Abstract

We give a fully polynomial-time randomized approximation scheme (FPRAS) for the all-terminal network reliability problem, which is to determine the probability that, in a undirected graph, assuming each edge fails independently, the remaining graph is still connected. Our main contribution is to confirm a conjecture by Gorodezky and Pak (Random Struct. Algorithms, 2014), that the expected running time of the “cluster-popping” algorithm in bi-directed graphs is bounded by a polynomial in the size of the input.

Acknowledgements We thank Mark Huber for bringing reference [8] to our attention, Mark Walters for the coupling idea leading to Lemma 12, and Igor Pak for comments on an earlier version. We also thank the organizers of the “LMS – EPSRC Durham Symposium on Markov Processes, Mixing Times and Cutoff”, where part of the work is carried out.

1 Introduction

Network reliability problems are extensively studied \#P-hard problems [5] (see also [3, 22, 18, 2]). In fact, these problems are amongst the first of those shown to be \#P-hard, and the two-terminal version is listed in Valiant’s original thirteen [24]. The general setup is that in a given (undirected or directed) graph, every edge (or arc) $e$ has an independent probability $p_e$ to fail, and we are interested in various kinds of connectivity notions of the remaining graph. For example, the two-terminal connectedness [24] asks for the probability that for two vertices $s$ and $t$, $s$ is connected to $t$ in the remaining graph, and the (undirected) all-terminal network reliability asks for the probability of all vertices being connected after

Approximating Network Reliability

When \( p_e \) is independent of \( e \), \textsc{Reliability} is an evaluation of the Tutte polynomial. The Tutte polynomial is a two-variable polynomial \( T_G(x, y) \) associated with a graph \( G \), which encodes much interesting information about \( G \). As \((x, y)\) ranges over \( \mathbb{R}^2 \) or \( \mathbb{C}^2 \) we obtain a family of graph parameters, the so-called Tutte plane. As already noted, the study of the computational complexity of these parameters has a long history. \textsc{Reliability} with a uniform failure probability \( 0 < p < 1 \) is equivalent to evaluating the Tutte polynomial \( T_G(x, y) \) on the line \( x = 1 \) and \( y = \frac{1}{p} > 1 \). Our algorithm is the first positive result on the complexity of the Tutte plane since Jerrum and Sinclair presented an FPRAS for the partition function of the ferromagnetic Ising model, which is equivalent to the Tutte polynomial on the positive branch of the hyperbola \((x - 1)(y - 1) = 2\) [14]. It also answers a well-known open problem from 1980s, when the \#P-hardness of \textsc{Reliability} was established [13, 22] and the study of approximate counting initiated. This problem is explicitly proposed in, for example, [26, Conjecture 8.7.11] and [15]. We note that many conjectures by Welsh ([26, Chapter 8.7] and [27]) remain open, and we hope that our work is only a beginning to answering these questions.

Another related and important reliability measure is \textit{reachability}, introduced and studied by Ball and Provan [3]. A directed graph \( G = (V, A) \) with a distinguished root \( r \) is said to be \textit{root-connected} if all vertices can reach \( r \). Reachability, denoted \( Z_{\text{reach}}(G, r; \mathbf{p}) \) for failure probabilities \( \mathbf{p} = (p_e)_{e \in A} \), is the probability that, if each arc \( e \) fails with probability \( p_e \) independently, the remaining graph is still root-connected.

We define the computational problem formally.

Name \textsc{Reachability}

Instance A directed graph \( G = (V, A) \) with root \( r \), and failure probabilities \( \mathbf{p} = (p_e)_{e \in A} \).

Output \( Z_{\text{reach}}(G, r; \mathbf{p}) \).

Exact polynomial-time algorithms are known when the graph is acyclic [3] or has a small number of cycles [10]. However, in general the problem is \#P-hard [22].
Ball [1] showed that Reliability is equivalent to Reachability in bi-directed graphs. A bi-directed\(^2\) graph is one where every arc has an anti-parallel twin with the same failure probability. It is shown [1] that \(Z_{\text{rel}}(G; p) = Z_{\text{reach}}(\overrightarrow{G}; r; p')\), where \(\overrightarrow{G}\) and \(p'\) are obtained by replacing every undirected edge in \(G\) with a pair of anti-parallel arcs having the same failure probability in either direction, and \(r\) is chosen arbitrarily. See Lemma 12.

Our FPRAS for Reliability utilizes this equivalence via approximating Reachability in bi-directed graphs. The core ingredient is the “cluster-popping” algorithm introduced by Gorodezky and Pak [8]. The goal is to sample root-connected subgraphs with probability proportional to their weights, and then the reduction from counting to sampling is via a sequence of contractions. A cluster is a subset of vertices not including the root and without any out-going arc. The sampling algorithm randomizes all arcs independently, and then repeatedly resamples arcs going out from minimal clusters until no cluster is left, at which point the remaining subgraph is guaranteed to be root-connected. This approach is similar to Wilson’s “cycle-popping” algorithm [28] for rooted spanning trees, and to the “sink-popping” algorithm [4] for sink-free orientations. Gorodezky and Pak [8] have noted that cluster-popping can take exponential time in general, but they conjectured that in bi-directed graphs, the algorithm runs within polynomial-time.

We confirm this conjecture. Let \(p_{\text{max}}\) be the maximum failure probability of edges (or arcs). Let \(m\) be the number of edges (or arcs) and \(n\) the number of vertices.

\[\textbf{Theorem 1.} \text{ There is an FPRAS for Reliability (or equivalently, Reachability in bi-directed graphs). The expected running time is } O\left(\varepsilon^{-2}p_{\text{max}}(1 - p_{\text{max}})^{-3}m^2n^3\right) \text{ for an } (1 \pm \varepsilon)\text{-approximation. There is also an exact sampler to draw (edge-weighted) connected subgraphs with expected running time at most } p_{\text{max}}(1 - p_{\text{max}})^{-1}m^2n.\]

We analyze the “cluster-popping” algorithm [8] under the partial rejection sampling framework [9], which is a general approach to sampling from a product distribution conditioned on avoiding a number of “bad” events. Partial rejection sampling is inspired by the Moser-Tardos algorithm for the Lovász Local Lemma [20]. It starts with randomizing all variables independently, and then gradually eliminating “bad” events. At every step, we need to find an appropriate set of variables to resample. We call an instance extremal [19, 23], if any two bad events are either disjoint or independent. For extremal instances, the resampling set can be simply chosen to be the set of all variables involved in occurring bad events [9], and the algorithm becomes exactly the same as the Moser-Tardos resampling algorithm [20]. In particular, all three “popping” algorithms [28, 4, 8] are special cases of partial rejection sampling for extremal instances. In case of “cluster-popping”, the bad events are exactly minimal clusters.

The advantage of the partial rejection sampling treatment is that we have an explicit formula for the expected number of resampling events for any extremal instance [19, 9], which equals to the ratio between the probability of having exactly one bad event and the probability of avoiding all bad events. In order to bound this ratio, we use a combinatorial encoding idea and design a mapping from subgraphs with a unique minimal cluster to root-connected subgraphs. To make this mapping injective, we record an extra vertex and an arc so that we can recover the pre-image. This extra cost is upper-bounded by a polynomial in the size of the graph.

\[^2\text{ There are other definitions of “bi-directed graphs” in the literature. Our definition is sometimes also called a symmetric directed graph.}\]
Cluster-popping only draws root-connected subgraphs in the bi-directed setting. In order to sample connected subgraphs in the undirected setting, we provide an alternative proof of the equivalence between Reliability and Reachability in bi-directed graphs, which essentially is a coupling argument. This coupling has a new consequence that, once we have a sample of a root-connected subgraph, it is easy to generate a connected subgraph according to the correct distribution.

In Section 2 we introduce the “cluster-popping” algorithm and the partial rejection framework. In Section 3 we analyze its running time in bi-directed graphs. For completeness, in Section 4 we include the approximate counting algorithm due to Gorodezky and Pak [8]. In Section 5 we give a coupling proof of the equivalence between Reliability and Reachability in bi-directed graphs. In Section 6 we conclude by mentioning a few open problems.

2 Cluster-popping

Let \( G = (V, A) \) be a directed graph with root \( r \). The graph \( G \) is called root-connected if there is a directed path in \( G \) from every non-root vertex to \( r \). Let \( 0 < p_e < 1 \) be the failure probability of arc \( e \), and define the weight of a subgraph \( S \) to be \( \text{wt}(S) := \prod_{e \in S} (1 - p_e) \prod_{e \not\in S} p_e \). Then reachability, \( Z_{\text{reach}}(G, r; p) \), is defined as follows,

\[
Z_{\text{reach}}(G, r; p) := \sum_{S \subseteq A, (V, S) \text{ is root-connected}} \text{wt}(S).
\]

Here, \( p = (p_e : e \in A) \) denotes the vector of failure probabilities.

Let \( \pi_G(\cdot) \) (or \( \pi(\cdot) \) for short) be the distribution resulting from choosing each arc \( e \) independently with probability \( 1 - p_e \), and conditioning on the resulting graph being root-connected. In other words, the support of \( \pi(\cdot) \) is the collection of all root-connected subgraphs, and the probability of each subgraph \( S \) is proportional to its weight \( \text{wt}(S) \). Then \( Z_{\text{reach}}(G, r; p) \) is the normalizing factor of the distribution \( \pi(\cdot) \). Gorodezky and Pak [8] have shown that approximating \( Z_{\text{reach}}(G, r; p) \) can be reduced to sampling from \( \pi(\cdot) \) when the graph is bi-directed.

The “cluster-popping” algorithm of Gorodezky and Pak [8], to sample root-connected subgraphs from \( \pi(\cdot) \), can be viewed as a special case of partial rejection sampling [9] for extremal instances. With every arc \( e \) of \( G \) we associate a random variable that records whether that arc has failed. Bad events are characterized by the following notion of clusters.

\begin{definition}
In a directed graph \( (V, A) \) with root \( r \), a subset \( C \subseteq V \) of vertices is called a cluster if \( r \not\in C \) and there is no arc \( u \to v \in A \) such that \( u \in C \) and \( v \not\in C \).

We say \( C \) is a minimal cluster if \( C \) is a cluster and for any proper subset \( C' \subset C \), \( C' \) is not a cluster.
\end{definition}

If \( (V, A) \) contains no cluster, then it is root-connected. For each vertex \( v \), let \( A_{\text{out}}(v) \) be the set of outgoing arcs from \( v \). We also abuse the notation to write \( A_{\text{out}}(S) = \bigcup_{v \in S} A_{\text{out}}(v) \) for a subset \( S \subset V \) of vertices. Notice that \( A_{\text{out}}(S) \) contains edges between vertices inside \( S \). To “pop” a cluster \( C \), we re-randomize all arcs in \( A_{\text{out}}(C) \). However, re-randomizing clusters does not yield the desired distribution. We will instead re-randomize minimal clusters.

\footnote{It is easy to see that in a undirected graph, reachability is the same as all-terminal reliability.}
Algorithm 1 Cluster Popping.

Let $S$ be a subset of arcs by choosing each arc $e$ with probability $1 - p_e$ independently.

while There is a cluster in $(V,S)$ do

Let $C_1, \ldots, C_k$ be all minimal clusters in $(V,S)$, and $C = \bigcup_{i=1}^{k} C_i$.

Re-randomize all arcs in $A_{out}(C)$ to get a new $S$.

end while

return $S$.

Claim 3. Any minimal cluster is strongly connected.

Proof. Let $C$ be a minimal cluster, and $v \in C$ be an arbitrary vertex in $C$. We claim that $v$ can reach all vertices of $C$. If not, let $C'$ be the set of reachable vertices of $v$ and $C' \subset C$. Since $C'$ does not have any outgoing arcs, $C'$ is a cluster. This contradicts to the minimality of $C$.

Claim 4. If $C_1$ and $C_2$ are two distinct minimal clusters, then $C_1 \cap C_2 = \emptyset$.

Proof. By Claim 3, $C_1$ and $C_2$ are both strongly connected components. If $C_1 \cap C_2 \neq \emptyset$, then they must be identical.

For every subset $C \subseteq V$ of vertices, we define a bad event $B_C$, which occurs if $C$ is a minimal cluster. Observe that $B_C$ relies only on the status of arcs in $A_{out}(C)$. Thus, if $C_1 \cap C_2 = \emptyset$, then $B_{C_1}$ and $B_{C_2}$ are independent, even if some of their vertices are adjacent. By Claim 4, we know that two bad events $B_{C_1}$ and $B_{C_2}$ are either independent or disjoint. Thus the aforementioned extremal condition is met. Moreover, it was shown [9, Theorem 8] that if the instance is extremal, then at every step, we only need to resample variables involved in occurring bad events. This leads to the cluster-popping algorithm of Gorodezky and Pak [8], which is formally described in Algorithm 1.

The correctness of Algorithm 1 is first shown by Gorodezky and Pak [8]. It can also be easily verified using [9, Theorem 8].

Theorem 5 ([8, Theorem 2.2]). The output of Algorithm 1 is drawn from $\pi_G$.

An advantage of thinking in the partial rejection sampling framework is that we have a closed form formula for the expected running time of these algorithms on extremal instances. Let $\Omega_k$ be the collection of subgraphs with $k$ minimal clusters, and $Z_k := \sum_{S \in \Omega_k} \text{wt}(S)$. Then $Z_0 = Z_{\text{reach}}(G,r;p)$, since any subgraph in $\Omega_0$ has no cluster and is thus root-connected.

Theorem 6 ([9]). Let $T$ be the number of resampled events of the partial rejection sampling algorithm for extremal instances. Then $\mathbb{E} T = Z_1 Z_0^{-1}$. In particular, for Algorithm 1, $T$ is the number of popped clusters.

The less-than-or-equal-to direction of Theorem 6 was shown by Kolipaka and Szegedy [19], which is the direction we will need later. The other direction is useful to show running-time lower bounds, but that is not our focus in this paper.

3 Running time of Algorithm 1 in bi-directed graphs

Gorodezky and Pak [8] have given examples of directed graphs in which Algorithm 1 requires exponential time. In the following we focus on bi-directed graphs. A graph $G$ is called bi-directed if $u \rightarrow v$ is present in $G$, then $v \rightarrow u$ is present in $G$ as well, and the failure
Approximating Network Reliability

We replace each strongly connected component by a single vertex. For a vertex $u$, we construct an injective mapping $\phi: \Omega_1 \rightarrow \Omega_0 \times V \times A$. For each subgraph $S \in \Omega_1$, $\phi(S)$ is defined by “repairing” $S$ so that no minimal cluster is present. We choose in advance an arbitrary ordering of vertices and arcs. Let $C$ be the unique minimal cluster in $S$ and $v$ be the first vertex in $C$. Let $R$ denote the set of all vertices which can reach the root $r$ in the subgraph $S$. Since $S \in \Omega_1$, $R \neq \emptyset$. Let $U = V \setminus R$. Since $G$ is root-connected, there is an arc in $A$ from $U$ to $R$. Let $u \rightarrow w'$ be the first such arc, where $u \in U$ and $w' \in R$. We let $\phi(S) := (S_{fix}, v, u \rightarrow w')$,

where $S_{fix} \in \Omega_0$ is defined next. Figure 1 is an illustration of these objects.

Consider the subgraph $H = (U, S[U])$, where

$$S[U] := \{ x \rightarrow y \mid x \in U, y \in U, x \rightarrow y \in S \}.$$ 

We consider the directed acyclic graph (DAG) of strongly connected components of $H$, and call it $\tilde{H}$. (We use the decoration $\hat{\cdot}$ to denote arcs, vertices, etc. in $\tilde{H}$.) To be more precise, we replace each strongly connected component by a single vertex. For a vertex $w \in U$, let $[w]$ denote the strongly connected component containing $w$. For example, $[v]$ is the same as the minimal cluster $C$ by Claim 3. We may also view $[w]$ as a vertex in $\tilde{H}$ and we do not distinguish the two views. The arcs in $\tilde{H}$ are naturally induced by $S[U]$. Namely, for $[x] \neq [y]$,

an arc $[x] \rightarrow [y]$ is present in $\tilde{H}$ if there exists $x' \in [x], y' \in [y]$ such that $x' \rightarrow y' \in S$.

We claim that $\tilde{H}$ is root-connected with root $[v]$. This is because $[v]$ must be the unique sink in $\tilde{H}$ and $\tilde{H}$ is acyclic. If there is another sink $[w]$ where $v \not\in [w]$, then $[w]$ is a minimal cluster in $H$. This contradicts $S \in \Omega_1$.

Since $\tilde{H}$ is root-connected, there is at least one path from $[u]$ to $[v]$. Let $\tilde{W}$ denote the set of vertices of $\tilde{H}$ that can be reached from $[u]$ in $\tilde{H}$ (including $[u]$), and $W := \{ x \mid [x] \in \tilde{W} \}$. Then $W$ is a cluster and $[u]$ is the unique source in $\tilde{H}[\tilde{W}]$. As $\tilde{H}$ is root-connected, $[v] \in \tilde{W}$. Define

$$S_{flip} := \{ x \rightarrow y \mid [x] \neq [y], x, y \in W', \text{ and } x \rightarrow y \in S \},$$

which is the set of edges to be flipped. Notice that $S[W]$ is different from $S_{flip}$, namely all arcs that are inside strongly connected components are ignored in $S_{flip}$. Now we are ready to define $S_{fix}$. We reverse all arcs in $S_{flip}$ and add the arc $u \rightarrow w'$ to fix the minimal cluster.

![Figure 1](image-url)
we can recover all arcs in vertices reachable from $W$. However this makes the argument less intuitive.

What is left to do is to recover arcs in $S[U']$. To do so, we need to find out which arcs have been flipped. We claim that $\tilde{H}_{\text{fix}}$ is acyclic. Suppose there is a cycle in $\tilde{H}_{\text{fix}}$. Since $\tilde{H}$ is acyclic, the cycle must involve flipped arcs and thus vertices in $\tilde{W}$. Let $[x] \in \tilde{W}$ be the lowest one under the topological ordering of $\tilde{H}[\tilde{W}]$. Since $\tilde{W}$ is a cluster, the outgoing arc $[x] \rightarrow [y]$ along the cycle in $\tilde{H}_{\text{fix}}$ must have been flipped, implying that $[y] \in \tilde{W}$ and $[y] \rightarrow [x]$ is in $\tilde{H}[\tilde{W}]$. This contradicts to the minimality of $[x]$. Since $\tilde{H}_{\text{fix}}$ is acyclic, the strongly connected components of $H_{\text{fix}} := (U, S_{\text{fix}}[U])$ are identical to those of $H = (U, S[U])$. Hence contracting all strongly connected components of $H_{\text{fix}}$ results in exactly $\tilde{H}_{\text{fix}}$. All we need to recover now is the set $\tilde{W}$. Let $\tilde{W}'$ be the set of vertices reachable from $[v]$ in $\tilde{H}_{\text{fix}}$. It is easy to see that $\tilde{W} \subseteq \tilde{W}'$. We claim that actually $\tilde{W} = \tilde{W}'$. For any $[x] \in \tilde{W}'$, there is a path from $[v]$ to $[x]$ in $\tilde{H}_{\text{fix}}$. Suppose $[x] \notin \tilde{W}$. Since $[v] \in \tilde{W}$, we may assume that $[y]$ is the first vertex along the path such that $[y] \rightarrow [z]$ where $[z] \notin \tilde{W}$. Thus $[y] \rightarrow [z]$ has not been flipped and is present in $\tilde{H}$. However, this contradicts the fact that $\tilde{W}$ is a cluster in $\tilde{H}$.

To summarize, given $S_{\text{fix}}$, $u \rightarrow u'$, and $v$, we may uniquely recover $S$. Hence the mapping $\varphi$ is injective. Moreover, flipping arcs does not change the weight as $p_v = p_{\hat{e}}$, and only adding the arc $u \rightarrow u'$ would. We have that $\text{wt}(S_{\text{fix}}) = \frac{1}{p_v - p_{u \rightarrow u'}} \text{wt}(S)$. The lemma follows.

Figure 2 is an example of these objects we defined.

Let $\tilde{H}_{\text{fix}}$ be the graph obtained from $\tilde{H}$ by reversing all arcs induced by $S_{\text{flip}}$. Observe that $[u]$ becomes the unique sink in $\tilde{H}_{\text{fix}}[\tilde{W}]$ (and $[v]$ becomes the unique source).

We verify that $S_{\text{fix}} \in \Omega_0$. For any $x \in R$, $x$ can still reach $r$ in $(V, S_{\text{fix}})$ since the path from $x$ to $r$ in $(V, S)$ is not changed. Since $u \rightarrow u' \in S_{\text{fix}}$, $u$ can reach $u' \in R$ and hence $r$. For any $y \in W$, $y$ can reach $u$ as $[u]$ is the unique sink in $\tilde{H}_{\text{fix}}[\tilde{W}]$. For any $z \in U \setminus W$, $z$ can reach $v \in W$ since the path from $z$ to $v$ in $(V, S)$ is not changed.

Next we verify that $\varphi$ is injective. To do so, we show that we can recover $S$ given $S_{\text{fix}}$, $u \rightarrow u'$, and $v$. First remove $u \rightarrow u'$ from $S_{\text{fix}}$. The set of vertices which can reach $r$ in $(V, S_{\text{fix}} \setminus \{u \rightarrow u'\})$ is exactly $R$ in $(V, S)$. Namely we can recover $U$ and $R$. As a consequence, we can recover all arcs in $S$ that are incident with $R$, as these arcs are not changed.

What is left to do is to recover arcs in $S[U]$. To do so, we need to find out which arcs have been flipped. We claim that $\tilde{H}_{\text{fix}}$ is acyclic. Suppose there is a cycle in $\tilde{H}_{\text{fix}}$. Since $\tilde{H}$ is acyclic, the cycle must involve flipped arcs and thus vertices in $\tilde{W}$. Let $[x] \in \tilde{W}$ be the lowest one under the topological ordering of $\tilde{H}[\tilde{W}]$. Since $\tilde{W}$ is a cluster, the outgoing arc $[x] \rightarrow [y]$ along the cycle in $\tilde{H}_{\text{fix}}$ must have been flipped, implying that $[y] \in \tilde{W}$ and $[y] \rightarrow [x]$ is in $\tilde{H}[\tilde{W}]$. This contradicts to the minimality of $[x]$. Since $\tilde{H}_{\text{fix}}$ is acyclic, the strongly connected components of $H_{\text{fix}} := (U, S_{\text{fix}}[U])$ are identical to those of $H = (U, S[U])$. Hence contracting all strongly connected components of $H_{\text{fix}}$ results in exactly $\tilde{H}_{\text{fix}}$. All we need to recover now is the set $\tilde{W}$. Let $\tilde{W}'$ be the set of vertices reachable from $[v]$ in $\tilde{H}_{\text{fix}}$. It is easy to see that $\tilde{W} \subseteq \tilde{W}'$. We claim that actually $\tilde{W} = \tilde{W}'$. For any $[x] \in \tilde{W}'$, there is a path from $[v]$ to $[x]$ in $\tilde{H}_{\text{fix}}$. Suppose $[x] \notin \tilde{W}$. Since $[v] \in \tilde{W}$, we may assume that $[y]$ is the first vertex along the path such that $[y] \rightarrow [z]$ where $[z] \notin \tilde{W}$. Thus $[y] \rightarrow [z]$ has not been flipped and is present in $\tilde{H}$. However, this contradicts the fact that $\tilde{W}$ is a cluster in $\tilde{H}$.

To summarize, given $S_{\text{fix}}$, $u \rightarrow u'$, and $v$, we may uniquely recover $S$. Hence the mapping $\varphi$ is injective. Moreover, flipping arcs does not change the weight as $p_v = p_{\hat{e}}$, and only adding the arc $u \rightarrow u'$ would. We have that $\text{wt}(S_{\text{fix}}) = \frac{1}{p_v - p_{u \rightarrow u'}} \text{wt}(S)$. The lemma follows.

We remark that an alternative way of repairing $S$ in the proof above is to reverse all arcs in $S[W]$ without defining $S_{\text{flip}}$. The key point is that doing so leaves the strongly connected components intact. However this makes the argument less intuitive.
Let $p_{\text{max}} = \max_{e \in A} p_e$. Combining Theorem 6 and Lemma 7, we have the following theorem. Notice that for each popping, we resample only a subset of arcs.

**Theorem 8.** Let $T$ be the expected number of popped clusters in Algorithm 1. For a root-connected bi-directed graph $G = (V, A)$, $\mathbb{E} T \leq \frac{p_{\text{max}}}{1 - p_{\text{max}}} mn$, where $n = |V|$, and $m = |A|$. The expected running time is at most $\frac{p_{\text{max}}}{1 - p_{\text{max}}} m^2 n$.

4 Approximate counting

We include the approximate counting algorithm of Gorodezky and Pak [8] for completeness. Let $G = (V, A)$ be an instance of Bi-directed Reachability with root $r$ and parameters $p$. We construct a sequence of graphs $G_0, \ldots, G_{n-1}$ where $n = |V|$ and $G_0 = G$. Given $G_{i-1}$, choose two arbitrary adjacent vertices $u_i$ and $v_i$, remove all arcs between $u_i$ and $v_i$ (in either direction), and identify $u_i$ and $v_i$ to get $G_i = (V_i, A_i)$. Namely we contract all arcs between $u_i$ and $v_i$, but parallel arcs in the resulting graph are preserved. If one of $u_i$ and $v_i$ is $r$, the new vertex is labelled $r$. Thus $G_{n-1} = \{r\}$. Since $A_i$ is always a subset of $A$, we denote by $p$, the parameters $p$ restricted to $A_i$.

For $i = 1, \ldots, n-1$, define a random variable $R_i$ as follows:

$$
R_i := \begin{cases} 
1 & (V_{i-1}, S_{i-1}) \text{ is root-connected in } G_{i-1}; \\
0 & \text{otherwise,}
\end{cases}
$$

where $S_{i-1} \subset A_{i-1}$ is a random root-connected subgraph drawn from the distribution $\pi_{G_i}(\cdot)$, together with all arcs $e$ between $u_i$ and $v_i$ added independently with probability $1 - p_e$. It is easy to see that

$$
\mathbb{E} R_i = \frac{Z_{\text{reach}}(G_{i-1}, r; p_{i-1})}{Z_{\text{reach}}(G_i, r; p_i)}, \quad \text{and} \quad Z_{\text{reach}}(G, r; p) = \prod_{i=1}^{n-1} \mathbb{E} R_i.
$$

Let $p_{\text{max}} = \max_{e \in A} p_e$ and $s = \lceil 5(1 - p_{\text{max}})^{-1}(n - 1)\epsilon^{-2}\rceil$ where $s$ is the desired precision. We estimate $\mathbb{E} R_i$ by the empirical mean of $s$ independent samples of $Z_i$, denoted by $\tilde{R}_i$, and let $\tilde{Z} = \prod_{i=1}^{n-1} \tilde{R}_i$ and $Z = Z_{\text{reach}}(G, r; p)$. Gorodezky and Pak [8] showed the following.

** Proposition 9 ([8, Section 9]).** $\Pr \left( \left| Z - \tilde{Z} \right| > \epsilon Z \right) \leq 1/4.$

In order to sample $Z_i$, we use Algorithm 1 to draw independent samples of root-connected subgraphs. Theorem 8 implies that each sample takes at most $\frac{p_{\text{max}}}{1 - p_{\text{max}}} m^2 n$ time in expectation. We need $O \left( \frac{n}{(\epsilon^2 (1 - p_{\text{max}})^{-1})} \right)$ samples for each $Z_i$. Putting everything together, we obtain the following theorem.

**Theorem 10.** There is an FPRAS for Bi-directed Reachability. The expected running time is $O \left( \epsilon^{-2} p_{\text{max}} (1 - p_{\text{max}})^{-1} m^2 n^3 \right)$ for an $(1 \pm \epsilon)$-approximation.

A natural question is what if $1 - p_{\text{max}}$ is close to 0. Intuitively, this means that some arc is very likely to fail. We note that, if $1 - p_e = O(n^{-3})$ for every arc $e$, then with high probability, sampling from the distribution $\pi(\cdot)$ yields a rooted spanning tree (with probability proportional to its weight). Thus, in this case, we can approximate $\pi(\cdot)$ by an efficient rooted spanning tree sampler, for example, the cycle-popping algorithm [28] (which runs in time $O(mn)$ in expectation).
5 Coupling between reliability and bi-directed reachability

In this section, we give an alternative proof of Ball’s equivalence between RELIABILITY and BI-DIRECTED REACHABILITY [1, Corollary 1]. Our proof constructs a coupling, between the (edge-weighted) distribution of connected subgraphs in the undirected setting, and the (edge-weighted) distribution of root-connected subgraphs in the bi-directed setting. This coupling, together with Algorithm 1, yields an efficient exact sampler for connected subgraphs.

We use \( \{u, v\} \) to denote an undirected edge, and \( (u, v) \) or \( (v, u) \) to denote a directed one (namely an arc). Let \( G = (V, E) \) be an undirected graph, and \( p = (p_e)_{e \in E} \) be a vector of failure probabilities. Let \( \overrightarrow{G} = (V, A) \) be the bi-directed graph obtained by replacing every edge in \( G \) with a pair of anti-parallel arcs. Namely, \( A = \{(u, v), (v, u) \mid \{u, v\} \in E\} \).

Moreover, let \( p_{(u,v)} = p_{(v,u)} = p_{(u,v)} \) and denote these failure probabilities by \( \mathbf{p}' \). For \( S \subseteq E \) or \( S \subseteq A \), let \( \text{wt}(S) = \prod_{e \in S} (1 - p_e) \prod_{e \notin S} p_e \).

Consider the following coupling between the product distribution over edges of \( G \) and the one over arcs of \( \overrightarrow{G} \). We reveal edges in a breadth-first search (BFS) fashion in both graphs, from the same “root” vertex \( r \). If an edge \( \{u, v\} \) is present in the subgraph of \( G \), we couple it with the arc \((u, v)\) or \((v, u)\), whose direction is pointing towards \( r \) in the subgraph of \( \overrightarrow{G} \). The arc in the other direction is drawn independently from everything else. The key observation is that to decide the set of vertices that can reach \( r \), at any point, only one direction of a bi-directed edge is useful and the other is irrelevant. One can verify that in the end, the subgraph of \( G \) is connected if and only if the subgraph of \( \overrightarrow{G} \) is root-connected.

We will formalize this intuition next.

Fix an arbitrary ordering of \( V \), which will be used for the exploration, and let the first vertex be a distinguished root \( r \). Let \( \mathcal{P}(S) \) denote the power set of \( S \) for a set \( S \). Define a mapping \( \Phi : \mathcal{P}(E) \to \mathcal{P}(A) \) as follows. For \( S \subseteq E \), we explore all vertices that can reach \( r \) in \((V, S)\) in a deterministic order, and add arcs to \( \Phi(S) \) in the direction towards \( r \). To be more specific, we maintain the set of explored and the set of active vertices, denoted by \( V_e \) and \( V_a \), respectively. At the beginning, \( V_e = \emptyset \) and \( V_a = \{r\} \). Given \( V_e \) and \( V_a \), let \( v \) be the first vertex (according to the predetermined ordering) in \( V_a \). For all \( u \in V \setminus V_e \), \( \{u, v\} \) is in \( \Phi(S) \) if \( \{u, v\} \in S \), add \( \{u, v\} \) to \( \Phi(S) \) and add \( u \) to \( V_a \) (\( u \) may be in \( V_a \) already). Then move \( v \) from \( V_a \) to \( V_e \). This process ends when all vertices that can reach \( r \) in \((V, S)\) are explored. Let \( \sigma_S \) be the arriving order of \( V_e \). We will call \( \sigma_S \) the traversal order. We remark that if \( \{u, v\} \in S \) then exactly one of the arcs \((u, v)\) and \((v, u)\) is in \( \Phi(S) \), and otherwise neither arc is in \( \Phi(S) \).

Strictly speaking, the exploration above is not a BFS (\( V_a \) may contain a newly added vertex that is lower in the predetermined ordering than all other older vertices). To perform a BFS we need to in addition maintain a layer ordering, which seems unnecessary. The key properties of the exploration are: 1) all edges incident to the current vertex are processed; 2) \( V_e \) is always connected (or root-connected for \( \Psi \) below).

Similarly, define \( \Psi : \mathcal{P}(A) \to \mathcal{P}(E) \) as follows. For \( S' \subseteq A \), we again maintain \( V_e \) and \( V_a \), and initialize \( V_e = \emptyset \) and \( V_a = \{r\} \). Given \( V_e \) and \( V_a \), let \( v \) be the first vertex in \( V_a \). For all \( u \in V \setminus V_e \), \( \{u, v\} \notin S' \), add \( \{u, v\} \) to \( \Psi(S') \) and add \( u \) to \( V_a \). Then move \( v \) from \( V_a \) to \( V_e \). This process ends when all vertices that can reach \( r \) in \((V, S')\) are explored. Analogously, let \( \sigma_{S'} \) be the arriving order of \( V_e \). We remark that if \( \{u, v\} \notin S' \), and \( v \) is visited before \( u \), then \( \{u, v\} \notin \Psi(S') \), even in case of \( \{v, u\} \in S' \).

Let \( \Omega := \{S \subseteq E \mid (V,S) \text{ is connected}\} \), and \( \overline{\Omega} := \{S \subseteq A \mid (V,S) \text{ is root-connected}\} \).

We have the following lemma.
Lemma 11. Let $\Phi$, $\Psi$, $\Omega$, and $\Omega'$ be defined as above. Then the following hold:

1. if $S \in \Omega$, then $\Phi(S) \subseteq \Omega'$;
2. if $S' \in \Omega'$, then $\Psi(S') \in \Omega$;
3. if $S \in \Omega$, then $\Psi(\Phi(S)) = S$;
4. $\Psi(\Omega') = \Omega$;
5. for any $S \in \Omega$, $\text{wt}(S) = \sum_{S' \in \Psi^{-1}(S)} \text{wt}(S')$.

Proof. 1. It is easy to verify that, at any point of the construction of $\Phi$, all vertices in $V_e$ can reach $r$, in both $(V, S)$ and $(V, \Phi(S))$. If $S \in \Omega$, then $V_e = V$ at the end of $\Phi$. Hence $(V, \Phi(S))$ is root-connected, and $\Phi(S) \in \Omega'$.

2. This item is completely analogous to item (1).

3. If $\{u, v\} \in S$ and $u$ is processed first during the exploration, then $(v, u) \in \Phi(S)$. The traversal orderings $\sigma_S$ and $\sigma_{\Phi(S)}$ are the same. Hence, during the construction of $\Psi(\Phi(S))$, $u$ is still processed first, and $(v, u) \in \Psi(\Phi(S))$. On the other hand, if $\{u, v\} \not\in S$, then neither $(u, v)$ nor $(v, u)$ is in $\Phi(S)$ and thus $\{u, v\} \not\in \Psi(\Phi(S))$.

4. This item is a straightforward consequence of items (1), (2), and (3).

5. By item (3), we have that $\Phi(S) \in \Psi^{-1}(S)$. Let

$$\Phi_e(S) := \{(u, v) \mid (u, v) \not\in \Phi(S) \text{ and } v < u \text{ in the traversal order } \sigma_{\Phi(S)}\}.$$

Note that $\Phi(S) \cup \Phi_e(S)$ covers all unordered pairs of vertices as $S \in \Omega$. Moreover,

$$\prod_{e \in \Phi(S)} (1 - p_e) \prod_{e \in \Phi_e(S)} p_e = \text{wt}(S).$$

Call $S'$ consistent with $\Phi(S)$ if $\Phi(S) \subseteq S'$ and $S' \cap \Phi_e(S) = \emptyset$.

We claim that $S' \in \Psi^{-1}(S)$ if and only if $S'$ is consistent with $\Phi(S)$. Suppose $S'$ is not consistent with $\Phi(S)$. Consider the exploration of $\Phi(S)$ and $S'$ in the construction of $\Psi$ simultaneously. Since $S'$ is not consistent with $\Phi(S)$, either $\Phi(S) \setminus S' \not= \emptyset$ or $S' \cap \Phi_e(S) \not= \emptyset$. Let $v$ be the first vertex during the exploration so that there is an arc $(u, v) \in \Phi(S) \setminus S'$, or $(u, v) \in S' \cap \Phi_e(S)$ for some $u \in V_e$. Since $S \in \Omega$, all vertices will be processed, and such a $v$ must exist. (In the latter case, since $(u, v) \in \Phi_e(S), v$ is active first.) If $(u, v) \in \Phi(S) \setminus S'$, then $(u, v) \not\in \Psi(S')$ but $(u, v) \in \Psi(S)$. If $(u, v) \in S' \cap \Phi_e(S)$, $(u, v) \not\in \Psi(\Phi(S))$ but $(u, v) \in \Psi(S')$. In either case, $\Psi(S') \not= \Psi(\Phi(S)) = S$ (by item (3)).

On the other hand, if $\Phi(S) \subseteq S'$ and $S' \cap \Phi_e(S) = \emptyset$, then we can trace through the construction of $\Psi(\Phi(S))$ and $\Psi(S')$ to verify that $\Psi(S') = \Psi(\Phi(S)) = S$.

The claim together with (*) implies that

$$\sum_{S' \in \Psi^{-1}(S)} \text{wt}(S') = \sum_{S' \text{ is consistent with } \Phi(S)} \text{wt}(S') = \prod_{e \in \Phi(S)} (1 - p_e) \prod_{e \in \Phi_e(S)} p_e = \text{wt}(S).$$

Lemma 12. $Z_{rel}(G; p) = Z_{reach}(G_r; p')$.

Proof. First notice that $Z_{rel}(G; p) = \sum_{S \in \Omega} \text{wt}(S)$ and $Z_{reach}(G_r; p') = \sum_{S \in \Omega'} \text{wt}(S)$.

By item (4) of Lemma 11, $\Psi(\Omega') = \Omega$, implying that $(\Psi^{-1}(S))_{S \in \Omega}$ is a partition of $\Omega'$.

Combining this with item (5) of Lemma 11,

$$\sum_{S \in \Omega} \text{wt}(S) = \sum_{S \in \Omega} \sum_{S' \in \Psi^{-1}(S)} \text{wt}(S') = \sum_{S' \in \Omega'} \text{wt}(S').$$

The lemma follows.
Lemma 12 is first shown by Ball [1, Corollary 2] via modifying edges one by one. Instead, our proof is essentially a coupling argument and has a new consequence that Algorithm 1 can be used to sample edge-weighted connected subgraphs. Recall our notation \( \pi_G(\cdot) \), and generalise it to undirected graphs. Thus, for an undirected (or directed) graph \( G \), \( \pi_G(\cdot) \) is the distribution resulting from drawing each edge (or arc) \( e \) independently with probability \( 1 - p_e \), and conditioning on the graph drawn being connected (or root-connected).

Lemma 13. If a random root-connected subgraph \( S' \) is drawn from \( \pi_{G}(\cdot) \), then \( \Psi(S') \) has distribution \( \pi_{G}(\cdot) \).

Proof. Since \( S' \in \tilde{G} \), by item (2) of Lemma 11, \( \Psi(S') \in \Omega \). Moreover, for any \( s \in \Omega \),

\[
\Pr[\Psi(S') = s] = \sum_{s' \in \Psi^{-1}(s)} \Pr[S' = s'] = \sum_{s' \in \Psi^{-1}(s)} \frac{\text{wt}(s')}{Z_{\text{reach}}(\tilde{G}, r; \mathbf{p})} = \frac{\text{wt}(s)}{Z_{\text{rel}}(G; \mathbf{p})} = \pi_{G}(s),
\]

where we used item (5) of Lemma 11 and Lemma 12 in the last line.

There is also a coupling going the reversed direction of Lemma 13, by drawing a random connected subgraph \( S \) from \( \pi_{G}(\cdot) \), mapping it to \( \Phi(S) \), and excluding all arcs in \( \Phi_c(S) \). All other arcs are drawn independently. The resulting \( S' \) has distribution \( \pi_{\tilde{G}}(\cdot) \). Its correctness is not hard to prove, given Lemma 11, but it is not the direction of use to us and we omit its proof.

Theorem 10 and Lemma 12 imply the counting part of Theorem 1. Theorem 8 and Lemma 13 imply the sampling part of Theorem 1.

6 Concluding remarks

In this paper we give an FPRAS for Reliability (or, equivalently, Bi-directed Reachability), by confirming a conjecture of Gorodezky and Pak [8]. We also give an exact sampler for edge-weighted connected subgraphs with polynomial running time in expectation. The core ingredient of our algorithms is the cluster-popping algorithm to sample root-connected subgraphs, namely Algorithm 1. We manage to analyze it using the partial rejection sampling framework.

Reliability is equivalent to counting weighted connected subgraphs, which is the evaluation of the Tutte polynomial \( T_G(x, y) \) for points \( x = 1 \) and \( y > 1 \). An interesting question is about the dual of this half-line, namely for points \( x > 1 \) and \( y = 1 \), whose evaluation is to count weighted acyclic subgraphs. It is well known that for a planar graph \( G \), \( T_G(x, 1) = T_{G^*}(1, x) \) where \( G^* \) is the planar dual of \( G \) [21]. Hence, Theorem 1 implies that in planar graphs, \( T_G(x, 1) \) can be efficiently approximated for \( x > 1 \). Can we remove the restriction of planar graphs?

Another interesting direction is to generalize Algorithm 1 beyond bi-directed graphs. What about Eulerian graphs? Is approximating Reachability NP-hard in general?
