Some interneurons of the hippocampus exhibit NMDA receptor-independent long-term potentiation (LTP) that is induced by presynaptic glutamate release when the postsynaptic membrane potential is hyperpolarized. This “anti-Hebbian” form of LTP is prevented by postsynaptic depolarization or by blocking AMPA and kainate receptors. Although both AMPA and kainate receptors are expressed in hippocampal interneurons, their relative roles in anti-Hebbian LTP are not known. Because interneuron diversity potentially conceals simple rules underlying different forms of plasticity, we focus on glutamatergic synapses onto a subset of interneurons with dendrites in stratum oriens and a main ascending axon that projects to stratum lacunosum moleculare, the oriens-lacunosum moleculare (O-LM) cells. We show that anti-Hebbian LTP in O-LM interneurons has consistent induction and expression properties, and is prevented by selective inhibition of AMPA receptors. The majority of the ionotropic glutamatergic synaptic current in these cells is mediated by inwardly rectifying Ca2+-permeable AMPA receptors. Although GluR5-containing kainate receptors contribute to synaptic currents at high stimulus frequency, they are not required for LTP induction. Glutamatergic synapses on O-LM cells thus behave in a homogeneous manner and exhibit LTP dependent on Ca2+-permeable AMPA receptors.

Key words: inhibition; GABAergic; kainate; network; plasticity; interneuron

Introduction

Hippocampal GABAergic interneurons show extensive diversity as revealed by physiological and anatomical analyses (Klausberger and Somogyi, 2008). Interneuron plasticity also exhibits a high degree of diversity. Although long-term plasticity in hippocampal pyramidal cells obeys relatively stereotypical rules, several different forms of long-term potentiation (LTP) and long-term depression (LTD) have been described in GABAergic interneurons (Buzsáki and Eidelberg, 1982; Ouardouz and Laface, 1995; McMahon and Kauer, 1997; Cowan et al., 1998; Maccaferri et al., 1998; Laezza et al., 1999; Christie et al., 2000; Alle et al., 2001; Perez et al., 2001; Laezza and Dingledine, 2004; Lei and McBain, 2004; Lamsa et al., 2005, 2007a).

NMDA receptor (NMDAR)-independent LTP in hippocampal interneurons has recently received considerable attention (Perez et al., 2001; Lapointe et al., 2004; Lamsa et al., 2007a). Induction of one such form of LTP is prevented by the AMPA and kainate receptor antagonist 6,7-dithioctyl-2,3-dihydro-2,3-dimethyl-4H-1,3,2-benzofuran-4-one (NBQX) (Lamsa et al., 2007a; Kullmann and Lamsa, 2008). Ca2+-permeable AMPA receptors (CP-AMPARs) are common in many GABAergic interneurons (Jonas et al., 1994; Geiger et al., 1995; Racca et al., 1996; Catania et al., 1995; Tóth and McBain, 1998; Topolnik et al., 2005; Lamsa et al., 2007a). These receptor channels show a marked inward rectification (Jonas et al., 1994; Bowie and Mayer, 1995; Kamboj et al., 1995), which can explain the finding that LTP at synapses on some interneurons in the CA1 area is most successfully elicited by presynaptic activity when the postsynaptic membrane potential is hyperpolarized (Lamsa et al., 2007a). The phenomenon has been termed anti-Hebbian LTP to distinguish it from Hebbian NMDA receptor-dependent LTP (Kullmann and Lamsa, 2007). Although Ca2+ influx via CP-AMPARs provides a simple explanation for anti-Hebbian LTP induction, NBQX also blocks kainate receptors (Bureau et al., 1999; Cossart et al., 2002; Goldin et al., 2007), which are abundant in hippocampal interneurons (Cossart et al., 1998, 2002; Frerking et al., 1998; Bureau et al., 1999; Patermai et al., 2000; Rogawski et al., 2003; Yang et al., 2006; Goldin et al., 2007). Kainate receptors can also exhibit marked inward rectification and calcium permeability (Egebjerg and Heinemann, 1993; Köhler et al., 1993; Bowie and Mayer, 1995).

Dissecting the relative roles of AMPARs and kainate receptors in anti-Hebbian LTP is potentially confounded by the extensive interneuron diversity that exists in the hippocampus (Somogyi and Klausberger, 2005). We have therefore focused on a single interneuron type: oriens-lacunosum moleculare (O-LM) cells in...
the CA1 area (Lacaille et al., 1987; Blasco-Ibáñez and Freund, 1995; Sik et al., 1995; Yanovsky et al., 1997; Ali and Thomson, 1998). We find that glutamatergic synapses made by axons in the CA1 stratum (s.) oriens onto O-LM cells show anti-Hebbian LTP with remarkably uniform properties. Although GluR5-containing kainate receptors contribute to EPSCs, they are not necessary for LTP induction, which is fully prevented by blockade of CP-AMPARs. Restricting attention to an identified pathway within the hippocampal inhibitory circuitry thus reveals a far more uniform pattern of synaptic physiology, pharmacology, and plasticity than seen in the population of interneurons as a whole.

Materials and Methods

Hippocampal slices

Three- to four-week-old male Sprague Dawley rats were killed by cervical dislocation and decapitated. The brain was rapidly removed and placed in ice-cold (0 to +4°C) sucrose cutting solution containing the following (in mM): 75 sucrose, 87 NaCl, 2.5 KCl, 0.5 CaCl2, 7.5 MgCl2, 1.0 NaH2PO4, 25 NaHCO3, 25 glucose, pH 7.4, bubbled with 95% O2/5% CO2. Transverse hippocampal slices (350 μm thickness) were cut using a vibrating microtome (Leica VT 1000S; Leica Microsystems). Slices were kept submerged at 32°C in the sucrose solution for 20–25 min before being transferred to an interface chamber in which they were maintained in Earle’s balanced salt solution (Invitrogen) with 3 mM Mg2+ and 1 mM Ca2+ at room temperature (20–25°C) for at least 60 min before starting experiments.

Hippocampal slices were placed in a recording chamber (Luigs & Neumann) mounted on the stage of an upright microscope (Olympus BX51WI), in which they were held under a nylon mesh grid and superfused at 3–5 ml min⁻¹ with artificial CSF (ACSF) at 31–33°C. The ACSF contained the following (in mM): 119 NaCl, 2.5 KCl, 2.5 CaCl2, 1.3 MgSO4, 1.25 NaH2PO4, 25 NaHCO3, 11 glucose, final pH 7.4 (equilibrated with 95% O2/5% CO2). A cut was made between the CA3 and CA1 subfields to prevent the spread of bursting activity. Slices were visualized using a 20× immersion objective with 2–4× zoom and infrared differential interference contrast (DIC) optics.

Electrophysiology

Somatic perforated-patch recordings were made from neurons in CA1 s. oriens and alveus. Electrodes were made from borosilicate glass capillaries (GC150F; Harvard Apparatus) pulled on a Sutter microelectrode puller. Pipette resistance was typically 8–18 MΩ for perforated-patch and 4–7 MΩ for whole-cell recordings. A Multiclamp 700B amplifier was used for recording (Molecular Devices). Infrared DIC images of the cell at different magnification (20, 40, and 80×) were obtained with a CCD camera (Till Photonics) during electrophysiological experiments. Gramicidin stock solution (100 mg mL⁻¹; Sigma-Aldrich) was prepared in dimethyl sulfoxide daily. The pipette filling solution containing gramicidin was prepared by diluting the stock solution 1:1000 in potassium gluconate pipette solution. The pipette solution contained the following (in mM): 145 potassium gluconate, 8 NaCl, 20–25 KOH-HEPES, 0.2 EGTA, and 1–5 5-lidocaine N-ethyl bromide (QX-314 Br), pH 7.2; osmolarity, 295 mosm L⁻¹. The gramicidin-containing solution was sonicated several times for short periods (3–5 s) every 20 min, and the gramicidin-containing pipette solution was discarded after 1 h. The electrode tip was filled with gramicidin-free filtered potassium gluconate solution. The series resistance was continuously monitored throughout the experiment, and recordings were started when it was <150 MΩ. Bridge balance and pipette capacitance compensation were adjusted throughout the recordings. The presence of QX-314 in the filling solution allowed for detection of inadvertent patch rupture. Suprathreshold depolarizing current steps were injected intermittently to evoke action potentials. Failure to generate action potentials indicated membrane rupture in which case the experiment was aborted.

On completion of perforated-patch recordings, the pipette was slowly retracted under infrared DIC observation. Once the pipette detached from the cell, it was rapidly withdrawn from the slice. Next, the same cell was approached with a new pipette and repatched in whole-cell configuration. Infrared images obtained during the perforated-patch recording and the whole-cell recordings were compared, in order to verify that the same cell was repatched (supplemental Fig. 1, available at www.jneurosci.org as supplemental material).

The whole-cell filling solution contained the following (in mM): 135 CsCl, 10 KOH-HEPES, 10 BAPTA, 8 NaCl, 2 Mg-ATP, 0.3 GTP, and 5 QX-314 Br, pH 7.2, 290 mosm. Spermine tetrahydrochloride (0.5 mM; Sigma) was included in the filling solution to maintain polyamine-mediated rectification of AMPA/kainate receptors during whole-cell recording. In addition, Neurobiotin (0.3–0.5%: Alomone Labs) or biocytin (0.5%; Sigma-Aldrich) was included in the solution for post hoc anatomical analysis of cells. Capacitance compensation was applied in the cell-attached configuration before membrane rupture. Series resistance was not compensated during voltage-clamp recordings, but regularly monitored with small hyperpolarizing voltage steps (−5 mV). The series resistance at the start of whole-cell voltage-clamp experiments was 19.3 ± 1.1 MΩ (n = 11) and changed by <5 MΩ during the recordings. Data were not corrected for junction potentials.

Stimulation and data acquisition. Monosynaptic EPSPs or EPSCs were evoked by alternately stimulating in the s. oriens/alveus in area CA1 at 0.067 Hz via two concentric bipolar electrodes (outer diameter, 125 μm; FHC), connected to constant current isolated stimulators (DS3; Digitimer; 20–200 μA; duration, 50 μs). The stimulators were controlled by a custom data acquisition program (LabView; National Instruments) or by pClamp 10 software (Molecular Devices). Evoked EPSPs were recorded from the resting membrane potential or in some experiments during a brief (500 ms) hyperpolarizing step (5–10 mV) to avoid action potential generation. For LTP induction, one of the pathways was stimulated at 100 Hz for 1 s, delivered twice with a 20 s interval. Simultaneously, the postsynaptic cell was voltage clamped (1200–2000 ms) at −70 to −90 mV or at 0 mV (somatic potential). The pulse duration was longer than the stimulation train to keep the postsynaptic cell clamped during possible polysynaptic activity after the train. In the 1 Hz pairing protocol, the cell was stepped in voltage-clamp mode from −60 to 0 mV (somatic potential) for 300 ms, and a single presynaptic stimulus was delivered concomitantly to the depolarizing step (Lamata et al., 2005). Voltage steps to 0 mV were accompanied by repetitive firing of action currents (supplemental Fig. 2, available at www.jneurosci.org as supplemental material). No series resistance compensation was used in voltage clamp. The voltage error resulting from perforated-patch series resistance was estimated and added to the voltage step to depolarize the somatic membrane potential to 0 mV. The series resistance was calculated from brief (100–200 ms) depolarizing steps with and without bridge balance compensation. In whole-cell recordings, EPSC current–voltage relationships were estimated over a postsynaptic membrane potential range from −90 to +60 mV using 500 ms steps in voltage-clamp mode.

Miniature EPSCs (mEPSCs) were recorded in 120 s sweeps, with the seal test monitored in between sweeps. The first recordings were made 15 min after breaking through into the whole-cell configuration to allow for stabilization of the cell input resistance (280 ± 45 MΩ; n = 14). At least 6 min of recording were used for the analyses in each condition. To look for mEPSC rectification 120-s-long recording periods were alternately obtained at −60 mV and at +40 to +50 mV. When the cell was clamped at depolarized potentials, the recording was started with a 5–20 s delay to allow for relaxation of voltage-activated currents and a stable holding current.

In all recordings, data were low-pass filtered (4–5 kHz) and acquired at 10–20 kHz on a PC for off-line analysis. Data were analyzed using LabView, pClamp 10, or Igor Pro (Wavemetrics).

Drugs. The GABA receptor blockers picrotoxin (100 μM) and (25)-3-[(1S)-1-(3-chlorophenyl)ethyl]-2-amino-2-hydroxypropyl](phenylmethyl)phosphinic acid (CGP55845) (1 μM) were routinely added to the extracellular solution in all experiments. Where indicated, the NMDA receptor antagonist DL-2-amino-5-phosphonovaleric acid (DL-APV) (100 μM) was also included. Other drugs were applied via superfusion (3–5 μl/min). Tetrodotoxin (TTX) (1 μM) was present during mEPSC
Properties of Anti-Hebbian LTP in O-LM Interneurons

Data analysis and statistics

In the analysis of LTP experiments, the initial slope of the EPSPs (3–5 ms from onset) was measured to restrict analysis to monosynaptic excitatory inputs. The initial slope time window and EPSP onset were determined from the average of all baseline EPSPs. For coefficient of variation (CV) analysis, EPSP initial slope values were taken from 5 min recording periods in the tetanized and control pathways. The mean and SD values (20 data points each) were used to estimate CV−2 for periods before (−5–0 min) and 15–20 min after the high-frequency stimulation. The noise variance (Varnoise) was measured from 3 to 5 ms time window preceding the stimulation and subtracted from the EPSP slope variance (VarEPSP) before calculation of CV−2, using the following formula: mean EPSP2/(VarEPSP − Varnoise), where mean EPSP is the mean EPSP slope (Min et al., 1998).

In whole-cell current–voltage (I–V) recordings, the EPSP rectification index was obtained by dividing the amplitude of the EPSP recorded at +60 mV by that measured at −60 mV. To analyze the AMPAR- and kainate receptor-mediated components of stimulus-evoked synaptic transmission, the peak EPSP amplitude in control conditions was quantified as the difference between a 10 ms baseline before stimulation and the mean value in a 1–3 ms window around the peak of the average monosynaptic response. The slope and decay time constants were evaluated for individual events. The EPSC decay time constant was evaluated by fitting a monoeponential function. To estimate the charge transfer of evoked EPSCs, the rising slope and decay time constant were evaluated for the single pulse-evoked EPSC (control) and the EPSC after the fifth pulse in [1-(4-aminoophenyl)-4-methyl-7,8-methyleneoxy-5H-2,3-benzodiazepine (GYK153655)]. These experimentally derived kinetic variables were used to simulate EPSC waveforms made up of a linear rise and monoeponential decay. Waveforms were scaled by the amplitude of the EPSC after the single or fifth pulse in control and GYKI conditions, respectively. Charge transfer was estimated by integrating these waveforms and the ratio of the two integrals evaluated. Hence, this ratio compared the summated, GYKI-insensitive EPSC to a single pulse-evoked EPSC in control conditions, and would thus be an overestimation and an upper limit of the contribution of the GYKI-insensitive component.

Mini-analysis was done in Igor Pro, version 6.01, using a modified version of the miniift procedure (Hwang and Copenhagen, 1999). The procedure detects events based on the first and second derivatives and a user-specified amplitude detection threshold. See supplemental Figures 3 and 4, and supplemental Table 1 (available at www.jneurosci.org as supplemental material).

Data are shown as mean ± SEM. Data were recorded. Chemicals were purchased from Sigma-Aldrich, and drugs were purchased from Tocris Cookson or Ascent Scientific.

Figure 1. Long-term potentiation in O-LM interneurons is induced at negative postsynaptic membrane potential. A, Recording in perforated-patch mode showing that glutamatergic synapses onto an O-LM cell do not exhibit NMDA receptor-dependent Hebbian LTP. The plot shows initial slopes of EPSPs in response to extracellular stimulation of two glutamatergic pathways (solid and open symbols) targeting the O-LM cell. After a baseline, 1 Hz stimulation (120 pulses) was delivered in one pathway (solid symbols) while postsynaptic membrane potential was simultaneously depolarized to 0 mV. This did not change EPSP slope. Twenty consecutive traces of EPSPs in both pathways before (5 min) and after (25 min) the pairing are shown above each plot. Pairing protocol is illustrated in an inset, and the timing is indicated by an arrow. B, Mean ± SEM of baseline-normalized EPSP in three O-LMs cells studied in perforated patch as in A. The two pathways are superimposed; solid and open symbols indicate the paired and control pathways as in A. Schematic shows the experimental design and positioning of extracellular stimulation electrodes. C, Robust LTP is induced in glutamatergic synapses onto O-LM cells if high-frequency afferent stimulation occurs when the cell membrane potential is clamped at negative potentials. Recording is in perforated patch; the plot shows EPSP initial slopes in response to stimulation of two glutamatergic pathways (solid and open symbols) targeting an O-LM cell. After baseline, HFS (100 Hz, timing indicated by an arrow) was delivered in one pathway (solid symbols) while membrane potential was voltage clamped to −70 mV during the train. This anti-Hebbian pairing induced a robust pathway-specific LTP of the EPSP. The open symbols indicate EPSPs in the control pathway. EPSPs in both pathways before (5 min) and after (35 min) the HFS are shown above. The scaling is as in A. Stimulation protocol is illustrated in the inset. APV indicates continuous presence of NMDAR blocker α-APV (100 μM). D, Mean ± SEM of baseline-normalized EPSP in 16 O-LMs cells studied in perforated patch as in C, postsynaptic membrane potential clamped to −70 to −90 mV during HFS. P indicates significance between the two pathways (unpaired t test). E, Pairing 100 Hz afferent stimulation with depolarization to 0 mV in perforated patch fails to elicit LTP in O-LM cells. The solid and open symbols represent tetanized and control pathways. Pairing protocol is illustrated in inset; arrow shows timing. APV indicates that NMDARs are blocked by 100 μM α-APV. Consecutive EPSPs in the two pathways during baseline (5 min) and after the pairing (35 min) are shown above. The scaling is as in A. F, Mean ± SEM of EPSP slope in two pathways tested in eight O-LM cells in perforated patch and plotted as in B and D. G, Fluorescence micrographs showing immunoreactivity for mGluR1α (middle; red) and somatostatin (middle; blue) in the soma of a recorded and biocytin-labeled O-LM cell (arrow) shown in E. An mGluR1α-immunopositive and biocytin-labeled distal dendrite is shown on the right (green, red). Note immunoreactivity in cells that were not recorded (arrowhead). Scale bars: left, middle panels, 20 μm; right panels, 10 μm.
baseline-normalized within each pathway, using a 10 min baseline, and analyzed with Student’s paired t test. Within each cell, the change in slope in the paired pathway was compared with that of the control pathway with an unpaired t test.

**Anatomical analysis**

Neurons were filled with Neurobiotin (Vector Labs) or biocytin (Sigma-Aldrich) during whole-cell recordings (at least 30 min). Slices were fixed overnight at 4°C in a solution containing 4% paraformaldehyde, 0.05% glutaraldehyde, and −0.2% picric acid in 0.1 M sodium phosphate buffer (PB) (BDH). During fixation, slices were kept between two cellulose nitrate membrane filter papers (Whatman) to minimize deformation. The next day, slices were washed thoroughly in 0.1 M phosphate buffer and stored in PB plus 0.05% sodium azide (BDH) at 4°C. For resectioning, slices were embedded and fixed in 20% gelatin and resected at 70 μm thickness using a vibrating microtome (Leica VT1000S; Leica Microsystems). The sections were washed once in 0.1 M PB, and several times in 50 mM Tris-buffered saline (TBS) (Sigma-Aldrich) with 0.3% Triton X-100, and then incubated for at least 5 h with Alexa Fluor 488-labeled streptavidin (Invitrogen); diluted 1:1000 in TBS with 0.3% Triton X-100. Sections were mounted in Vectashield (Vector Laboratories) under coverslips and examined with a fluorescent microscope. Images were captured using a CCD camera (C4747-95; Hamamatsu Photonics) with an appropriate filter set (Ferraguti et al., 2005) (see supplemental Methods, available at www.jneurosci.org as supplemental material) and analyzed using the Openlab 4.0.4 image analysis software package (Improvement).

O-LM cells were identified on the basis of the main axon ascending from s. oriens, with an axonal arborization mostly in s. lacunosum moleculare (n = 83), or metabotropic glutamate receptor subtype 1a (mGlur1a) immunoreactivity in the somatodendritic plasma membrane and characteristic somatostatin immunoreactivity in the soma (Badea et al., 1993; Blasco-Ibáñez and Freund, 1995; Maccaferri and McBain, 1995; Sik et al., 1995; Ali and Thomson, 1998). Some cells provided additional minor innervations to other layers. O-LM cells had a horizontal dendritic arborization bearing many filopodial spines and appendages in s. oriens and the alveus (McBain et al., 1994). For immunofluorescence experiments, sections were processed as described previously (Jinno et al., 2007) (see supplemental Methods, available at www.jneurosci.org as supplemental material). On completion of immunoreactions, sections were processed for visualization of Neurobiotin as described previously (Losonczy et al., 2002). For illustration, selected cells were reconstructed from several 70 μm sections using a drawing tube.

**Results**

**Consistent anti-Hebbian LTP properties in hippocampal CA1 O-LM cells**

We patched horizontal cells in s. oriens of the CA1 area under infrared DIC microscopy. In plasticity studies, cells were first recorded in the perforated-patch mode and then repatched in whole-cell voltage clamp using a new pipette. This repatching method allowed us to study synaptic plasticity with minimal disturbance of the cytosol, with subsequent whole-cell access to test synaptically currents in voltage clamp and fill cells with biocytin for post hoc anatomical identification (supplemental Fig. 1, available at www.jneurosci.org as supplemental material). Of 212 cells recorded and subsequently processed histologically, 83 cells were identified as O-LM interneurons (supplemental Table 2, available at www.jneurosci.org as supplemental material). The data reported here focus exclusively on the 83 identified cells.

We first asked whether Hebbian NMDA receptor-dependent LTP could be evoked in identified O-LM cells. NMDAR-dependent LTP can be induced in a subpopulation of unidentified nonpyramidal cells in the CA1 area, mainly in s. radiatum by pairing low-frequency (1–2 Hz) stimulation of presynaptic afferents with postsynaptic depolarization. A small population of interneurons in s. pyramidale and s. oriens also show NMDAR-dependent LTP (Wang and Kelly, 2001; Lamsa et al., 2005, 2007a), and we therefore asked whether O-LM cells could belong to this group. EPSPs were elicited with two extracellular stimulation electrodes positioned in s. oriens. GABA_A and GABA_B receptors were blocked with picrotoxin (100 μM) and CGP55845 (1 μM), respectively. Analyses were focused on the EPSP initial slope to avoid contamination of the monosynaptic response by polysynaptic activity (Maccaferri and McBain, 1996; Lamsa et al., 2005; Glickfeld and Scanziani, 2006). After recording a stable
Fast glutamatergic excitation of O-LM interneurons at negative membrane potential is mediated via CP-AMPA and kainate receptors

Repatching the cells in whole-cell mode allowed us to study EPSCs underlying the EPSPs in O-LM cells. In 12 of 16 cells tested...
for anti-Hebbian LTP and repatched, whole-cell access resistance was suitable for voltage-clamp recordings and I-V analysis. EPSCs were systematically highly inward rectifying in all O-LM cells exhibiting anti-Hebbian LTP (Fig. 3A). In addition, the rectification index (RI) (detected 20–60 min after the HFS) did not differ significantly between potentiated (0.14 ± 0.07) and control pathways (0.04 ± 0.05; p = 0.15; n = 10 cells; t test). In two of the three cells that failed to reach the LTP criterion, the EPSC I-V relationship was successfully measured: EPSCs were similarly inward rectifying in both pathways (RI mean, 0.13 and 0.10, respectively). EPSC rectification indices taken from 25 O-LM cells in this study showed that there is little variation among the cells (Fig. 3B). We thus conclude that O-LM cells consistently exhibit highly rectifying EPSCs, characteristic of Ca2+-permeable AMPA receptors (Angulo et al., 1997). The influx of Ca2+ via such receptors may explain anti-Hebbian LTP induction. The similarity of RI between LTP and control pathways implies that LTP is not accompanied by a change in the proportion of rectifying receptors at the potentiated synapses.

Because the rectification analysis focused on the peak of the EPSCs, which is dominated by fast AMPA receptors, it says little about whether kainate receptors are involved in the Ca2+ influx during anti-Hebbian pairing. We therefore estimated the contribution of kainate receptors to glutamatergic synapses onto identified O-LM interneurons. We recorded from horizontal cells in the whole-cell voltage-clamp configuration, and examined the effect of selective blockade of AMPA receptors with GYKI53655 (50 μM). The amplitude of single stimulus-evoked EPSCs (57 ± 7 pA) was strongly attenuated by GYKI53655 in every O-LM cell studied, leaving only 7 ± 1% residual amplitude (n = 11) (Fig. 3C). To examine the kinetics and pharmacological properties of the residual EPSC, we delivered trains of stimuli at 100 Hz (five pulses) in the continued presence of GYKI53655. This revealed an EPSC that exhibited substantial summation: the ratio of the charge transfer to the residual EPSC, with a charge transfer car-

| Table 1. EPSC kinetics in control (single shock) and in 50 μM GYKI53655 (fifth shock) |
|---------------------------------|-----------|----------|------------|---------|
| Amplitude (pA)                  | 10–90% Rise time (ms) | Slope (pA/ ms) | Decay time constant (ms) | Area (nC) |
| Control                         | 79.7 ± 6.7 | 0.8 ± 0.1 | 58.4 ± 4.6 | 4.1 ± 0.2 | 385.8 ± 63.9 |
| GYKI53655                       | 6.5 ± 1.0  | 1.7 ± 0.3 | 1.8 ± 0.3  | 8.9 ± 1.0 | 70.1 ± 13.0 |

Means ± SEM are presented for four cells in which monosynaptic EPSCs could be distinguished. EPSC amplitude was measured from baseline preceding the first/fifth shock in control and GYKI53655, respectively. Data were used to estimate charge transfer.

We applied a second approach to look at the contribution of AMPA and kainate receptors to synaptic transmission in O-LM cells. The relative contributions of AMPA and kainate receptors should be reflected in the kinetics and pharmacological properties of mEPSCs recorded in the presence of TTX (1 μM) (GABA and glutamate NMDARs were blocked as above). Cells were initially held at −60 mV. This revealed a population of spontaneous inward currents with fast rise time and variable decay time constants (n = 14 cells) (Fig. 4A; supplemental Fig. 5, available at www.jneurosci.org as supplemental material).

Given the wide distribution of mEPSC kinetics in the cells, we asked whether fast- and slow-decaying events show different sensitivities to membrane potential by clamping the cell at depolarized potentials (+40 to +50 mV). The frequency of detected events decreased to 9 ± 3% of the frequency at −60 mV (p < 0.05; n = 4; paired t test) (Fig. 4B). This was accompanied by a nonsignificant reduction in the mean amplitude of detected events (p = 0.13). The decrease in frequency and amplitude of detected events is consistent with the hypothesis that most events fall below detection threshold on depolarization, most simply explained by rectification of the receptors mediating the EPSCs. Indeed, the maximal event amplitude decreased from 50.8 ± 1.5 pA at −60 mV (n = 4) to 11.2 ± 1.2 pA at +40 to +50 mV. mEPSCs at positive voltages were detected too infrequently to obtain reliable estimates of the distribution of decay time constants.

Overall, the analysis of mEPSCs is in line with the outcome of stimulus-evoked EPSCs, and indicates that highly rectifying glutamate receptors mediate the majority of EPSCs in O-LM cells. We next studied the effect of selective AMPAR antagonists on mEPSCs, to determine whether a subpopulation of kainate receptor-mediated events could be detected. After baseline recording of mEPSCs (6 min), slices were exposed either to GYKI53655 (50 μM) or to a low concentration of NBQX (1 μM), which has been shown to act as a relatively selective blocker of AMPA receptors (Bureau et al., 1999). All detected mEPSCs were blocked with GYKI53655 (n = 5 cells), and in separate experiments a similar result was obtained with 1 μM NBQX (n = 5 cells). This argues that the overwhelming majority of mEPSCs were mediated by AMPA rather than kainate receptors (Fig. 4C) (Wilding and Huettner, 1995; Cossart et al., 2002; Goldin et al., 2007). Because a population of mEPSCs resistant to 50 μM GYKI53655 or 1 μM NBQX could not be detected, we conclude that the variable mEPSC decay time constants in O-LM cells (Fig. 4A) result mainly from differential electrotonic filtering (Williams and Mitchell, 2008) of mainly AMPA receptor-mediated mEPSCs arising at diverse locations in the dendritic arborization (McBain and Dingledine, 1993).
also be calcium-permeable, in LTP induction. Indeed, their relatively slower kinetics is suited to temporal summation, and their contribution to synaptic transmission is revealed by high-frequency stimulation, similar to that used in the anti-Hebbian LTP induction protocol. Therefore, we next attempted to dissect the relative contributions of AMPA and kainate receptors in anti-Hebbian LTP induction.

Because the small size of the kainate receptor-mediated EPSC precluded reliable measurement of the rectification index, and associated calcium permeability (Egebjerg and Heinemann, 1993; Köhler et al., 1993; Bowie and Mayer, 1995; Kamboj et al., 1995; Rogawski et al., 2003), we used selective kainate and AMPA receptor antagonists to address the question. We first tested the effect of the relatively selective AMPA receptor blocker, 1 μM NBQX, on LTP induction using sequential perforated-patch–whole-cell recording as described above. We recorded EPSPs in two pathways and after a baseline NBQX was washed in. This strongly inhibited the EPSP initial slope to 13 ± 2% of baseline in both pathways within 7 min (n = 4 cells; both pathways). High-frequency stimulation was then delivered to one pathway while the somatic membrane potential was clamped at −70 to −90 mV. Washout of NBQX was started immediately after the HFS, and recovery of the EPSPs was followed in both pathways for at least 25 min. Initial slopes in the tetanized and control pathways recovered to 38 ± 9 and 43 ± 11% of the baseline, respectively, in 20–25 min (p = 0.43; n = 4) (Fig. 5A,B). Thus, selective blockade of AMPA receptors was sufficient to prevent the induction of anti-Hebbian LTP.

We next studied the effects of the GluR5 blocker UBP-302 in separate slices. Slices were exposed to UBP for at least 20 min before an experiment so that EPSPs were stable before the start of baseline recording. HFS in the presence of UBP resulted in LTP in five of six tested O-LM cells. The baseline-normalized initial slope was potentiated to 155 ± 13%, 15–20 min after the HFS (all six cells included). The EPSP in the control pathway was 103 ± 11% of baseline (p < 0.01). Thus, in contrast to the effect of blocking AMPA receptors, UBP-302 did not prevent anti-Hebbian LTP induction.

We next tested the effect of GYKI53655, another AMPAR antagonist, using the same experimental design. A lower concentration (25 μM) than in the previous experiments (Fig. 3C) was used to facilitate washout of the drug. Bath application of GYKI reduced the initial slope to 9 ± 2% of baseline within 8 min (n = 22 pathways in all 11 O-LM cells tested). High-frequency stimulation paired with hyperpolarization fully blocked LTP. Surprisingly, however, the EPSP recovered less in the tetanized pathway (67 ± 5%) than in the control pathway (81 ± 3%) during GYKI washout (n = 5; p < 0.05; paired t test) (Fig. 6A,B).

To determine whether this unexpected difference was a result of the specific induction protocol tested, we repeated the experiments with a Hebbian pairing. HFS was delivered in the presence of GYKI53655 together with depolarization to 0 mV. After washout, a qualitatively similar but statistically insignificant (p = 0.12) trend was seen for the tetanized pathway to recover less than the control pathway (41 ± 5 and 56 ± 4%, respectively, 25 min after HFS; n = 6) (Fig. 6C,D). These results suggest that a small LTD can be elicited in the tetanized pathway, uncovered by blocking AMPA receptors, although the size of the phenomenon precludes easy identification of the underlying mechanisms.

Discussion

We have dissected the roles of CP-AMPA and kainate receptors in the induction of anti-Hebbian LTP at excitatory synapses onto
CA1 O-LM interneurons. Although synaptic currents are mediated by both AMPA and kainate receptors, CP-AMPAR but not kainate receptors are necessary for LTP induction. Moreover, by exploring different induction protocols, we conclude that long-term plasticity properties are strikingly homogeneous in this population of hippocampal interneurons.

LTP induction via CP-AMPARs

Unlike some other hippocampal interneurons (Ouardouz and Lacaille, 1995; Christie et al., 2000; Lamsa et al., 2005, 2007b), O-LM cells in the CA1 area do not exhibit NMDAR-dependent LTP. Rather, experiments with selective AMPAR blockers showed that CP-AMPARs are critical for LTP induction. Glutamate release by high-frequency tetanic stimulation was not sufficient to induce LTP when AMPARs were blocked. Given the pharmacological dependence of LTP on AMPARs and the fact that CP-AMPARs are highly inward rectifying, it was not surprising that LTP induction showed a strict dependence on the postsynaptic membrane potential. In line with the data presented here, we have previously shown that blockade of inward-rectifying AMPA/kainate receptors with polyamines at an intracellular site prevents LTP in several interneurons in s. oriens including O-LM cells (Lamsa et al., 2007a). Our results strongly suggest that Ca\(^{2+}\) influx via CP-AMPARs is necessary to trigger LTP (Lapointe et al., 2004; Lamsa et al., 2007a). Indeed, CP-AMPARs provide spatially restricted calcium signaling in interneuron dendrites, which is a prerequisite for pathway specificity of LTP (Goldberg et al., 2003a,b; Kaiser et al., 2004; Rózsa et al., 2008).

We cannot rule out the possibility that LTP is accompanied by changes in AMPA receptor subunit composition, as has been reported in other cell types (Liu and Cull-Candy, 2000; Bellone and Lüscher, 2005; Plant et al., 2006; Liu and Zukin, 2007). However, we found no evidence that such a switch accompanied anti-Hebbian LTP, because the rectification ratios were similar in the conditioned and control pathways. After potentiation, calcium permeability of AMPARs is presumably preserved in these synapses. Analysis of changes in CV supports the notion that LTP at these synapses is presynaptically expressed.

mGluRs contribute to LTP induction in CA1 O-LM cells (Perez et al., 2001). Antagonists of mGluR1 or genetic lesion of the receptor prevent LTP in horizontal cells when the whole-cell recording method is used (Lapointe et al., 2004). However, the fact that tetanic stimulation in the presence of AMPAR antagonists was not sufficient to induce LTP when postsynaptic membrane potential was either hyperpolarized or depolarized indicates that synaptic activation of metabotropic glutamate receptors alone is insufficient to induce LTP. It is also
unclear whether mGluR1 receptor activation by presynaptic tetanization would provide spatially restricted postsynaptic calcium dynamics, which would be required to induce synapse-specific LTP as described here (Goldberg et al., 2003b; Topolnik et al., 2005; Kullmann and Lamza, 2008). We suggest that mGluRs have a permissive rather than instructive role in anti-Hebbian LTP induction (Kullmann and Lamza, 2008).

Interestingly, when AMPARs were blocked during tetanization, the conditioned pathway recovered less than the control pathway. In these experiments, 25 μM GYKI was used instead of 50 μM to improve recovery of EPSPs during the drug washout. Given that this apparent depression was more pronounced when HFS were given at negative potentials, it is possible that it was induced via residual CP-AMPA receptor activation during tetanic stimulation (Laezza and Dingledine, 2004). The mechanisms of LTD in interneurons show extensive heterogeneity, providing multiple candidates to be tested to determine its induction mechanism (McMahon and Kauer, 1997; Laezza et al., 1999; Lei and McBain, 2004). Heterosynaptic potentiation of the control pathway in these experiments cannot be fully excluded either (Cowan et al., 1998).

Contribution of kainate receptors to excitation of O-LM cells

The involvement of kainate receptors in the induction of anti-Hebbian LTP was hypothesized for three reasons. First, kainate receptors can exhibit marked polyamine-dependent inward rectification akin to rectifying AMPA receptors (Bowie and Mayer, 1995; Kamboj et al., 1995). Second, such receptors can also be highly permeable to Ca^{2+} (Rogawski et al., 2003; Wilding et al., 2005). Third, synaptic kainate receptors are widely expressed in GABAergic interneurons including O-LM cells and can contribute to their recruitment to firing (Bureau et al., 1999; Mulle et al., 2000; Paternain et al., 2000; Rodriguez-Moreno et al., 2000; Cossart et al., 2002; Yang et al., 2006; Goldin et al., 2007). Although we confirm that kainate receptors contribute to EPSCs evoked in O-LM cells in rat hippocampal slices, they do not appear to play a major role in synaptic excitation of these cells. Moreover, although our experiments suggest that GluR5-containing kainate receptors mediate the majority of kainate receptor-mediated synaptic currents, blockade of these receptors did not prevent LTP induction in O-LM cells. Although GluR6-containing receptors have also been reported in hippocampal interneurons, a suitable selective blocker is not available to test whether such receptors also contribute (Mulle et al., 2000; Paternain et al., 2000).

A recent study in mice reported that the majority of synaptic excitation of CA1 O-LM cells is mediated by kainate receptors,
with a relatively small contribution of AMPARs (Goldin et al., 2007). In contrast, our results show that, in identified O-LM cells in the rat hippocampal CA1 area, synaptic excitation is almost entirely mediated via AMPARs. Kainate receptor-mediated EPSCs were only elicited during repetitive activation of afferents. In agreement with previously reported findings in mice (Goldin et al., 2007), mEPSCs in O-LM cells in the rat showed a wide range of decay time constants. However, mEPSCs showed pharmacologically and biophysically homogeneous properties, being blocked by selective AMPAR antagonists and showing inward rectification. This supports the conclusion that the mEPSCs were mediated via CP-AMPARs and not by kainate receptors, and suggests that their kinetic variability was mainly attributable to electrotonic filtering (McBain and Dingleline, 1993). Unlike O-LM cells in mice, we found no evidence of pure kainate receptor-mediated synaptic events in the rat. The discrepancy might be at least partially explained by species specificity (Lanthorn et al., 1984; Salin et al., 1995).

**Characteristic properties of LTP in O-LM cells**

Although long-term plasticity properties in hippocampal interneurons show extensive heterogeneity, the present study shows LTP in O-LM cells to be remarkably uniform with respect to several parameters. First, LTP induction showed a consistent voltage dependence in all studied O-LM interneurons, induced when the postsynaptic membrane potential was hyperpolarized during afferent activity, but unsuccessful at strongly depolarized potential. Second, LTP was restricted to the tetanized afferent pathway, implying synapse specificity. Third, LTP was systematically associated with a reduction in CV of the EPSP, consistent with a presynaptic locus of expression (Edwards et al., 1990). Fourth, LTP was critically dependent on AMPA receptors in all studied O-LM interneurons. An explanation for the consistency may partially stem from the recording method. Perforated-patch recording may be more suitable for LTP studies than the whole-cell configuration (Isaac et al., 1996; Lamsa et al., 2005), because this method allows stable and long-lasting recordings with minimal disruption of intracellular signaling cascades (Akaike, 1996).

The prevalence and consistency of the plasticity rules at the glutamatergic synapses onto O-LM cells suggest that long-term plasticity properties may be more uniform within individual interneuron types than previously expected. Glutamatergic afferents innervating stratum oriens in which O-LM cell dendrites are located include the local axons of CA1 pyramidal cells, CA3 pyramidal axons, and the alvear pathway of entorhinal afferents. The only known input to O-LM cells is from CA1 pyramidal cells, which form the majority of glutamatergic synapses on this cell type (Blasco-Ibáñez and Freund, 1995), which may explain the relatively uniform synaptic plasticity behavior. However, because most interneuron types receive glutamatergic afferents from several presynaptic loci, we cannot infer that the same patterns of plasticity occur at all synapses (Maccari and McBain, 1995).

**Conclusions**

Although “horizontal” interneurons in stratum oriens of the hippocampal CA1 area are often studied as a single group of interneurons (for review, see Maccari and McBain, 2005), they include several cell types in addition to O-LM cells (Klausberger and Somogyi, 2008). Despite the similarity of the somatodendritic shapes of these cells, interneurons in this layer are diverse and fall into several different categories. Each shows unique properties and a characteristic place in the circuitry (Sik et al., 1995; Losonczy et al., 2002; Gulyás et al., 2003; Ganter et al., 2004; Jinno et al., 2007). Whether other horizontal cell types in s. oriens show similar or different types of long-term synaptic plasticity remains to be studied systematically. Many of the mechanisms of long-term plasticity in interneurons in the hippocampus are still unclear, and to date AMPA/kainate, NMDA, and GluR1 receptors have been shown to play a role in LTP in nonpyramidal cells in s. oriens (Ouardouz and Lacaille, 1995; Perez et al., 2001; Lamsa et al., 2007a). Sampling across interneuron types could explain some of the heterogeneity reported in previous studies on plasticity in which interneuron types were not identified (for review, see Kullmann and Lamsa, 2008). Heterogeneous properties of synaptic plasticity across interneuron types may reflect a diversity of cell type-specific patterns, which would provide flexibility in the hippocampal inhibitory network.
