indicated (+/−). M+, in vitro methylated DNA. (B) Bisulfite sequencing analysis. Black circles represent methylated CpGs and white circles represent unmethylated CpGs.

Found at: doi:10.1371/journal.pgen.1000745.s003 (1.22 MB TIF)

Figure S4 PCDH hypermethylation in stromal-predominant Wilms’ tumours. COBRA was carried out for PCDHG3, PCDHGB4, and HDAC3. Arrowheads show methylated (M) and unmethylated (UM) DNA fragments; presence or absence of restriction enzyme is indicated (+/−). M+, in vitro methylated DNA.

Found at: doi:10.1371/journal.pgen.1000745.s004 (2.02 MB TIF)

Figure S5 Pharmacological demethylation of WT19 cells. Quantitative real-time RT-PCR of 5q31 transcripts, mock-treated (+) or 5-azacytidine treated (−) cells. Grey bars indicate genes associated with hypermethylated CGIs, white bars represent genes with CpG islands with no detectable methylation and black bars are used for SLC25A2, HPRT is an X-chromosome housekeeping control gene. DIAPH1 and HDAC3 are located on chromosome 5q31 outside the LRES. Expression data for PCDHB@ genes and PCDHG@ genes is shown relative to TBP, together with SLC25A2 and TAF7 genes, which are located within the LRES. Induction of the WT hypermethylated control genes RASSF1 and H19 is also shown.

Found at: doi:10.1371/journal.pgen.1000745.s005 (2.41 MB TIF)

Figure S6 Hypermethylation of PCDHG@, PCDHG@, PCDHG@, PCDHG@, and PCDHG@ in HCT116
cells demonstrated using COBRA analysis. Arrowheads show methylated (M) and unmethylated (UM) DNA fragments; presence or absence of restriction enzyme is indicated (+/−). Found at: doi:10.1371/journal.pgen.1000745.s006 (1.25 MB TIF)

Figure S7 Suppression of colony formation is not dependent on non-specific toxicity of transfected genes. Mutant β-catenin (Y33, tyrosine at amino-acid 33) expression does not suppress colony formation in HEK293 cells. HEK293 cells were transfected with CTNNA1 cDNA cloned in the same expression vector (pcDNA3.1/Zeo) as PCDH constructs. After selection and staining, plates were photographed and colony counts determined for each transfection. Representative plates (above) and mean colony counts (below) are shown. Verification of β-catenin protein expression after transfection is shown by immunoblotting below the histograms, together with tubulin to control loading. Found at: doi:10.1371/journal.pgen.1000745.s007 (1.35 MB TIF)

Figure S8 Kidneys of heterozygous Pcdh@ mutant mice show no malformations (see Text S1). Histology of three-month old wild-type (wt, n = 2) and heterozygous Pcdh@ mutant kidneys (het, n = 3) was examined on cryosections. Staining of adjacent sections with cresyl-violet (left column) and nuclear fast red (middle and right columns) was used to highlight the cytoarchitecture of the specimens. The overall morphology of the heterozygous kidneys appeared normal and showed no malformations. Scale bars = 500 μm. At higher magnifications, findings were comparable in three-month old wild-type and heterozygous littermates and displayed normal cytoarchitecture in aged heterozygous mice (boxed areas are shown in the right column, scale bars = 100 μm). Found at: doi:10.1371/journal.pgen.1000745.s008 (1.02 MB TIF)

Table S1 Wilms’ tumour hypermethylated genes identified by MeDIP-chip. Summary table of hypermethylated genes identified by MeDIP-chip in five Wilms’ tumours (P<0.05). Ensembl gene ID, gene symbol, and co-ordinates by chromosome and gene start (HG18 genome build) are given. The frequency of hypermethylation is given in the final column. Blanks in the Gene name column represent Refseq unannotated genes. Found at: doi:10.1371/journal.pgen.1000745.s009 (0.23 MB XLS)

Table S2 COBRA methylation summary. Methylation data from normal and tumour samples ascertained by combined bisulphite restriction analysis (COBRA). U, unmethylated; M, predominantly methylated; m, partially methylated. L and R, tumours of the left and right kidneys, respectively. Found at: doi:10.1371/journal.pgen.1000745.s010 (0.04 MB XLS)

Table S3 Clinical details of nephrogenic rests and Wilms’ tumours. Age at diagnosis: m, age in months. Histology: FH, favorable histology; UH, unfavorable histology; TR, triphasic; B, blastemal predominant; E, epithelial predominant; S, Stromal predominant; A, anaplastic; T, teratoid; R, regressive. Outcome: A, alive; R, relapsed; D, died. WT1 mutation: Y, yes; N, no. WT1 mutation details: G/L, germline. Blank entry, not done. Found at: doi:10.1371/journal.pgen.1000745.s011 (0.02 MB XLS)
