We report the first experimentally-determined metal isotope equilibrium fractionation factors for a metal sulphide at ambient temperatures and pressures. Mackinawite, referred here as FeSm (where the subscript m indicates mackinawite), can be a reactive component in diagenetic pyrite formation and the extent of equilibration between FeSm and dissolved Fe(II) has direct implications the δ^{56}Fe signatures recorded in diagenetic pyrite. The measured equilibrium Fe isotope fractionation between Fe(II)aq and FeSm is Δ^{56}Fe_{Fe(II)-FeS} = -0.52 ± 0.16 ‰ at 2°C and Δ^{56}Fe_{Fe(II)-FeS} = -0.33 ± 0.12 ‰ at 25°C and pH 4. At the experimental pH the equilibrium fractionation factor between all dissolved Fe(II) species and FeSm (Δ^{56}Fe_{Fe(II)-FeS}) equates to the fractionation factor between Fe^{2+}aq and FeSm (Δ^{56}Fe_{Fe^{2+}-FeS}). The measured fractionations are of the same order as other non–redox fractionations measured in low-temperature Fe-C-O systems. We show that at low temperature, the Fe(II)aq – FeSm system is slowly asymptotic to isotopic equilibrium and consequently, FeSm is likely to partially conserve kinetically derived isotopic signatures generated on precipitation. Combined with the range of published kinetic fractionations measured on FeSm precipitation, our data suggest that, subject to the degree of isotope exchange during equilibration, FeSm can display δ^{56}Fe compositions encompassing a range of ~ 1.4 ‰.
1. INTRODUCTION

In the past decade, transition metal isotope analyses have become widespread as a means of probing present-day and ancient environmental processes and the evolution of (bio)geochemical cycles. Many of these studies have utilised metal-sulphide isotope systems, and interpreting their results has often been restricted to the lack of provision of experimental data that quantify the direction and extent of isotope fractionations. The iron isotope system applied to Fe sulphides and especially pyrite, the major environmentally significant transition metal sulphide, is an eloquent example. Fe isotope data reported here are expressed in the conventional per mil notation with respect to the IRMM-014 standard, where $\delta^{56(57)}\text{Fe} = \left[\frac{^{56(57)}\text{Fe}_{\text{sample}}}{^{56(57)}\text{Fe}_{\text{IRMM-014}}} - 1\right] \times 1000$. Most terrestrial igneous rocks have very homogeneous $\delta^{56}\text{Fe}$ signatures clustered around ~ 0 ‰ (e.g. Beard and Johnson, 2004; Dauphas and Rouxel, 2006, for review). Fe isotope excursions (where $\delta^{56}\text{Fe}$ varies from ~ +1 ‰ to ~ -3.5 ‰) recorded in Precambrian, anoxic, sulphidic sediments (e.g. Rouxel et al., 2005) in which pyrite is the dominant Fe-S species, raised divergent interpretations (e.g. Archer and Vance, 2006; Rouxel et al., 2005). Various theories have been proposed to explain those variations (e.g. Yamaguchi et al., 2005; Anbar and Rouxel, 2007; Johnson et al., 2008). Major questions are whether or not i) pyrite is a passive recorder of the Fe(II) reservoir; ii) its formation is accompanied by significant Fe isotope fractionation; and iii) microbial activity is responsible for those Fe isotope signatures. To date, none of the proposed mechanisms responsible for the observed variations has experimentally been confirmed.

Experimental data on aqueous Fe species, Fe-oxides and Fe-carbonates have been documented and demonstrate that the largest Fe isotope fractionations are produced during redox reactions in both biologically mediated (Brantley et al., 2001,2004; Anbar, 2004; Johnson et al., 2004; Beard et al., 1999,2003; Icopini et al., 2004; Croal et al., 2004) and abiotic systems (Anbar et al., 2000; Bullen et al., 2001; Skuland et al., 2002 Brantley et al., 2004; Welch et al., 2003; Matthews et al., 2004; Teutsch et al., 2005; Jang et al., 2008, Handler et al., 2009; McAnena, 2009, Beard et al., 2010). Smaller, but significant fractionations have been seen in abiotic non-redox reactions (Wiesli et al., 2004;
Wiedehold et al., 2006; Dideriksen et al., 2008; Mikutta et al., 2009), including the ligand-exchange process involved in mackinawite (\(\text{FeS}_m\)) formation (Butler et al., 2005).

\(\text{FeS}_m\) is a metastable nanoparticulate tetragonal Fe(II) monosulphide (Rickard and Luther, 2007, and references therein) and is a potential reactive iron source in pyrite forming systems since \(\text{FeS}_m\) dissolves and reacts to form pyrite (Rickard and Luther, 1997). Isotopic mobility and potential equilibration between \(\text{FeS}_m\) and coexisting dissolved Fe(II) species (Fe(II)\(_{aq}\)) have direct implications for the ultimate Fe isotope signature of pyrite preserved in geological record. Rickard (2006) showed that in acidic environments, the pH dependent solubility of \(\text{FeS}_m\) is described by 
\[
\log K_{\text{sp}1} = \log \{\text{Fe}^{2+}\} + \log \{\text{H}_2\text{S}\} - 2\log \{\text{H}^+\} \geq 3.5.
\]
In neutral to alkaline environments, \(\text{FeS}_m\) solubility is pH independent. Total dissolved Fe(II) is dominated by FeS clusters, FeS\(_0\)\(_{aq}\), and 
\[
\log K_{\text{sp}2} = \log \{\text{FeS}_0\}_{aq} = -5.7.
\]
For all natural environments where its solubility product is exceeded, \(\text{FeS}_m\) is the first Fe-S phase to precipitate.

The kinetics and mechanisms of \(\text{FeS}_m\) formation from aqueous solutions have been reported (Rickard, 1995) and the fast precipitation process is a ligand-exchange reaction consistent with Eigen-Wilkins kinetics in which the rate of formation is determined by the exchange of water and sulphide molecules in hexaqua iron(II) sulphide between the outer sphere and the inner sphere complexes. \(\text{FeS}_m\) is readily formed in aqueous solutions as a nanoparticulate precipitate (Wolthers et al., 2003; Michel et al., 2005; Ohfuji and Rickard, 2006; Rickard et al., 2006; Jeong et al., 2008). \(\text{FeS}_m\) nucleation involves the initial formation of FeS\(_0\)\(_{aq}\) (Theberge and Luther, 1997; Luther and Rickard, 2005).

Since \(\text{FeS}_m\) formation is fast and readily reversible (cf. Rickard, 2006), the \(\text{FeS}_m\)-Fe(II)\(_{aq}\) system is particularly suitable for equilibrium fractionation studies. However, experimental measurements are limited to kinetic fractionation factors (Butler et al., 2005). Butler and co-workers (Butler et al., 2005; Guilbaud et al., 2010a) observed that the precipitation of FeS\(_m\) nanoparticles from Fe(II) solution at low temperature is accompanied by a kinetic fractionation ranging from \(\Delta^{56}\text{Fe}_{\text{Fe(II)-FeS}} \sim + 0.9\) to ~ 0.3 \(\%\) (where \(\Delta^{56}\text{Fe}_{A-B} = \delta^{56}\text{Fe}_A - \delta^{56}\text{Fe}_B\)). After rapid precipitation, isotope exchange occurs between FeS\(_m\) and Fe(II)\(_{aq}\), and its rate slows down to asymptote to a steady state after 168 hours, at which point FeS\(_m\) remains depleted in heavier isotopes with respect to Fe(II)\(_{aq}\). The observation that during
precipitation, FeSm incorporates the lighter isotopes (Butler et al., 2005, Guilbaud et al., 2010a) has often been generalised to pyrite, assuming that a fractionation of a similar magnitude would be recorded during pyrite formation (Severmann et al., 2006; Matthews et al., 2004; Rouxel et al., 2005; Archer and Vance, 2006; Yamagushi et al., 2005). This resulted in various interpretations for the highly $^{56}$Fe depleted Archean pyrite signatures. Furthermore, the calculated reduced partition factor ($\beta^{56/54}$) for the Fe$^{2+}$-pyrite couple, described by Eq. 1, predict $^{56}$Fe enrichment in pyrite (e.g. Polyakov et al., 2000; Polyakov and Mineev, 2007; Blanchard et al., 2009):

$$10^3 \ln \alpha^{56/54}_{\text{Fe}^{2+}-\text{pyrite}} = 10^3 \ln \beta^{56/54}_{\text{Fe}^{2+}} - 10^3 \ln \beta^{56/54}_{\text{pyrite}}$$

(1)

where $\alpha$ stands for the fractionation factor and $\beta$ for the reduced partition factor.

Butler et al. (2005) noted that even at steady state, the observed $\Delta^{56}$Fe$_{\text{Fe(II)-FeS}}$ did not necessarily represent isotopic equilibrium. Their arguments were based on the fact that i) FeSm is a sparingly soluble mineral (Rickard, 2006) and isotopic exchange is likely to happen via dissolution-precipitation between the mineral surface and the solution rather than the bulk mineral and the solution; and ii) the temperature independence within the range 2-40°C which supports kinetic effects rather than equilibrium. Formation and dissolution of FeSm is kinetically anisotropic (i.e. the rate of dissolution does not equate the rate of precipitation), and the dissolution kinetics are inhibited by transport of reaction components through the diffusion boundary layer (cf. Rickard and Sjoberg, 1983). Extrapolations of kinetic isotope fractionations to equilibrium values gave unreasonably large apparent equilibrium factors for O isotope studies (Matsuhisa et al., 1978). Matsuhisa et al. (1978) developed the three-isotope method to overcome this problem and determine experimentally equilibrium isotope fractionations.

In this contribution, we use the three isotope method to determine experimentally the equilibrium Fe isotope fractionation between Fe$^{2+}_{\text{aq}}$ and FeSm. We assess whether or not isotopic equilibrium can be rapidly reached at low temperatures in the aqueous Fe-S system and we discuss our results in terms of computationally derived data and implications of sedimentary pyrite formation. So far, only one other experimental data has been published on Fe isotope fractionations occurring within the Fe-S system (Butler et al., 2005). Schuessler et al. (2007) studied the equilibrium fractionation between
pyrrhotite and silicate melts. Our results are the first reported experimental equilibrium metal isotope fractionation in any metal sulphide aqueous system.

2. METHODS

2.1. Reagents

Experiments were performed at Cardiff University under oxygen free conditions (<1 ppmv O<sub>2</sub>) in an MBraun Labmaster 130® re-circulating anoxic chamber. All reagents and acids were analytical grade and solutions were prepared under oxygen free conditions using 18.2 MΩ cm deionised water, sparged with O<sub>2</sub> free grade N<sub>2</sub> for 20-40 min (Butler et al., 1994). Rigorous exclusion of oxygen is essential because FeS<sub>m</sub> is pyrophoric and Fe(II)<sub>aq</sub> itself is prone to oxidation. Iron(II) solution was made by dissolution of Mohr's salt Fe(NH<sub>4</sub>)<sub>2</sub>(SO<sub>4</sub>)<sub>2</sub>·6H<sub>2</sub>O (Sigma Aldrich™) in purged water. Mohr's salt was used for its ability to resist oxidation in solution. Sulphide solution was made by dissolution of Na<sub>2</sub>S·9H<sub>2</sub>O (Sigma Aldrich™) in purged water.

2.2. Preparation of ⁵⁶Fe enriched FeS<sub>m</sub>

Two isotopically distinct reservoirs of ⁵⁶Fe enriched freeze-dried FeS<sub>m</sub> (referred as ⁵⁶FeS<sub>m</sub>) were produced. ⁵⁶FeS<sub>m</sub> was prepared by mixing a source of ⁵⁶Fe enriched iron with Fe(NH<sub>4</sub>)<sub>2</sub>(SO<sub>4</sub>)<sub>2</sub>·6H<sub>2</sub>O. The ⁵⁶Fe metal, for which the enrichment is given by m(⁵⁶Fe)/m(Fe) = 0.997 and m(⁵⁷Fe)/m(Fe) = 0.002, was supplied by CortecNet™.

An accurately weighed aliquot of ⁵⁶Fe metal was dissolved in 40 mL hot 3 M HCl, evaporated to incipient dryness to remove the excess acid and the solution was made up to 100 mL. The pH of the solution was determined by an Orion Research EA920® pH meter and was 3 ± 0.1. After N<sub>2</sub> purging, the solution was introduced into the anoxic chamber. In the glove-box, ⁵⁶Fe solution was mixed with 20 mL 1.4 M hydroxylamine hydrochloride to reduce quantitatively Fe<sup>³⁺</sup> to Fe<sup>²⁺</sup>. Quantitative
reduction to Fe$^{2+}$ is crucial to prevent formation of S(0) with addition of dissolved HS$. The$^{56}$Fe(II) solution was mixed with 250 mL 0.16 M Fe(II) solution made from the dissolution of Fe(NH$_4$)$_2$(SO$_4$)$_2$.6H$_2$O in N$_2$ sparged water. Reduction efficiency was checked by quantifying the residual [Fe$^{3+}$] in the solution with thiocyanate (e.g. Vogel, 1951). An aliquot of the solution was acidified with 2 mL 2M HCl, reacted with 5 mL 4M thiocyanate and made up to 50 mL. The aliquot was analysed with a Perkin Elmer Lambda2® dual beam UV-Vis. Typical response was less than 0.2 ppm for [Fe$^{3+}$] which represents $\sim 0.005\%$ of total [Fe].

$^{56}$FeS was precipitated by mixing the bulk $^{56}$Fe solution with equimolar Na$_2$S.9H$_2$O. The precipitate was filtered with a Buchner filter (Whatman® No. 1 paper) and the filtrate was filtered with a 0.45 μm membrane Millipore™ filter. Freshly precipitated $^{56}$Fe$_m$ was re-suspended in water and re-filtered three times, freeze-dried for three days (Rickard et al., 2006) and stored in the glove-box. The $^{56}$FeS reservoirs produced in this way had isotopic compositions of $\sim 308 \%$ and $\sim 2.6 \%$.

2.3. Procedure

In the glove-box, $^{56}$Fe$_m$ was weighed into a serum bottle, 20 mL 0.05 M Fe(II) solution (pH 4) were added and the serum bottle was sealed with a butyl stopper and an aluminium crimp seal. The mass fraction of Fe in Fe$_m$ and the Fe(II) solution was $\sim 0.45:0.55$. The serum bottles were placed for ageing on a shaking platform for 25°C experiments and in Haake F6/C25® and Haake DC10/K10® refrigerated circulators for 2°C experiments. After ageing (ageing time up to four months for the 25°C experiment and one month for the 2°C experiments), the solid phase was separated from the aqueous phase by vacuum filtration on a 0.45 μm membrane Millipore® filter. With this filter size, filtrates are clear and filters do not clog (e.g. Wolthers et al., 2003; Butler et al., 2005; Rickard, 2006; Rickard et al., 2006; Guilbaud et al., 2010a). The filtrate solution was acidified with concentrated HCl and $^{56}$Fe$_m$ was dissolved by the addition of a few drops of concentrated HCl. H$_2$S was allowed to degas from sample in a fume hood.

2.4. Analysis
Samples (Fe(III) in HCl) were taken to dryness and re-dissolved in 5% HNO₃. Total [Fe] in solutions was determined spectrophotometrically with the thiocyanate method (e.g. Vogel, 1951). No column chemistry was performed since our samples were experimentally synthesised from analytical grade reagents. ⁵⁶/⁵⁴Fe and ⁵⁷/⁵⁴Fe isotope ratios were measured on a GV IsoProbe (formerly Micromass) multiple-collector inductively coupled plasma mass spectrometer (MC-ICP-MS). The detailed analytical protocol has been described elsewhere (Guilbaud et al., 2010b). The major challenge for accurate and precise measurement of Fe isotopes is the removal of atomic and polyatomic interferences induced by the Ar plasma. This was achieved by increasing the signal-to-background ratio (using high concentration samples and introducing collision gases into the hexapole to decrease and/or remove the interferences) and by stabilising the instrumental mass bias minimising the hexapole potential and decreasing the extraction voltage.

3-10 ppm Fe solutions were introduced into an ApexQ inlet system at 50 µL min⁻¹ to maximise the signal to ~0.3 V on mass 54, ~6 V on mass 56 and ~0.02 V on mass 57. Hexapole rf amplitude was set at 50% which enhances transmission of Fe masses. The analysis was run in hard extraction mode (-250 V). 1.8 mL min⁻¹ Ar and 2 mL min⁻¹ H₂ were introduced into the hexapole collision cell to remove completely ArN⁺ on mass 54 and ArOH⁺ on mass 57 and to decrease ArO⁺ on mass 56 to 0.006 V which represents 0.1% of the Fe peak. Cr⁺ interferences on mass 54 were monitored on mass 52 but never detected. Analyte size and matrix were the same in samples and standards and the instrumental mass bias was corrected by bracketing each sample with the IRMM-014 standard (e.g. Schoenberg and von Blanckenburg, 2005; Guilbaud et al., 2010b). On-peak-zero correction was measured on a 5% v/v HNO₃ solution prior to each Fe solution (samples or standards). Data collection consisted of 5 blocks of 20 5 x 1s integrations, followed by a 4 min rinse in 5% v/v HNO₃ + 2% v/v HF. This protocol permits to eliminate memory effects and any Fe build-up in the instrument (e.g. Ellam, 2006; Guilbaud et al., 2010b).

2.5. The three isotope method
The three isotope method (Matsuhisa et al., 1978) is a robust experimental method that allows the
determination of equilibrium fractionation factors for elements with three or more stable isotopes. Its
principle is to track the evolution of a two end-member system initially far from isotopic equilibrium.
It involves the spike-enrichment of one phase in order to shift its isotopic composition away from the
terrestrial mass fractionation line (TFL, Fig. 1). The system is then allowed to exchange and
equilibratare towards a secondary fractionation line (SFL, or equilibrium fractionation line). Since the
SFL is mass dependent, it is parallel to the TFL and lies between the composition of the spiked
starting material and the TFL. Any deviation from the bulk composition along the SFL is the
measured equilibrium isotopic fractionation between the two phases. In low temperature systems, in
which the kinetics are slow, experiments might fail to reach equilibrium, i.e. to reach the secondary
fractionation line in adequate time for experimental purposes. In such cases, the equilibrium
fractionation can be determined from the best fits of the evolution of the phases.

The three isotope method was first used for studies on O (e.g. Matsuhisa, 1979; Matthews et al.,
1983a,b). More recently, three studies applied this method to the Fe isotope systematics: between
oxide and silicate phases at high temperature (Shahar et al., 2008), between chloro-complexes in
aqueous solutions (Hill and Schauble, 2008), and between Fe(II)\textsubscript{aq} and goethite (Beard et al., 2010).
Although some workers have used enriched Fe(II)\textsubscript{aq} solutions, we preferred the solid phase (i.e.
mackinawite) to be the enriched phase for practical reasons in our experiments. The preparation of
clean, contamination-free \textsuperscript{56}Fe enriched Fe\textsubscript{Sm} is easier experimentally than preparing \textsuperscript{56}Fe enriched
Fe(II)\textsubscript{aq} from \textsuperscript{56}Fe(0) metal, which would involve the use of metal-complexing species to keep the
solution reduced, and which consequently may influence the experimental results.

The equilibrium isotope fractionation between Fe(II)\textsubscript{aq} and Fe\textsubscript{Sm}, $\Delta^{57}\text{Fe}_{\text{Fe(II)}-\text{FeS}}$, is the difference
between the intersections of the regression lines of all the data set (samples and their duplicates),
$\delta^{57}\text{Fe}_{\text{Inters},i}$, with the SFL (slope = 0.678). The values of the intersections are given by Eq. 2:

$$
\delta^{57}\text{Fe}_{i,\text{Inters}} = \frac{b - d}{c_j - a}
$$

(2)

where $a$ and $c$ are the slopes of the regression lines and the SFL, respectively, $b$ and $d$ are the
intercepts of the regression lines and the SFL, respectively, and $i$ stands for the phase of interest.
2.6. Analytical and experimental errors using spiked material in the Fe three isotope system

The analytical precision of our measurements is the reproducibility (2\(\sigma\), \(n = 15\)) obtained by measuring the external Fe standard (Baker™) before and during the analytical run and was ± 0.08 ‰ and ± 0.17 ‰ for \(\delta^{56}\)Fe and \(\delta^{57}\)Fe, respectively. Ammonium and sulphate ions present in solutions made from the Mohr’s salt were also present in the external Fe Baker™ standard and are thus considered in the given precision. The use of \(^{56}\)Fe spiked material enhances considerably the proportion of mass 56 with respect to other Fe isotopic masses, and therefore the precision on \(\delta^{56}\)Fe is poorer for spiked samples than for unspiked samples. We analysed seven different aliquots of the starting \(^{56}\)FeS\(_m\) and found a precision of ± 0.3 ‰ and ± 0.2 ‰ for \(\delta^{56}\)Fe and \(\delta^{57}\)Fe, respectively. It is important to note that although the precision is, as predicted, diminished for \(\delta^{56}\)Fe in the spiked material than for “normal” iron (the precision on \(\delta^{57}\)Fe being similar), the error remains small when considered within the context of the enrichment of the spiked material for which \(\delta^{56}\)Fe = 308.3 ‰ and \(\delta^{57}\)Fe = 5.8 ‰.

Working with metastable nanoparticulate phases that are oxygen sensitive and responsive to small pH variations generally makes experimental errors large compared to analytical errors, as is shown by the duplicate experiments in Table 1 (see discussion below). In order to give conservative uncertainties on the predicted intercepts, we based the total error on the experimental error rather than the smaller analytical error. The uncertainties on \(\delta^{56(57)}\)Fe\(_{\text{Inters.Fe(II)}}\) and \(\delta^{56(57)}\)Fe\(_{\text{Inters.FeS}}\), the upper and lower intercepts between the 95% envelopes on the regression lines, were calculated with the R 2.4.1.® statistical package. The coordinates of the lower and upper 95 % confidence envelopes are calculated conventionally from the regression lines of the entire data set (experimental samples and their duplicates) by Eq. 3 (e.g. Ludwig, 1980; Borradaile, 2003):

\[
Y = y \pm t_{\alpha/2} s_y \left[ \frac{1}{n} + \frac{(x - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right]^{\frac{1}{2}} \tag{3}
\]

where \(Y\) is the coordinate of the 95% envelope for each corresponding \(x\) on the regression line (\(y = ax + c\)), \(n\) is the number of data points, \(t_{\alpha/2}\) is the value of the t-statistic for a two-tailed test (with \(n - 2\),
the coordinate of the regression line, $x_i$ is the coordinate of data points and $\bar{x}$ is the centroid of the x coordinates. Uncertainties on $\Delta^{56(57)}\text{FeFeS-Fe(II)}$ are propagated from the uncertainties on $\delta^{56(57)}\text{Fe}$ with Eq. 4:

$$\sigma_{\Delta^{56(57)}\text{Fe}} = \left[ (\sigma_{\delta^{56(57)}\text{Fe}_{\text{lower}}}^2 + (\sigma_{\delta^{56(57)}\text{Fe}_{\text{upper}}}^2) \right]^{\frac{1}{2}}$$

(4)

3. RESULTS

Experimental quality control was performed by monitoring the mass conservation law. At any time during the experiment, the weighed sum of the constituents must equal the isotopic signature of the bulk (Eq. 5, Fig. 2):

$$(f \times \frac{^{56}\text{Fe}}{^{56}\text{Fe}_{\text{FeS}}} + (1-f) \times \frac{^{56}\text{Fe}}{^{56}\text{Fe}_{\text{Fe(II)}}} = \frac{^{56}\text{Fe}}{^{56}\text{Fe}_{\text{bulk}}}$$

(5)

where $f$ is the mass fraction of Fe in FeS$_m$. Note that this equation uses the ratio $^{56}\text{Fe}/\text{Fe}$ rather than the usual $^{56}\text{Fe}/^{54}\text{Fe}$. This is due to the fact that unlike $^{18}\text{O}$ in the O system, $^{57}\text{Fe}$ and $^{54}\text{Fe}$ are not trace isotopes with respect to $^{56}\text{Fe}$. As a result, when mass balancing equations, the error will be significantly increased using usual isotopic ratios (see Criss, 1999; Eq 1.14a-b-c) instead of the (mass of isotope)/(mass of element) ratios. There is a systematic $^{56}\text{Fe}$ enrichment for early experiments, resulting in a shift from mass balance towards higher $\delta^{56}\text{Fe}$ values. The likely explanation is that this phenomenon is due to $^{56}\text{FeS}_m$ nanoparticles passing through the 0.45 $\mu$m filter in the early stages of the experiment, i.e. before FeS$_m$ nanoparticles have agglomerated. Note that only 5 % of $^{56}\text{FeS}_m$ are required to pass through the filter to shift the Fe(II)$_{aq}$ isotope signature by 10 ‰. It is well known that because of the rapid aggregation of FeS$_m$ nanoparticles into flocs (e.g. Wolthers et al., 2003; Ohfuji and Rickard, 2006; Guilbaud et al., 2010a), samples which have aged in suspension are readily trapped on a 0.45 $\mu$m filter during vacuum filtration, and form an efficient filter bed such that no FeS$_m$ contribution is seen in the liquid phase. Because imperfectly mass-balanced experiments only concern the very first experiments, it has no observable effect on our extrapolation and predicted fractionations.
3.1. Experiment starting with $\delta^{56}$Fe$_{FeS} \sim 308 \text{‰}$ at 25°C and 2°C

Experimental conditions, analytical results and fractionations are presented in Table 1. The experiment starting with $\delta^{56}$Fe$_{FeS} \sim 308 \text{‰}$, the bulk composition of the system was 102 ± 3 ‰. The extent of isotopic exchange $F$ is given by (Graham et al., 1981; Criss, 1999; Johnson et al., 2002) Eq. 6:

$$F = \frac{\delta^{56}Fe - \delta^{56}Fe_0}{\delta^{56}Fe_{eq} - \delta^{56}Fe_0}$$

where the subscripts 0 and eq stand for initial and equilibrium, respectively. The advantage when using enriched starting material, is that the value of the equilibrium $\delta^{56}Fe_{eq} \sim 300$ per mil is negligible compared to the starting fractionation ($\sim 300$ per mil) and so $F$ can be determined precisely.

Fig. 3 describes the evolution of the isotope composition of Fe(II)$_{aq}$ and FeS$_m$ as a function of time. Isotopes exchange rapidly within the first 96 hours of ageing. After 96 hours, the exchange slows down and the extent of isotopic exchange is asymptotic to the equilibrium composition. At the end of the experiment, 75 % of isotopes had exchanged at 2°C and 85 % of isotopes had exchanged at 25°C after 4 months ageing. At equilibrium, the three isotope method predicts $^{56}$Fe enriched FeS$_m$ with respect to Fe(II)$_{aq}$ for both 25°C and 2°C (Fig. 4). Fe isotope fractionation is larger at 2°C where $\Delta^{56}$Fe$_{(\text{II})-\text{FeS}} = -0.52 \pm 0.16 \text{%}$ than at 25°C where $\Delta^{56}$Fe$_{(\text{II})-\text{FeS}} = -0.33 \pm 0.12 \text{%}$, although within error, these are strictly the same.

3.2. Experiment starting with $\delta^{56}$Fe$_{FeS} \sim 2.6 \text{‰}$ at 25°C

It was assumed that decreasing the initial fractionation between the phases from $\sim 308 \text{‰}$ to $\sim 2.6 \text{‰}$ would further narrow down the error bars on the predicted $\Delta^{56}$Fe$_{(\text{II})-\text{FeS}}$. However in actuality, because the initial compositions of the starting materials are closer, the projection on the SFL is more complicated since both experimental and analytical errors become considerable with respect to the initial fractionation. As a result, although trends were visible on a three isotope plot, the 95 %
confidence envelopes were larger than the predicted fractionation and we could not use those results to further discuss their relevance.

4. DISCUSSION

4.1. Equilibrium fractionation and mechanisms of isotope exchange

The surface chemistry of mackinawite has been established titrimetrically (Wolthers et al., 2005). At pH 4, the surface of FeSm nanoparticles is positively charged (Wolthers et al., 2005), and therefore Fe$^{2+}_{\text{aq}}$ adsorption to the FeSm surface is insignificant. The constant size of the two different Fe pools (i.e. FeSm and Fe(II)$_{\text{aq}}$) and matching mass balance throughout our data set further imply that vacuum filtration quantitatively separated FeSm from the Fe(II) solution, without any Fe$^{2+}_{\text{aq}}$ to be adsorbed and removed from the solution.

At pH 4, the dominant Fe bearing species in the aqueous solution is the hexaqua Fe$\left[\text{H}_2\text{O}\right]_6^{2+}$ (normally referred as Fe$^{2+}$). Up to ~ 45% of the total dissolved Fe(II) was constituted by the weak outer-sphere SO$_4^{2-}$ ligand complex, Fe$\left[\text{H}_2\text{O}\right]_6\text{SO}_4^{0\text{aq}}$ (PHREEQC Interactive 2.15.0® gave 45% and Visual MINTEQ 2.61® 42%). In Fe$\left[\text{H}_2\text{O}\right]_6\text{SO}_4^{0\text{aq}}$, there is no strong Fe-SO$_4^{2-}$ bond. Its participation in Fe(II)$_{\text{aq}}$ speciation has thus a negligible effect on the recorded Fe isotope fractionation since the ligand-exchange mechanism occurring remains unaffected. Rickard (2006) showed that under acidic conditions, the equilibrium solubility of FeSm is described by log $K_{\text{sp}} = \log \{\text{Fe}^{2+}\} + \log \{\text{H}_2\text{S}\} - 2 \log \{\text{H}^+\}$. Under neutral to alkaline conditions, the equilibrium solubility of FeSm is pH independent, and FeSm dissolves into Fe$^0_{\text{aq}}$. In our experiment, the Fe(II)$_{\text{aq}}$ solution was ~ pH 4 and $\Sigma[\text{S(II)}] = 0.05$ M. Fig. 5 shows the solubility curves for FeSm at various $\Sigma[\text{S(II)}]$. For $\Sigma[\text{S(II)}] = 0.05$ M (this study) the dominant Fe(II) species at pH 4 is Fe$^{2+}$. For these reasons, the measured equilibrium fractionation between Fe(II)$_{\text{aq}}$ and FeSm equates to the equilibrium isotope fractionation between the chemical species Fe$^{2+}_{\text{aq}}$ and FeSm, $\Delta^{56}\text{Fe}_{\text{Fe}^{2+}}$. FeS.
The Fe isotope equilibrium fractionation factor for the exchange reaction between Fe(II)\textsubscript{aq} and FeS\textsubscript{m} (Eq. 7), $\alpha_{\text{Fe(II)} \textsubscript{aq} - \text{FeS} \textsubscript{m}}^{56/54}$, is $0.99948 \pm 0.00002$ at 2°C and $0.99967 \pm 0.00002$ at 25°C, and is given by Eq. 8:

$$\begin{align*}
56\text{FeS}_m + ^{54}\text{Fe(II)}_\text{aq} & = ^{54}\text{FeS}_m + 56\text{Fe(II)}_\text{aq} \\
\alpha_{\text{Fe(II)}_\text{aq} - \text{FeS}_m}^{56/54} & = \frac{[\delta^{56}\text{Fe}_{\text{Fe(II)}_\text{aq}}] + 1000}{[\delta^{56}\text{Fe}_{\text{FeS}_m}] + 1000}
\end{align*}$$

(7)

(8)

Our experimentation demonstrates that at equilibrium, the Fe isotope composition of mackinawite is $^{56}\text{Fe}$ enriched with respect to the Fe isotope composition of Fe(II)\textsubscript{aq}. This compares with the kinetic Fe isotope fractionation occurring during FeS\textsubscript{m} precipitation (Butler et al., 2005; Guilbaud et al., 2010a) and confirms the conclusion by Butler et al. (2005) who argued that the fractionation observed between FeS\textsubscript{m} and Fe(II)\textsubscript{aq} after 168 hours ageing does not represent equilibrium, but a dynamic steady state. Similarly, Böttcher et al. (1998) came to the same conclusion from their S isotope study on FeS\textsubscript{m} precipitation. As mentioned above, Rickard (2006) discussed the solubility of FeS\textsubscript{m} and showed that FeS\textsubscript{m} is sparingly soluble ($pK_{sp} = 3.5 \pm 0.25$). Butler et al. (2005) suggested that if the mechanism responsible for Fe isotope exchange is dissolution-precipitation, it might be restricted to the mineral-media interface, rather than between whole FeS\textsubscript{m} particles and the solution. The rates of precipitation (including nucleation and crystal growth) and dissolution of FeS\textsubscript{m} in the FeS\textsubscript{m}-H\textsubscript{2}O system are well known (e.g. Rickard, 1995; Pankow and Morgan, 1980; Rickard and Luther, 2007). The rate of FeS\textsubscript{m} dissolution is limited by the transport of components through the particle diffusion boundary layer. This means that the driving force for the rate is essentially the chemical components potential (including Fe\textsuperscript{2+}, S(-II) and H\textsuperscript{+}) between the FeS\textsubscript{m} surface and the solution. As the bulk system approaches equilibrium, the chemical potential becomes smaller and the rate decreases.

Guilbaud et al. (2010a) studied the kinetics of isotope exchange during FeS\textsubscript{m} precipitation. They showed that atom exchange between FeS\textsubscript{m} and Fe(II)\textsubscript{aq} is consistent with i) FeS\textsubscript{m} nanoparticles that have a core–shell structure, in which case Fe isotope mobility is restricted to exchange between the surface shell and the solution and ii) nanoparticle growth via an aggregation–growth mechanism rather than growth by Ostwald ripening. This means that during the rapid aggregation of FeS\textsubscript{m}
nanoparticle flocks, where the non-exchanging core is progressively growing with respect to the surface layer, the rate of isotope exchange continuously slows down. Models presented by Guilbaud et al. (2010a) best fit the isotopic data for FeS\textsubscript{m} nanoparticles comprised of a non-exchanging core and a \(0.8\) nm thick surface layer. Interestingly, studies on growth mechanisms for ZnS nanoparticles (e.g. Huang et al., 2003) and other Fe oxides nanoparticulate systems (e.g. Waychunas et al., 2005) indicate that in the nanoscale domain, particles are likely to grow via aggregation growth rather than via Ostwald-ripening. Since the rate of FeS\textsubscript{m} dissolution is controlled by the diffusion boundary layer (e.g. Pankow and Morgan, 1980; Rickard and Sjoberg, 1983), this tends to further inhibit the rate of approach to equilibrium. Experimentally, after 30 days, Fe isotopic exchange reaches an apparent constant value of \(75\%\) and \(85\%\) of exchange for 2°C and 25°C, respectively.

4.2. Implications for the equilibrium fractionation at higher pH

For \(\Sigma[S(\text{-II})] = 0.05\) M and pH > 5.2, FeS\textsubscript{m} solubility is pH independent and total dissolved Fe(II) species are dominated by FeS\textsuperscript{0\textsubscript{aq}} (Fig. 5). Rickard and Morse (2005) characterised FeS\textsuperscript{0\textsubscript{aq}} as multinuclear Fe-S complexes whose stoichiometry ranges from Fe\textsubscript{2}S\textsubscript{2} to Fe\textsubscript{150}S\textsubscript{150} where the first condense phase precipitates. Luther and Rickard (2005) showed that metal sulphide clusters in the Fe-S, Cu-S and Zn-S systems are structurally congruent with the first-formed solid phase. This leads to a limited energy barrier in the nucleation of these phases from solution. Rickard and Morse (2005) put emphasis on the structural similarity between Fe\textsubscript{2}S\textsubscript{2} and FeS\textsubscript{m}. This means that the alkaline dissolution of FeS\textsubscript{m} into FeS\textsuperscript{0\textsubscript{aq}} may involve less Fe-S bond breaking than under acidic conditions, and the majority of Fe(II) is ligated by S both in solution or in the solid phase. For these reasons we propose that under neutral to alkaline conditions, the resulting Fe isotope fractionation between FeS\textsubscript{m} and FeS\textsuperscript{0\textsubscript{aq}} is small and insignificant. The equilibrium isotope distribution between Fe\textsuperscript{2+\textsubscript{aq}} and FeS\textsubscript{m} is independent of the two FeS\textsubscript{m} forming pathways (Eq. 9 and 10):

\[
\begin{align*}
\text{pH} < 5.2 : \text{Fe}^{2+} + H_2S & \rightarrow \text{FeS}_m \\
\text{pH} > 5.2 : \text{Fe}^{2+} + H_2S & \rightarrow \text{FeS}^0_{\text{aq}} \rightarrow \text{FeS}_m
\end{align*}
\]
Consequently, we propose that $\Delta^{56}\text{Fe}_{\text{Fe}^{2+}-\text{FeS}_0} \approx \Delta^{56}\text{Fe}_{\text{Fe}^{3+}-\text{FeS}_0}$, and that the fractionation factor determined in this study is applicable to equilibrium isotope distributions between $\text{Fe}^{2+}_{\text{aq}}$ and $\text{FeS}_0$ at alkaline pH. It is important to emphasise however that, unlike at acid pH, the analytically measured isotopic fractionation between $\text{Fe(II)}_{\text{aq}}$ (i.e. all dissolved Fe(II) species) and $\text{FeS}_0$ at neutral to alkaline pH is controlled by the predominance of the $\text{FeS}^0_{\text{aq}}$ reservoir over the $\text{Fe}^{2+}_{\text{aq}}$ reservoir.

Unfortunately, the low total dissolved Fe concentrations present at alkaline pH make this area difficult to access experimentally.

4.3. Comparison with calculated predictions

To our knowledge, no calculated data exist for the equilibrium fractionation between $\text{Fe(II)}_{\text{aq}}$ and $\text{FeS}_0$. However, $\beta$-factors for aqueous Fe(II), pyrite and the Fe(II) monosulphide troilite have been documented (e.g. Schauble et al., 2001; Anbar et al., 2005; Polyakov et al., 2000; Polyakov and Mineev, 2007; Blanchard et al., 2009). Schauble et al. (2001) used published vibrational data and empirical force field model (the Modified Urey-Bradley Force Field model, MUBFF) to estimate the $\beta$-factors of numerous Fe(II) and Fe(III) aqueous complexes including hexaqua Fe(II). Jarzecki et al. (2004) and Anbar et al. (2005) used Density Function Theory (DFT) to estimate the $\beta$-factors of hexaqua Fe(III) and hexaqua Fe(II). Polyakov and Mineev (2000) and Polyakov et al. (2007) used Mössbauer and inelastic nuclear resonant X-ray scattering (INRXS) data to provide $\beta$-factors for pyrite and troilite among others. In order to interpret natural data measured in pyrite, they assumed that the $\beta$-factors for mackinawite would be similar to those for troilite, since both are Fe(II) monosulphides. Blanchard et al. (2009) used first principle calculations (Schauble et al., 2001,2006) to discuss the pyrite $\beta$-factors given by the technique from Polyakov and co-workers. Fig. 6 shows the temperature dependence of equilibrium $\Delta^{56}\text{Fe}_{\text{Fe(II)-sulphide}}$ for pyrite, troilite and our experiment. $\beta$-factors for $\text{Fe(II)}_{\text{aq}}$ are from Schauble et al. (2001) and Anbar et al. (2005). $\beta$-factors for pyrite and troilite are from Blanchard et al. (2009), Polyakov and Mineev (2000) and Polyakov et al. (2007). Our results demonstrate that mackinawite and troilite, do not display similar fractionations with respect to
Fe(II)\textsubscript{aq}, which is expected since troilite is a hexagonal Fe(II) monosulphide, with no stability region at low temperature (Rickard and Luther, 2007). Equilibrium enrichment of heavier Fe isotopes in FeS\textsubscript{m} is consistent with calculated fractionations for pyrite, which is predicted to incorporate heavy isotopes.

Beard et al. (2010) observed that in general, comparisons between predicted and observed equilibrium fractionations are more consistent for fluid-fluid or mineral-mineral fractionations, rather than for fluid-mineral fractionations. In our case, calculated values for FeS\textsubscript{m} β-factors are needed to assess the consistency between theory and experiments.

### 4.4. Comparison with other experimental studies

Experimental studies have shown that redox processes produce the largest equilibrium Fe isotope fractionations. At 20°C, equilibrium fractionation between Fe(III)\textsubscript{aq} and Fe(II)\textsubscript{aq} is \(\sim +3\)‰ (Johnson et al., 2002; Welch et al., 2003), \(\Delta^{56}\text{Fe}_{\text{Fe(II)aq-hematite}}\) \(\sim -3\)‰ (Johnson et al., 2002; Skulan et al., 2002; Welch et al., 2003); \(\Delta^{56}\text{Fe}_{\text{Fe(II)aq-magnetite}}\) \(\sim -1.3\)‰ (Johnson et al., 2005), and \(\Delta^{56}\text{Fe}_{\text{Fe(II)aq-Fe(III)oxide}}\) \(\sim -0.9\)‰ (Bullen et al., 2001) and Beard et al. (2010) observed a \(\Delta^{56}\text{Fe}_{\text{Fe(II)aq-goethite}}\) of \(\sim 1\)‰. In our experiment, [Fe] was equimolar in FeS\textsubscript{m} and Fe(II)\textsubscript{aq} and no redox process was involved. By analogy, Wiesli et al. (2004) found that the equilibrium fractionation recorded between the non-redox Fe(II)\textsubscript{aq}-siderite couple was \(\sim 0.48\)‰.

Amongst all transition metal-sulphides, only the behaviour of Cu and Zn isotopes during the precipitation of CuS and ZnS have been studied. CuS precipitates from Cu(II)\textsubscript{aq} with \(\Delta^{65}\text{Cu}_{\text{Cu(II)aq-CuS}} = 3.06 \pm 0.14\)‰ (Ehrlich et al., 2004). Ehrlich et al. (2004) interpreted this result as a redox effect, since the precipitate is reduced to Cu(I)S from the aqueous Cu(II). Like FeS and CuS, Archer (2007) showed that ZnS precipitates from Zn(II)\textsubscript{aq} with depletion in heavy isotopes (\(\Delta^{66}\text{Zn}_{\text{Zn(II)aq-ZnS}} \sim 0.4\)‰). However, both Ehrlich et al., 2004 and Archer (2007) argued that their values were likely to be kinetic fractionations, CuS and ZnS being significantly less soluble than FeS\textsubscript{m} (\(K\text{sp}_{\text{FeS}} = 3.5\), (Rickard, 2006); \(K\text{sp}_{\text{CuS}} = 22.2\), (Smith et al., 1976); \(K\text{sp}_{\text{sphalerite}} = 10.93\), (Dyrsen and Kremling, 1990); where \(K\text{sp}\) values given here are for free hexaqua species and the minerals).
As shown above, after 30 days, Fe isotopic exchange reaches an apparent constant value of ~75% and ~85% of exchange for 2°C and 25°C, respectively. This compares with the extent of exchange between Fe(III)_{aq} and ferrihydrite nanoparticles, which reaches a maximum of 26% after 11 days (Poulson et al., 2005). The study by Poulson et al. (2005) was carried out at pH 4.7 with 3 nm ferrihydrite nanoparticles, which is similar to the experimental conditions presented here. Interestingly, the surface of ferrihydrite nanoparticles display a different coordination than the core (Michel et al., 2007) and ferrihydrite nanoparticles may also grow by aggregation growth (Waychunas et al., 2005, Michel et al., 2007) and have a low solubility (K_{sp} = 3-3.4, Schwertman, 1991; Majzlan et al., 2004). We suspect that the origin of the difference between our results and those by Poulson et al. (2005) lies in the large surface layer that promotes atom exchange for transition metal sulphides such as FeS_m and ZnS (Guilbaud et al., 2010a; Zhang et al., 2003).

4.5. Implications for modern natural systems

In marine sedimentary environments, the predominant Fe aqueous species include Fe(III)hydroxyl complexes and Fe^{2+} (Turner et al., 1981). Rickard and Morse (2005) argued that in anoxic, sulphidic environments, Fe(III) species are not significant and concluded that Fe^{2+} is the dominant Fe non-sulphide species under those conditions. In anoxic sedimentary systems isolated from hydrothermal inputs, sources for Fe^{2+} include i) microbial Fe(III) reduction and ii) sulfidation of detrital and/or authigenic highly reactive Fe(III) oxides. Both mechanisms occur at the early stages of diagenesis (Canfield et al., 1992; Poulton and Raiswell 2002). Raiswell and Canfield (1998) showed that modern anoxic/suboxic sediments (e.g. Black Sea, Cariaca Basin, Framvaren Fjord) are enriched in highly reactive Fe minerals. Mechanisms for Fe(III) (oxy)hydroxides reduction to Fe(II) are summarised by Wells et al. (1995). Sulfidation of Fe(III) oxyhydroxides, such as goethite, is a fast process (Rickard, 1974; Pyzik and Sommer, 1981; Wei and Osseo-Asare, 1996) that occurs via dissolution of the mineral surface, reduction of Fe(III) to Fe(II) and subsequent precipitation of FeS_m. In such environments, the major source for S(-II) is bacterial sulphate reduction, BSR (Raiswell and Berner, 1985) which occurs at a lower rate than Fe reduction (e.g. Berner, 1981; Canfield et al., 1992).
Canfield et al. (1992) thus concluded that enrichment in dissolved S(-II) in those environments could only occur after complete sulfidation of Fe(III) oxides. Hence, FeS\text{m} and dissolved Fe(II) should coexist in most environments in which \( \Sigma \{S(-II)\} \) and \( \Sigma \{Fe(II)\} \) are low (where I.A.P just exceeds \( K_{spFeS} \)) or where \( \Sigma \{Fe(II)\} \) is significantly greater than \( \Sigma \{S(-II)\} \), \textit{i.e.} in some marginal environments (costal, deltaic and ridge areas), at the oxic-anoxic interface where sulphide starts forming from sulphate reduction or within the anoxic zone in which \( H_2S \) reduces Fe(III) species to Fe\(^{2+}\). In environments in which Fe reduction is extensive, the process may be localised to the boundary between the suboxic and the anoxic zones. Rickard and Morse (2005) noted that FeS\text{m} has been principally observed in Fe rich environments, and rarely observed under “normal” marine conditions. They showed that where FeS\text{m} is present, Fe(II) remains in solution as Fe\(^{0}\)\text{aq} or as Fe(II)\text{aq} at quite large concentrations. Our results and those from Butler et al. (2005) converge to the same conclusion: in the 2-40°C range, the Fe-S system is slow to attain isotopic equilibrium. This means that for surface environments, the equilibrium number cannot be simply applied, and naturally occurring FeS\text{m} is likely to conserve its slow-exchange kinetic signature. Severmann et al. (2006) measured the Fe isotope compositions of highly reactive Fe in the anoxic margin basins. They documented \( \delta^{56}\text{Fe} \) values for pore waters, pyrite, and HCl extractable solid phases (\textit{i.e.} FeS\text{m} and Fe(OH)\text{3}). Fig. 7 compares the natural measurements with experimentally determined kinetic and equilibrium fractionations between Fe(II)\text{aq} and the solids. The data suggest that under diagenetic conditions, the solid products are not in equilibrium with the pore water. Rickard et al. (2007) showed in a cross-over plot that there is no direct link between FeS\text{m}, AVS, and pyrite within the same sediment, since Fe(II)\text{aq} can remain dissolved for large temporal and spatial scales in anoxic environments. Therefore, the measured compositions of natural sediments do not necessarily provide fractionation factors between the phases but reflect complicated interaction between the solids and the surrounding liquid.

The temperature dependence of the isotopic exchange suggests that at higher temperatures, the system would reach equilibrium more rapidly. Rouxel et al. (2008) and Bennett et al. (2009) measured the Fe isotope composition of Fe sulphide particles in hydrothermal environments and their results indicate that the composition of those particles is consistent with kinetic fractionations recorded for FeS\text{m} (Butler et al., 2005), in other words, far from the equilibrium data presented here. However,
caution is required with regard to extrapolating these data to temperatures in excess of 100°C, since at those temperatures, mackinawite does not form or transforms into pyrrhotite. Note that hydrothermal Fe sulphide particles can also consist of pyrite and chalcopyrite, for which Fe isotope fractionations upon formation have not been experimentally constrained.

### 4.6. Implications for ancient sedimentary signatures

In the Fe-S system, Fe is eventually sequestered into pyrite. At least 28 different reactions have been reported for low temperature aqueous synthesis of pyrite (Rickard and Luther, 2007). The use of FeS$_m$ as the Fe(II) reactant for one of these reactions is popular amongst the experimental community since FeS$_m$ first precipitates in protocols, giving sufficient nutrient concentration to produce a useful mass of pyrite. In modern natural environments, as mentioned above, FeS$_m$ as a reactant is limited to inshore and freshwater systems or as a surface product of Fe oxyhydroxide sulfidation. Thus the Fe isotope fractionation recorded during the formation of FeS$_m$ need not influence the Fe isotope composition of pyrite from all geological environments. However, it is possible that FeS$_m$ may have played a major role for diagenetic pyrite formation in sedimentary systems older than ~2.4 Ga, in which oceans were Fe(II)$_{aq}$ rich and anoxic (e.g. Holland, 1984). Interestingly, it is in those Proterozoic to Archean sediments that pyrite displays the largest Fe isotope excursions. There has been widespread interest in the possible use $\delta^{56}$Fe$_{pyrite}$ as a paleo-proxy for seawater compositions (e.g. Anbar and Rouxel, 2007; Archer and Vance, 2006). But the fractionation involved during the pyrite formation stage is still unknown. Rouxel et al. (2005) showed that Proterozoic pyrites display positive $\delta^{56}$Fe, which is in agreement with the equilibrium calculations for pyrite (Polyakov et al., 2007; Polyakov and Mineev, 2000) and our experimental prediction for mackinawite. However the negative isotopic composition of Archean pyrites implies that further fractionating mechanisms are involved.

The results of this experimentation, along with those reported by Butler et al. (2005), suggest that FeS$_m$ Fe isotope compositions are contained in a ~1.4‰ range depending on the degree of FeS$_m$ precipitation and equilibration. Depending on the rate of pyrite formation, pyrite might record the
lowest δ⁵⁶Fe where Fe₅₆S₅₆Fe is rapidly incorporated into pyrite. Mechanistically, Fe₅₆S₅₆m dissolves into FeS₅₆aq which reacts with S(-II) to form pyrite. The final composition of pyrite will thus depend on the fractionation occurring during Fe₅₆S₅₆m dissolution, on the extent of mixing with free hexaqua Fe(II) and on the extent of pyritisation. For higher temperatures, i.e. during later stages of diagenesis, isotopic equilibration between Fe₅₆S₅₆m and Fe(II)₅₆aq might be reached.

5. CONCLUSIONS

We have determined the Fe isotope equilibrium fractionation between Fe(II)₅₆aq and mackinawite at 2°C and 25°C using the three-isotope method. Equilibrium fractionation Δ⁵₆FeFe(II)-FeS is -0.52 ± 0.16 ‰ at 2°C and -0.33 ± 0.12 ‰ at 25°C and is equivalent to the distribution between the species Fe²⁺₅₆aq and Fe₅₆S₅₆m (Δ⁵₆FeFe²⁺-FeS). Fractionations produce ⁵⁶Fe enriched mackinawite and ⁵⁶Fe depleted dissolved Fe(II). Our results contrast with the kinetic fractionation of Δ⁵₆FeFe(II)-FeS = +0.85 to +0.30 ‰ determined by (Butler et al., 2005) with which mackinawite remains depleted even after long term ageing. This means that depending on the degree of Fe₅₆S₅₆m precipitation from solution, and the degree of isotope exchange during equilibration, Fe₅₆S₅₆m displays δ⁵₆Fe values in a ~ 1.4 ‰ range. At low temperatures, equilibrium is not reached in periods of less than years. This means that in natural systems, Fe₅₆S₅₆m is likely to be depleted with regard to its equilibrium value and record a kinetic signature. Further experiments are required to assess the mechanisms responsible for the Fe isotope exchange between aqueous and solid phases.

Our experimental predictions are significantly below the calculated fractionations for the hexagonal Fe(II) monosulphide troilite. There is no obvious evidence why troilite and mackinawite should produce similar β-factors.

Here, we provide the first experimentally determined equilibrium numbers for any metal sulphides. This work is fundamental to isolate and understand each step of Fe isotope fractionations during the formation of pyrite under diagenetic conditions. Further experiments are required to investigate the Fe isotope fractionations occurring in the neutral to alkaline region, where Fe(II)₅₆aq speciation is dominated by the clusters FeS⁰₅₆aq. However, we predict that the fractionation between
FeS$_{aq}$ and FeS$_{m}$ will be small. Experimental isotopic studies in this system would be helpful in further elucidating the roles of the aqueous sulphide clusters in the nucleation of solid phases from solution.

**ACKNOWLEDGEMENTS**

We are thankful to Alan Matthews, Veniamin Polyakov, Marek Pękala and two anonymous reviewers for constructive discussions that helped to improve substantially the experimental set up and the manuscript. We also thank Kathleen Keefe and Vincent Gallagher for technical support. This work was funded by an ECOSSE PhD studentship to RG and NERC research grant NE/E003958/1 to IBB.

Predicted equilibrium:
- upper limit: 2.20
- lower limit: 2.08

\(\Delta^{57}\text{Fe(II)-FeSm %a}\) = \(0.48 \pm 0.17\)

\(\Delta^{56}\text{Fe(II)-FeSm %a}\) = \(0.51 \pm 0.16\)
Table 1: Experimental conditions and isotopic analysis. Analytical precision of the isotopic data is the 2 standard deviation (2σ) of the external standard (Baker™ Fe solution) and was ± 0.08 ‰ and ± 0.17 ‰ for δ^{56}Fe and δ^{57}Fe respectively. Δ^{56}Fe_{Fe(II)-FeS} and Δ^{56}Fe_{Fe(II)-FeS} were calculated from the difference between the predicted Fe isotope compositions of both FeS_m and Fe(II)_aq at equilibrium. Errors on Δ^{56}Fe_{FeS-Fe(II)} are determined by the intercepts between the 95% confidence envelopes and the secondary fractionation line from Eqs. 3 and 4. The mass balance and the extent of reaction \( F \) were calculated from Eqs. 5 and 6, respectively. The FeS fraction represent the \( [\text{Fe}]_{\text{FeS}} / [\text{Fe}]_{\text{Fe(total)}} \) ratio, for which \([\text{Fe}]_{\text{FeS}}\) and \([\text{Fe}]_{\text{Fe(II)}}\) were measured spectrophotometrically at the end of each experiment.

![Diagram](image)

Fig. 1: Principle of the three isotope method. Starting materials are represented by squares. Starting \( \text{Fe(II)}_{\text{aq}} \) lies on the terrestrial fractionation line (TFL), enriched \(^{56}\text{FeS}\) has a composition shifted from the TFL. Circles represent the evolution of isotopic compositions of both phases with time. When the system reaches isotopic equilibrium, the final compositions will lie on the secondary fractionation line (SFL). If \( \Delta_{\text{equilibrium}} = 0\% \), final compositions will meet at the bulk composition represented by a star. If \( \Delta_{\text{equilibrium}} \neq 0\% \), it equals the difference between \( \delta_{\text{Fe(II)}, \text{equilibrium}} \) and \( \delta_{\text{FeS}, \text{equilibrium}} \).
Fig. 2: Experimental mass balance for the $\delta^{56}\text{Fe}_{\text{FeS}} \sim 308 \%o$ and $\delta^{56}\text{Fe}_{\text{FeS}} \sim 2.6 \%o$ starting experiments, calculated from Eq. 5. Grey areas represent the experimental external precision based on the reproducibility of the replicates.

Fig. 3: Time evolution of Fe isotope compositions of Fe$_m$ (circles) and Fe(II)$_{aq}$ (triangles) at 25°C (filled signs) and 2°C (open signs). 2°C experiments were stopped after one month. 25°C experiments were stopped after four months. The grey area is the bulk composition of the system including errors.

Fig. 4: Three isotope plots starting with $\delta^{56}\text{Fe}_{\text{FeS}} \sim 308 \%o$ and predicted equilibrium Fe isotope fractionations on the SFL between Fe$_m$ (open circles) and Fe(II)$_{aq}$ (filled circles). $\Delta^{56}\text{Fe}_{\text{Fe(II)-FeS}}$ is the difference between the intersections of the regression lines with the SFL. 95 % confidence envelopes are calculated from Eq. 3.
Fig. 5: Modified from Rickard (2006). Total dissolved Fe(II) activity in equilibrium with FeS$_m$ for various total [S(-II)] (bold lines). pH dependent and independent reactions are showed as fine lines. Our experiment corresponds to the region marked by a circle. The grey star represents the limit at which FeS$_{aq}$ becomes the dominant Fe(II)$_{aq}$ species, as opposed to Fe$^{2+}$ (pH ~ 5.2 for Σ[S(-II)] = 0.05 M).

Fig. 6: A: β-factors for troilite (bold-dot line, Polyakov et al., 2007), Fe(II)$_{aq}$ (grey dot lines, Schauble et al., 2001; Anbar et al., 2005) and pyrite (plain lines, Blanchard et al., 2009; Ployakov and Mineev, 2000; Polyakov et al., 2007). B: Temperature dependence of Δ$^{56}$Fe$_{Fe(II)-mineral}$ for average pyrite (bold line), average troilite (dot-line) and our experimental results (filled squares) calculated from the β-factors from A. Grey areas correspond to the uncertainties from calculations.
Fig. 7: Plot of the isotopic compositions of pore water versus the solid highly reactive iron phases, modified after Johnson et al. (2008). Data for pyrite (filled squares) and HCl extracted phases (grey diamonds and open circles) are from Severmann et al. (2006). Compositions for FeSm were derived from HCl extraction data where Fe(II)$_{\text{HCl}} > 80\%$, as suggested by Johnson et al. (2008). Kinetic $\Delta^{56}\text{Fe}_{\text{Fe(II)aq-FeSm}}$ are from Butler et al. (2005). We used our 2°C values for equilibrium $\Delta^{56}\text{Fe}_{\text{Fe(II)aq-FeSm}}$. Kinetic and equilibrium $\Delta^{56}\text{Fe}_{\text{Fe(II)aq-Fe(OH)3}}$ are from Johnson et al. (2004).
