Abstract. The Atmospheric Chemistry Experiment (ACE) mission was launched in August 2003 to sound the atmosphere by solar occultation. Carbon monoxide (CO), a good tracer of pollution plumes and atmospheric dynamics, is one of the key species provided by the primary instrument, the ACE-Fourier Transform Spectrometer (ACE-FTS). This instrument performs measurements in both the CO 1-0 and 2-0 ro-vibrational bands, from which vertically resolved CO concentration profiles are retrieved, from the mid-troposphere to the thermosphere. This paper presents an updated description of the ACE-FTS version 2.2 CO data product, along with a comprehensive validation of these profiles using available observations (February 2004 to December 2006). We have compared the CO partial columns with ground-based measurements using Fourier transform infrared spectroscopy and millimeter wave radiometry, and the volume mixing ratio profiles with airborne (both high-altitude balloon flight and airplane) observations. CO satellite observations provided by nadir-looking instruments (MOPITT and TES) as well as limb-viewing remote sensors (MIPAS, SMR and MLS) were also compared with the ACE-FTS CO products. We show that the ACE-FTS measurements provide CO profiles with small retrieval errors (better than 5% from the upper troposphere to 40 km, and better than 10% above). These observations agree well with the correlative measurements, considering the rather loose coincidence criteria in some cases. Based on the validation exercise we assess the following uncertainties to the ACE-FTS measurement data: better than 15% in the upper troposphere (8–12 km), than 30% in the lower stratosphere (12–30 km), and than 25% from 30 to 100 km.

1 Introduction

Carbon monoxide (CO) plays an important role in atmospheric chemistry and is one of the key species that needs to be measured globally and at different altitudes. The primary emission sources of CO are associated with combustion processes (transport, heating, industrial activities and biomass burning), along with biogenic sources and oceans. It is also produced from the oxidation of methane and non-methane hydrocarbons (see Fig. 1). At surface level, the volume mixing ratios range from a background concentration of 50 parts per billion by volume (ppbv) to excess of 700 ppbv where high emissions occur. Large uncertainties remain in the estimated strengths of both natural and anthropogenic sources. The main sink for CO is chemical destruction by reaction with the hydroxyl radical (OH). In the lower atmosphere, where CO has a lifetime of several weeks to a few months, its observation allows the characterization of both emission sources and atmospheric transport of pollution plumes (Logan, 1981). In the upper troposphere, CO can also be transported across the tropical tropopause. In the stratosphere, CO is produced by the oxidation of methane and is converted to carbon dioxide (CO2) by reaction with OH. Above 50 km, in the mesosphere and thermosphere, photolysis of CO2 is the main source of CO, which reaches a concentration of 5–20 parts per million by volume (ppmv) at 80 km. At these altitudes, CO is also a useful dynamical tracer which can be used to study atmospheric transport processes, and, in particular, upward transport in high latitude summer regions and downward transport in the high latitude winter regions (e.g. Solomon et al., 1985).

Several remote sensing and in situ techniques provide routine measurements to monitor the spatial and temporal changes in the concentration of atmospheric CO. The accuracy, sampling and vertical, horizontal and temporal coverage of these measurements depend on the instrument and the observation technique (e.g. ground-based, airborne, or satellite-borne) and, in the case of optical measurements, of the spectral range and resolution used. Ground-based remote sensing techniques, in particular those available from the numerous sites in the Network for the Detection of Atmospheric Composition Change (NDACC, formerly NDSC, see http://www.ndacc.org) that are equipped with Fourier Transform Infrared (FTIR) instruments, have provided long-term CO atmospheric measurements (Kurylo, 1991; Yurganov et al., 2004; 2005; Velazco et al., 2007). Airborne MOZAIC (Measurements of OZone aboard In-service ARbus airCraft) flights provide routine monitoring of CO in the upper troposphere over large areas (Nedelec et al., 2005). Currently there
are extensive CO observations from space from several nadir looking remote sensors, such as MOPITT/Terra (Edwards et al., 2004; Clerbaux et al., 2008), SCIAMACHY/Envisat (Frankenberg et al., 2005), TES/Aura (Rinsland et al., 2006a; Luo et al., 2007a), and the recently launched IASI/Metop (Turquety et al., 2004; Clerbaux et al., 2007), which are yielding a global view of the CO tropospheric distribution. Although some of them (TES, SCIAMACHY) are also able to partly sound the atmosphere using a limb geometry, their ability to retrieve vertical information is limited. From space, vertically resolved profiles can be derived from measurements using limb geometry, in emission or absorption. The currently available limb-sounders working in emission are SCIAMACHY, MIPAS/Envisat (Funke et al., 2007), which uses the mid-infrared spectral range, SMR/Odin (Murtagh et al., 2002) and MLS/Aura (Pumphrey et al., 2007), which both rely on millimeter-wave spectroscopy. In absorption the single instrument currently providing CO measurements is the infrared Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS) (Bernath et al., 2005). It is worth noting that, among these instruments, only the ACE-FTS is capable of sounding CO simultaneously from the mid-troposphere to the mesosphere.

Intercomparison experiments are needed to validate the CO products obtained by different remote sounding instruments (Clerbaux et al., 2002; Emmons et al., 2004; Jin et al., 2005; Sussmann and Buchwitz, 2005; Dils et al., 2006; Barret et al., 2006; Luo et al., 2007a; Pumphrey et al., 2007; Warner et al., 2007; Rinsland et al., 2008). As the ACE mission approached its first public data release, a comprehensive exercise was undertaken to validate the retrieved profiles with the other datasets available. This paper aims at validating CO partial columns and profiles with correlative independent measurements. The paper is organized as follows: First, we describe the ACE mission, the ACE-FTS instrument and the CO version 2.2 (v2.2) data product from the ACE-FTS. Second, the co-located observations provided by different ground-based, balloon, airborne and satellite

(a) Microwindow for interferer O$_3$: the mixing ratio profiles of this interfering species are fitted simultaneously with the target CO profile.
(b) Microwindow for interferer CH$_4$: the mixing ratio profiles of this interfering species are fitted simultaneously with the target CO profile.

Instruments are outlined. Next, we discuss the comparisons between the ACE-FTS CO data and correlative observations available from March 2004 to December 2006, and, finally, we conclude with the reliability of v2.2 ACE-FTS CO data at different latitudes and altitude levels.

2 CO observations from the ACE-FTS

2.1 The ACE mission and the ACE-FTS instrument

The ACE mission (Bernath et al., 2005) on board the Canadian SCISAT-1 satellite was launched on 12 August 2003. The principal instrument of the mission, known as ACE-FTS, is a high resolution (0.02 cm$^{-1}$, corresponding to a maximum optical path difference of 25 cm) infrared Fourier transform spectrometer operating from 2 to 13 microns (750–4400 cm$^{-1}$), that measures the vertical distribution of trace
Table 2. Estimated total error on the retrieved CO partial columns from the ACE-FTS measurements, along with the relative contribution of the instrumental noise. The latter is the main contributor to the error budget. The other contributions include principally uncertainties in the retrieved temperature profiles (a 1 K uncertainty on each retrieval altitude was considered) and fitted interfering species.

gases, pressure, and temperature, by solar occultation. The baseline species retrieved from the v2.2 occultation measurements are O$_3$, CH$_4$, H$_2$O, NO, NO$_2$, ClONO$_2$, HNO$_3$, N$_2$O, N$_2$O$_5$, HCl, CCl$_3$, CCl$_2$F$_2$, HF, and CO (Boone et al., 2005). While in orbit, the SCISAT instruments observe up to 15 sunrises and 15 sunsets per day. The vertical sampling is about 3–4 km, on average, from the cloud tops up to about 105 km. Thanks to its excellent signal-to-noise ratio (effective SNR better than 200–300 over much of its spectral range) and 2 s measurement time, ACE-FTS provides accurate measurements with high vertical sampling, but its horizontal resolution is limited by the 500 km path length of solar occultation technique.

2.2 ACE-FTS CO retrievals

The ACE-FTS CO profiles (Boone et al., 2005) are retrieved by analysing sequences of solar occultation measurements taken during a sunrise or sunset, as seen from the satellite. These analyses take advantage of absorptions in both the fundamental 1-0 (4.7 µm) and the overtone 2-0 (2.3 µm) CO ro-vibration bands (Clerbaux et al., 2005). Because a large range of optical thicknesses is encountered during a sequence of measurements, the CO retrieval can best be performed using transmittance information from both absorption bands. Figure 2 illustrates the CO spectra as recorded at different tangent altitudes during one ACE-FTS occultation sequence. At high altitudes (>60 km), the CO generated from the CO$_2$ photo-dissociation is the strongest absorber in the 4.7 µm spectral range, but the lines saturate at lower tangent heights and the interferences from other atmospheric species (H$_2$O, O$_3$, N$_2$O, CO$_2$) increase. Both the saturation and the interferences prevent an accurate tropospheric CO retrieval using this spectral region only.

In the ACE-FTS retrieval process, which uses a global-fit method in a general non-linear least squares minimization scheme (Boone et al., 2005), a set of microwindows that vary with altitude in the fundamental band and in the overtone band are used to retrieve CO. The use of the intense 1-0 band provides information on the upper parts of the atmosphere, whereas the 2-0 band provides information at the lowest altitudes, when the signal from the fundamental band saturates. The microwindow sets used for the ACE-FTS version 2.2 retrievals are indicated in Fig. 2 and listed in Table 1. The molecules that are explicitly included as interferers in the retrieval of the target molecule are reported, and the mixing
Figure 4. ACE-FTS CO seasonal measurements in 2005 at 7.5 km. The data are interpolated to a 4° latitude x 8° longitude grid. The grey crosses indicate the ACE-FTS measurement locations (tangent heights). The lowest altitude measured by the ACE-FTS varies with the satellite orbit and the presence of clouds.

Ratio profiles for these interfering gases are fitted simultaneously with the target CO profile. The ACE-FTS profiles are provided on a 1-km vertical grid. To obtain the 1-km grid data products, an a posteriori piecewise quadratic interpolation scheme method is used to interpolate between the altitudes of the original measurement grid. It is worth noting that sometimes the first CO level (at low altitude) should be treated with caution. The v2.2 data products are provided with a fitting error calculated for each altitude. A detailed budget of the retrieval and instrumental errors can be estimated (see Clerbaux et al., 2005). It includes contributions from the instrumental noise, from the instrument line shape function, from the so-called smoothing effect (the fact that the information is integrated over several km on the vertical), and from uncertainties in the temperature and interfering trace gases profiles. Table 2 summarizes the retrieval errors in terms of partial columns, as currently estimated for the ACE-FTS version 2.2 CO retrievals. The error is the largest (2%) for the 6–12 km columns, where the errors due to interfering species and temperature uncertainties have the strongest impact; it decreases to 0.5% for the 12–25 and 25–50 km columns and finally increases again to about 1% for the 50–80 and 80–100 km columns. The errors in the individual retrieved levels of the CO profile is less than 10% in the troposphere (except for the very first levels below 8 km) and the stratosphere, and between 5 and 20% at higher altitudes. The measurement noise provides the dominant contribution to the error budget over the entire altitude range, with contributions ranging from 60–70% in the upper troposphere and the stratosphere to more than 90% higher up (Table 2).

2.3 ACE-FTS CO distributions

The very high signal-to-noise ratio achieved by the ACE-FTS and its ability to sound deep down in the atmosphere provide profile measurements of weakly absorbing species into the upper troposphere. This excellent tropospheric sounding performance has been highlighted in several recent papers.
Figure 5. ACE-FTS CO seasonal measurements in 2005 at 16.5 km. The data are interpolated to a 4° latitude x 8° longitude grid. The grey crosses indicate the ACE-FTS measurement locations (tangent heights). Note that the tropical latitudes are not well covered in January–February–March and October–November–December as the satellite orbit was optimized to study the polar regions in winter.

(Rinsland et al., 2006b, 2007a, 2007b; Coheur et al., 2007; Dufour et al., 2007; Turquety et al., 2008). Previous scientific studies have discussed the CO vertical profiles (v1.0 and v2.2) obtained from ACE-FTS since March 2004 (just after scientific commissioning was completed on 21 February 2004) (e.g. Clerbaux et al., 2005 (v1.0); Rinsland et al., 2005; Folkins et al., 2006). For CO, version 2.2 provides improved performance in the troposphere, as many microwindows sensitive to lower altitudes were added to the retrievals.

The altitude spacing of the ACE-FTS measurements, controlled by the scan time and the orbit of the satellite, varies with the beta angle (the angle between the satellite velocity vector and a vector from the Earth to the Sun). The altitude spacing ranges from 2 km for long occultations with high beta (around 55°) to 6 km when the sun sets (or rises) exactly perpendicular to the Earth horizon (occultations with beta angle zero). Note that the altitude spacing compresses at low altitudes (below about 40 km), primarily a consequence of refraction distorting the solar image viewed through the atmosphere. This is clearly seen from Fig. 3, which shows the vertical sensitivity functions, known as averaging kernels, for a typical CO retrieval using an Optimal Estimation Method (Rodgers, 2000) without a priori constraints, such as to resemble the general least-square retrievals performed operationally for version 2.2. For the particular case of Fig. 3, the vertical sampling is as good as 1.5 km in the troposphere and around 4 km in the mesosphere. There have been improvements in the retrievals and averaging kernels near 20–25 km, compared to v1.0 (Clerbaux et al., 2005), due to the combined use of the 1-0 and 2-0 ro-vibrational bands to retrieve CO at those altitudes.

After 3.5 years of operation, ACE-FTS observations have been performed all over the globe, however there were more frequent measurements at high latitudes, as the primary goal of the mission was to study the polar ozone chemistry. Figures 4 to 6 provide representative plots of CO at different altitude levels (mid-troposphere, upper troposphere/lower stratosphere (UTLS), and stratosphere/mesosphere) for the
year 2005. The years 2004 and 2006 (not shown here) exhibit similar high concentration values at specific locations/altitudes. Figure 4 illustrates the seasonal CO abundance distribution as measured by ACE-FTS in the mid-troposphere (around 7.5 km) for different seasons in 2005. As can be expected (e.g. Clerbaux et al., 2004; Edwards et al., 2004), in the Northern Hemisphere, most of the pollution is associated with urban activity, with persistent high values above China (see Fig. 4b) and elevated levels over US, Europe and Asia in winter and spring (Fig. 4a and b). CO levels are lower in the Northern Hemisphere during summer and fall, when sunlight produces high OH levels which activate chemical loss of CO. In the Southern Hemisphere, the CO pollution plumes emitted locally, where vegetation burning occurs, such as in South America, Africa and Australia spread from regional to global scales. As reported by others (e.g. http://earthobservatory.nasa.gov/Newsroom/NewImages/images.php?img_id=17724) intense fire activity and hence high CO levels were observed (starting from September 2005) over the Amazon basin, with some additional contribution from fires in Southern Africa. The transported plume can be observed in Fig. 4c and d, around 30°S.

In the UTLS, vertical transport may be investigated from the satellite CO vertical distributions (Notholt et al., 2003; Edwards et al., 2006; Ricaud et al., 2007; Park et al., 2008). Figure 5 a–d shows the global scale seasonal distributions at 16.5 km altitude, from which the high CO concentrations from convection occurring at tropical latitudes can clearly be seen. The plots illustrate the seasonal changes in convective outflow and biomass burning activity. From July to September (Fig. 5c), when the Asian summer monsoon is the dominant circulation feature, high levels of CO are observed over Asia (also see Park et al., 2008). During the other months (Fig. 5b, d), maximum amounts are observed over Africa, South America and Asia, but horizontal transport can be observed throughout the tropics.

Figure 6a–b illustrates the strong downward transport of CO-rich air in the winter polar vortex. The CO produced in the lower thermosphere from CO₂ photolysis is transported to the middle stratosphere by the mean meridional circulation (Kasai et al., 2005b; Velasco et al., 2007). The plots show the descent of CO-rich air produced around 80 km when vortex situations occur, in March over the Arctic pole (Fig. 6, left plots) and in September over the Antarctic (Fig. 6, right plots). A complete discussion of the effects of unusual meteorological conditions on transport and chemistry for the 2004–2006 period is described in Manney et al. (2008, this Special issue).

3 Correlative CO measurements

3.1 The ACE validation exercise

The validation of the ACE-FTS version 2.2 data is organized by data product (see the other papers of this Special issue). CO data from the first three years of the mission, extending from February 2004 (since the first ACE-FTS CO data became available) to the end of 2006, were made available to the validation team and are included in this paper. Primarily, the 1-km interpolated grid data were used in the comparisons.

Validation data used for these CO comparisons were provided by eleven ground-based stations, from routine airborne measurements, from one accurate high-altitude balloon-borne observation, and from five satellite instruments (two using nadir observations, three using limb-viewing observations). Each instrument uses a different measurement technique, sounding geometry, and dedicated retrieval algorithm (which relies on a forward radiative transfer code, a spectroscopic database, and a minimization scheme) to extract the desired CO abundances from the raw data (see Table 3). All the instruments reported here used the HITRAN spectroscopic database (Rothman et al., 2005). Although the HITRAN edition might differ, the changes did not concern the CO line parameters and it was verified (E. Mahieu, personal communication) that it did not impact the retrieved results.

The CO measurements are retrieved over different altitude ranges (see Fig. 1 for a representation of the altitude spanned for each device), with different vertical resolutions and maximum sensitivity. To properly account for the different vertical sensitivities of the correlative observations, the CO profile of the instrument with the higher profiling capability is smoothed by convolution with the averaging kernel functions.
of the instrument with the lowest vertical sensitivity (Rogers and Connors, 2003):

\[ x_{\text{smoothed}} = x_{\text{hi}, \text{low}} + A_{\text{low}} (x_{\text{high}} - x_{\text{hi}, \text{low}}) \]  

(1)

where \( x_{\text{high}} \) is the high resolution profile, \( x_{\text{hi}, \text{low}} \) is the a priori profile used for the retrieval of the low resolution profile, and \( A_{\text{low}} \) is the averaging kernel matrix, with \( \frac{\partial \mathbf{A}}{\partial \hat{x}} \) characterizing the low resolution profiles. The rows of \( \mathbf{A} \) define the vertical resolution of the retrieval (full width at half maximum), and the trace of the matrix defines the number of statistically independent elements that can be retrieved, or degrees of freedom for signal (DOFS).

### 3.2 Ground-based data

Eleven ground-based stations routinely measuring CO profiles/columns at different locations around the globe contributed to this validation exercise. Ten of these stations use FTIR spectrometers to sound the troposphere and lower stratosphere, and one is operating in the millimeter wave spectral range.

#### 3.2.1 FTIR measurements

FTIR spectrometers make direct solar absorption observations throughout the day, under clear sky conditions. The infrared spectral range that is covered extends from about 600 to 4300 cm\(^{-1}\), a range similar to that of ACE-FTS. In this spectral range, a very large number of species of atmospheric relevance can be detected. Profiles or partial column
CO data can be derived (Notholt et al., 2003; Barret et al., 2003; Hase et al., 2004). The FTIR measurements contain about two pieces of information that allow to retrieve CO abundances in the lower to middle troposphere and in the upper troposphere-lower stratosphere, almost independently.

Figure 7 and Table 3 provide the geographical distributions along with retrieval information for the ground-based ACE-FTS CO validation stations, with the following abbreviations:

- THULE (Greenland, Goldman et al., 1999),
- KIRUNA (Sweden, Blumenstock et al., 2006),
- POKER FLAT (Alaska, Kasai et al., 2005a),
- HARESTUA (Norway, Paton-Walsh et al., 1997),
- ZUGSPITZE (Germanic Alps, Sussmann and Borst-dorff, 2007),
- JUNGFRAUJOCH (Swiss Alps, Rinsland et al., 2000),
- TORONTO (Canada, Wiacek et al., 2007),
- IZANA (Canary Islands, Schneider et al., 2005),
- LA REUNION (Indian Ocean, Senten et al., 2008),
- WOLLONGONG (Australia, Jones et al., 2007).

3.2.2 Microwave measurements

Microwave spectrometers observe molecular rotational/vibrational spectra in emission from thermally excited states in the spectral range ∼20–300 GHz. They can therefore operate day or night, limited only by tropospheric opacity due primarily to varying water vapour column density. They are not affected by aerosol loading. Since they observe in emission, they are not self-calibrating, and must be independently calibrated against millimeter sources of known intensity. For the instrument at CERVINIA (de Zafra et al., 2004), when used in a radiometer mode to get total column density, this calibration uncertainty, along with uncertainty in continuous measurements of tropospheric attenuation, are the only significant sources of error. For this instrument, observations are made at a slant angle of 9–10 degrees in a due north direction, giving a stratospheric/mesospheric point of intersection about 3 degrees north of the ground station location, and this has been used in considering closest matches with ACE-FTS measurements. The location of this station, in the Italian alps, and the retrieval details are also reported in Fig. 7 and Table 3.

3.3 Airborne data

3.3.1 SPIRALE (high altitude balloon)

The SPeectroscopie Infra-Rouge d’Absorption par Lasers Embarqués (SPIRALE) is a balloon-borne six tunable diode laser absorption spectrometer (Moreau et al., 2005). It is routinely operated at all latitudes, in particular as part of European satellite validation campaigns (Odin and Envisat). It can perform simultaneous in situ measurements of about ten long-lived and short-lived chemical species from about 10 to 35 km height, with high sampling frequency (∼1 Hz), thus enabling a vertical resolution of a few meters depending on the ascent rate of the balloon. The diode lasers emit in the mid-infrared (from 3 to 8 µm) and the beams are injected into a multipass Herriot cell that is located under the gondola and is largely exposed to ambient air. The cell (3.5 m long) is deployed during the ascent when pressure is lower than 300 hPa. The multiple reflections obtained between the

Fig. 7. Geographic locations of the 11 ground-based validation stations used in this paper. Note that there are only two stations located in the Southern Hemisphere (La Réunion and Wollongong), and that four stations are located at latitudes where dynamics can be perturbed by the location of the polar vortex (Thule, Kiruna, Poker Flat, and Harestua).

Fig. 8. Coincidences between ACE-FTS measurements (in light gray, ACE occultation latitude versus time of year) and the ground based stations, for the three years of the mission. The color code for each station is the same as in Fig. 7. The coincidence criteria are provided in Table 3. Note that if time coincidences occur for a same station, symbols might be superposed.
two cell mirrors give a total optical path of 430.78 m. Species concentrations are retrieved from direct infrared absorption, by fitting the experimental spectra to spectra calculated using the HITRAN 2004 database (Rothman et al., 2005). Specifically, the ro-vibrational line at 2086.3219 cm\(^{-1}\) was used for CO.

3.3.2 MOZAIC (airplane)

The MOZAIC program (Marenco et al., 1998) has equipped five commercial airliners with instruments to measure ozone and relative humidity since 1994, and carbon monoxide since 2001. Measurements are taken from take-off to landing (Thouret et al., 1998). Based on an infrared analyser, the carbon monoxide measurement accuracy is estimated at ±(5 ppbv+5%) for a 30 s response time (Nedelec et al., 2003). The five MOZAIC aircraft make near-daily flights between Europe and a variety of destinations throughout the world. Measurements for more than 26 000 long-haul flights are recorded in the MOZAIC data base that is freely accessible for scientific use (URL: http://mozaic.aero.obs-mip.fr/web/).

3.4 Nadir-looking satellites

3.4.1 MOPITT/Terra

The Measurements Of Pollution In The Troposphere (MOPITT) remote sensing instrument was developed by Canada and the US and was launched aboard the EOS Terra satellite in December 1999. It began routine measurements in March 2000 and is still in operation. The Terra spacecraft is in a near-circular, sun-synchronous orbit with an inclination of
Table 4. Averaged percent difference and standard deviation between ACE-FTS and each ground-based (GB) station. The calculation was done for partial CO columns, for each coincident set of profiles using \(100 \times \frac{|(\text{CO}_{\text{ACE}} - \text{CO}_{\text{GB}})|/2}{(\text{CO}_{\text{ACE}} + \text{CO}_{\text{GB}})}\). Values in italics correspond to the calculation after smoothing with the GB averaging kernel functions. Values in parentheses correspond to calculation after filtering situations for which different air masses might have been sounded.

approximately 98.2 degrees. The descending node crossing time is 10:30 a.m. MOPITT views the Earth over all latitudes with a pixel size of 22 km by 22 km and a cross-track swath that provides a near-global measurement of the distribution of CO every three days.

MOPITT operates by sensing infrared radiation from either the thermal emission/absorption at 4.7 \(\mu\)m to measure CO profiles. The measurement technique exploits gas correlation radiometry to determine tropospheric concentrations. Operational MOPITT CO products available are currently based exclusively on thermal-channel radiances (Deeter et al., 2003; Emmons et al., 2004). The information content in MOPITT retrievals is better than a column in tropical and mid-latitude scenes, with some amount of profile shape information (DOFS between 1 and 1.8), and a maximum sensitivity around 5–8 km (Deeter et al., 2004). As the other thermal infrared instruments, MOPITT generally lacks sensitivity near the surface except during daytime and at locations where the thermal contrast (temperature gradient) between the surface and lower atmosphere is significant (Clerbaux et al., 2008).

This paper uses the version 3 retrievals from NASA Langley.

3.4.2 TES/Aura

The Tropospheric Emission Spectrometer (TES) is an infrared FTS on board the EOS Aura satellite launched in July 2004 (Beer, 2006). TES routinely operates in a nadir global survey mode with one-day-on followed by one-day-off cycles. The nadir footprint for a TES profile is 5 km \(\times\) 8 km, separated by 180 km along orbit, since May 2005. TES nadir spectra are recorded at 0.06 cm\(^{-1}\) resolution and small micro-windows in the CO (1-0) band are used for CO profile retrievals. The signal levels in the TES filter detecting CO spectral absorptions are greatly enhanced due to the improved optical alignment after an optical bench warm-up performed in December 2005. As a result, the DOFS and the precision in TES CO retrievals are improved (Rinsland et al., 2006a). The DOFS for TES CO are up to two in the tropics and become less than one at high latitudes.

TES data are distributed by the NASA Langley Atmospheric Science Data Center. The data version used in this paper is V002. TES data consists of profiles of CO reported at 24 levels per pressure decade (e.g., 1000 hPa to 100 hPa) between the surface and 100 hPa (~16 km). Together with the retrieved profiles, the averaging kernels, the a priori profiles, and the retrieval errors are provided in the data files.
3.5 Limb-viewing satellites

3.5.1 MIPAS/Envisat

The Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) is a limb emission FTS operating in the mid infrared spectral region (Fischer et al., 2008). It is part of the Environmental Satellite (Envisat) which was launched into its sun-synchronous polar orbit, with 98.55° inclination at about 800 km altitude, in March 2002. MIPAS operated from July 2002 to March 2004 at full spectral resolution (0.035 cm$^{-1}$). Within this standard observation (nominal) mode, MIPAS covered the altitude range from 6 to 68 km with tangent altitudes from 6 to 42 km every 3 km, and further tangent altitudes at 47, 52, 60, and 68 km. MIPAS passes the equator in southerly direction at 10:00 a.m. solar local time 14.3 times a day. During each orbit up to 72 limb scans are recorded. Vertical profiles of CO are among the 20 trace species retrieved with the dedicated scientific IMK-IAA MIPAS data processor (von Clarmann et al., 2003). CO 1-0 emissions at 4.7 μm, strongly affected by non-local thermodynamic equilibrium (non-LTE) effects, are used in the retrieval scheme which fully accounts for non-LTE (Funke et al., 2007). In this study, we used MIPAS CO data (version 9.0) retrieved from MIPAS standard observations taken at full spectral resolution (spectra versions 4.61 and 4.62) during February–March 2004. The MIPAS vertical resolution varies between 6 and 12 km.

3.5.2 SMR/Odin

The Odin satellite was launched in February 2001 into a circular, sun-synchronous, quasi-polar orbit at 600 km altitude, with an inclination of 97.8° and ascending node crossing at 18:00 local time (Murtagh et al., 2002). The Sub-Millimetre Radiometer (SMR) aboard Odin measures thermal emission lines at the Earth’s limb in the 486–581 GHz spectral range (Frisk et al., 2003). Measurements of CO and O$_3$ in the SMR strato-mesospheric mode (vertical scan range of 7–110 km) are performed regularly (one or two days per month since 2004) by observing rotational lines at 576.27 GHz (CO) and 576.52 GHz (O$_3$). The horizontal resolution is on the order of 600 km, with a horizontal spacing along the orbit track of ~950 km.

The SMR CO data product discussed here is version-225 (or CTSO-v225, for Chaîne de Traitement Scientifique Odin), the reference version maintained at the Laboratoire d’Aérodynamique (Toulouse, France). CO profiles are retrieved from ~20 km to the lower thermosphere, with a typical resolution of 3 km throughout. The single-scan precision is
Fig. 12. Examples of co-located CO vertical mixing ratio profiles measured by ACE-FTS (blue) and by the MOZAIC airborne program (green). Note that the upper limit altitude of the MOZAIC measurement is often close to, or at the same altitude, as the ACE-FTS lowest measured altitude.

Fig. 13. Averaged percent difference between ACE-FTS and MOZAIC (CO\(_{\text{ACE}}\)−CO\(_{\text{MOZAIC}}\)/1/2(CO\(_{\text{ACE}}\)+CO\(_{\text{MOZAIC}}\)), calculated using all the coincident observations (thick red line), along with the corresponding standard deviation (thin red lines) for the years 2004 and 2005. The number of coincident profiles ranges between 4 (at 12 km) to 37 (at 8-9 km).

estimated at better than 25 ppbv in the stratosphere increasing up to 1–2 ppmv at ∼80 km (Barret et al., 2006). The SMR CO measurements and data analysis methodology were described in detail by Dupuy et al. (2004). Early qualitative comparisons with ACE-FTS were published by Jin et al. (2005), whilst a detailed comparison of SMR/Odin with Aura/MLS can be found in Barret et al. (2006).

3.5.3 MLS/Aura

The Microwave Limb Sounder (MLS) (Waters, 2006) is one of four instruments on the EOS Aura satellite (Schoeberl et al., 2006) which was launched in July 2004. MLS is essentially a small radio telescope, viewing the Earth’s limb in the orbit plane of the Aura satellite. Observations range from 82 degrees South to 82 degrees North every day and are spaced 140 km apart along the ground track. MLS detects thermally-emitted radiation in several bands of the sub-millimetre spectral region, at frequencies ranging from 118 GHz to 2500 GHz. The measurements are processed to obtain profiles of temperature, geopotential height and the mixing ratio of more than 14 chemical species.

The mixing ratio of CO is obtained from measurements of the spectral line at 230 GHz. Two separate spectrometers are centred on this spectral line: a conventional filter bank of 25 channels and a digital autocorellator spectrometer (DACS) with 129 channels. The DACS channels are 97.6 kHz wide giving a total width of 12.5 MHz. The conventional filter bank has channels of various widths ranging from 6 MHz to 96 MHz, giving a total bandwidth of over 1 GHz. Version 2.2 data products are used for these comparisons. The MLS retrieval technique is described in detail by (Livesey et al., 2006) and the validation of the 2.2 CO product is provided in (Pumphrey et al., 2007).

4 Validation results

4.1 Methodology used for the intercomparison

All the data used in this paper were obtained from the teams that are working on the routine retrieval and analysis of CO concentrations for their measurement device, and who helped us to select the most reliable data for the validation comparisons. The coincidence location criteria (ACE-FTS versus instrument) and the CO product to compare (profile, smoothed profiles, or integrated partial columns) were decided in agreement with the participants, and after discussion with the people involved in the validation of the ACE-FTS products, for consistent analyses.

In this paper, we used the same procedure to treat all the measurements provided by the participating groups:

1. Select the data that meet the location and time coincidence criteria (see Table 3),
2. Intercompare ACE-FTS versus instrument at the altitude range where both instruments are simultaneously sensitive,
3. Convolve the ACE-FTS profile with the instrument averaging kernels when relevant (see text for discussion) to account for the different instrumental vertical sensitivities,
4. Calculate the percent difference \( \frac{\text{CO}_{\text{ACE}} - \text{CO}_{\text{nadir}}}{\frac{1}{2}(\text{CO}_{\text{ACE}} + \text{CO}_{\text{nadir}})} \), averaged over all the coincident observations, and the corresponding standard deviation.

5. Check if the co-location criteria used are stringent enough to sound similar air masses (for polar cases).

4.2 Ground-based data

A summary of the number of coincidences with ACE-FTS occultation measurements (for which ACE-FTS CO retrievals were available) is given in Table 3 for each ground-based station, along with an indication of the vertical sensitivity of the observation and the associated accuracy. A more complete description of each station, instrument and CO retrieval setup (inversion algorithm used and spectroscopic databases) can be found in the above-mentioned references (Sect. 3.2). After some tests, the coincidence criteria were chosen such that the measurements were within 24 h and within 1000 km. This ensured that there were at least a few matches per station. In case several ground-based profiles were available for one ACE occultation, the one that occurred closest in time was chosen. Figure 8 illustrates the time and location coincidences between the ACE occultation measurements and each of the ground based stations for February 2004–December 2006.

For the ground-based stations, the number of coincident CO observations was found to vary between 2 and 39, depending on the location of the station, the frequency of ACE-FTS measurements at the latitude of the station and the cloud coverage. A smoothing of the ACE-FTS CO profiles was also performed according to Eq. (1), using the a priori profiles and averaging kernel functions provided along with the ground-based CO profile observations.

Figure 9 represents the averaged observations for the stations for which at least 20 co-located measurements were found, both with raw data and the smoothed ACE-FTS data. The direct comparison of profiles proved to be difficult (see percent difference in Fig. 9), as the ACE-FTS height range and vertical resolution differs strongly from that of the ground-based instruments. Although some individual profiles matched quite well, we decided, for the sake of consistency, to compare partial column values. These results are summarized as a scatterplot in Fig. 10. The integrated CO partial columns were calculated from the lowest altitude for which ACE-FTS CO results were available up to 25 km, unless indicated otherwise in Table 3. The density needed for the column calculations at the location of each measurement was obtained by interpolating the European Centre for Medium-Range Weather Forecasting (ECMWF) data in place and time. Table 4 summarizes the averaged percent relative difference and standard deviation per station. The averaged differences were found to range from 13% to 40%. We found a very good correlation of 0.91, although the data are scattered for high CO volume mixing ratio levels. The agreement has to be discussed keeping in mind the fact that the measurements are up to 1000 km apart and up to 24 h
later, so some variability in the CO content is to be expected.

When looking at Fig. 10 and Table 4, the largest disagreements and standard deviations are observed over stations located at very high latitudes and hence where measurements may sample different regions of the polar vortex. For observations at high latitudes that were measured close to or within the polar vortex, further investigation was performed in order to check if both the validation and the ACE-FTS instrument have sounded the same air masses. For these cases, potential vorticity (PV) maps in the region of both measurements were calculated using the MIMOSA contour advection model (Hauchecorne et al., 2002), on isentropic surfaces at 475 K (∼18 km) and the air masses were compared. The data potentially coming from different air masses are flagged with a different symbol (star) in Fig. 10 and the calculations of relative differences in Table 4 are provided with and without accounting for these specific situations.

4.3 Airborne data

4.3.1 SPIRALE (high altitude balloon)

Only one coincidence (Fig. 11) was found with the SPIRALE balloon measurements and it occurred on 20 January 2006 between 17:32 UT and 19:47 UT. The CO volume mixing ratio profile was obtained during ascent, between 10.0 and 27.3 km. The balloon measurement position remained rather constant, with a mean location of 67.6±0.2° N and 21.55±0.20° E. The comparison is made with the ACE-FTS sunrise occultation that occurred 13 h later (sr13151 on 21 January 2006 at 08:00 UT, 64.28° N, 21.56° E) and 413 km away from the SPIRALE position.

Similar to what was performed for ground-based stations, a potential vorticity map was calculated from the MIMOSA contour advection model in the region of both measurements. They show that SPIRALE and ACE-FTS sounded similar air masses within the well-established polar vortex for the whole range of altitudes. The dynamical situation was stable with the PV agreement obtained to better than 10%. Even though ACE-FTS has a vertical resolution of 3–4 km and that of SPIRALE is more of the order of meters, smoothing the latter data with a set of triangular convolution functions (each 3 km at the base corresponding to the ACE resolution) did not change the shape of the SPIRALE CO profile.

For CO, the SPIRALE total uncertainty is estimated to be 6% over the entire altitude range. As shown in Fig. 11, the agreement is better than 22% between SPIRALE and ACE-FTS profiles for the altitude range 14–20 km. Between 20 and 24 km, the ACE-FTS profile is lower than SPIRALE by 36–120%. Above 24 km, the ACE-FTS profile becomes larger than SPIRALE with relative differences reaching 120% around 26–27 km. Although the SPIRALE instrument is providing more accurate measurements than ACE-FTS, it is difficult to draw conclusions based on a single winter profile located 400 km away and measured within the polar vortex. The ACE-FTS high positive values around 27 km might also be related to the negative ones around 23 km.

4.3.2 MOZAIC (airplane)

The CO measurements recorded during the MOZAIC commercial flights in 2004 and 2005 were compared with the ACE-FTS data. The collocation criteria, within 24 h and within a geographic distance of ±9° latitude and ±10° longitude, provided 108 matches. As there is only a small height range (localized between 6 and 12 km) where the CO measurements from both instruments overlap, we added an extra constraint such that at least three km of common observations should exist. The number of available co-located observations then decreased to 39. Figure 12 illustrates two typical examples where the highly resolved MOZAIC CO profiles connect well with the ACE-FTS data. Figure 13 summarizes comparisons between the two datasets for 2004 and 2005, by plotting the average of the percentage relative difference between the coincident ACE-FTS and MOZAIC data. The standard deviation of the differences is also provided, along with the number of data points used at each altitude. The agreement is very good, as the averaged difference is found to be lower than 16% between 6 and 12 km, in 2004–2005, with a positive bias. A parallel work performed with other airborne data (Hegglin et al., 2008) reports a 10% agreement for CO in the same altitude range.

4.4 Nadir-viewing satellites: MOPITT/Terra and TES/Aura

The MOPITT and TES nadir-viewing instruments provide global measurements using the thermal infrared emission of the Earth and the atmosphere to measure CO vertical profiles. As these two instruments have a small horizontal pixel
Fig. 17. Examples of co-located CO vertical mixing ratio profiles for ACE-FTS (blue) and three limb-looking instruments (MIPAS, SMR and MLS; in green). The retrieval errors are also reported (horizontal blue bars for ACE-FTS fitting errors from v2.2 files, and horizontal green bars for each limb-instrument). As MIPAS data are less vertically resolved, the ACE-FTS profile was smoothed by the MIPAS averaging kernels (in red).

Table 5. Summary of percent average difference on partial columns for the validation instruments, as a function of altitude, using \((100 \times (\text{CO}_{\text{ACE}} - \text{CO}_{\text{Instru}}))/\frac{1}{2} (\text{CO}_{\text{ACE}} + \text{CO}_{\text{Instru}})\). When a smoothing was applied, data are provided in italics.

</table>
size and global coverage, coincidences with the ACE-FTS occultation measurements are numerous. This study was performed using the following criteria: same day and within 5° longitude, 5° latitude for MOPITT (version 3), and ±24 h, within 300 km for TES (version V002). The choice of the coincidence criteria depended on how the data products are stored for each mission. For both instruments more than 3000 cases were found, spanning 2004, 2005 and 2006.

As with every thermal infrared nadir-sounding instrument, TES and MOPITT lack sensitivity near the surface due to the small thermal contrast between the Earth’s skin temperature and the first atmospheric levels, and the observations...
they provide have a limited vertical resolution. Although the CO volume mixing ratio products are provided at several altitudes, the levels are strongly correlated and the number of pieces of independent information ranges between one (total column) and two (two partial columns), depending on the latitude, with a maximum sensitivity in the free troposphere and information up to about 16 km. As discussed in Luo et al. (2007a), both MOPITT and TES CO retrieved profiles are biased by their a priori; but when similar initial conditions are considered, TES and MOPITT agree reasonably (<5% global average with <20% root mean squares for individual cases). Accuracies for both instruments were estimated to be 10% using aircraft data (Emmons et al., 2004; Luo et al., 2007b), in places where the retrievals are not influenced by the a priori.

Interestingly, as MOPITT and TES both have their maximum sensitivity around 6–8 km, a useful comparison can be obtained in the upper troposphere. In order to account for the different vertical sensitivities in the comparisons, the ACE-FTS profiles have been smoothed using the corresponding MOPITT and TES characteristics and Eq. (1). Figure 14 shows one MOPITT/ACE-FTS and one TES/ACE-FTS example comparison of co-located profiles used in the validation exercise. It can be seen that, here again, we have only a few altitude levels in common between the measurements (ACE-FTS profiles start no lower than 5 km). As expected, when looking at the paired sets of observations, the ACE-FTS CO profiles show much more vertical variability, with often the 5–10 km CO mixing ratios being higher, and the 10–20 km CO mixing ratio being lower than the MOPITT or TES ones. As can be observed from Fig. 14, the smoothed ACE-FTS profiles match the nadir viewing observations very well. Figure 15 provides the mean and standard deviation results averaged for the thousands of coincident profiles studied for the period 2004–2006. For both instruments, without smoothing, the agreement is around 5.5 and 8.5 km, and the disagreement increases with a negative bias of –10 to –60% for MOPITT and around –25% for TES in the range 9 to 15 km. As MOPITT relies on a single global a priori whereas TES uses different latitude-varying a priori, we expected to find higher differences in the case of MOPITT. After convolution with the averaging kernels associated with each instrument, we have an almost perfect match (less than 2.2% discrepancy in the 5.5–15 km altitude range). Differences in retrieval diurnal sensitivity are also accounted for this way.

4.5 Limb-viewing satellites: MIPAS/Envisat, SMR/Odin and MLS/Aura

There are currently three spaceborne instruments providing regular CO measurements using limb geometry: MIPAS/Envisat (Funke et al., 2007), SMR/Odin (Barret et al., 2006) and MLS/Aura (Filippiak et al., 2005). As for ACE, these missions are not able to see the lowest layers of the atmosphere due to the increase in atmospheric opacity and occurrence of clouds.

A detailed validation study of SMR versus MLS is found in (Barret et al., 2006), and a detailed comparison of MLS CO results with other instruments is provided in (Pumphrey et al., 2007).

For each of the three instruments, the time and location coincidence criteria were carefully chosen in agreement with the participants (see Table 3 for the summary). Figure 16 illustrates the ACE latitudinal coverage as a function of the time with the coincidences associated with each limb
instrument indicated. When several observations matched the same ACE-FTS profile, we selected the closest in time.

For MIPAS, the CO measurements available (version 9.0) just overlapped with the beginning of the ACE mission. By the end of March 2004, MIPAS operation was suspended due to instrumental problems. MIPAS resumed its measurements by the beginning of 2005, however, with reduced spectral resolution. For comparison with ACE-FTS, only the high-resolution data are chosen. In the MIPAS sensitive range (10–70 km), the vertical resolution varies between 6 and 12 km, depending on altitude region and illumination conditions. The estimated precision is 10–30% except for the 20–45 km region with values around 30–70%. The accuracy is limited mainly by instrumental noise. Model errors due to uncertainties in the non-LTE modelling have been estimated to be less than 10% (Funke et al., 2007). During the February and March 2004 period, using a coincidence criterion of ±18 h, ±1000 km, about 100 matches were found. It is worth noting that a very strong polar vortex occurred in the 2004 Arctic winter, leading to downwelling of large amounts of CO into the upper stratosphere. The convolution of ACE-FTS profiles with MIPAS averaging kernel functions was found to be necessary, as MIPAS vertical resolution is lower than that of ACE-FTS, in particular during night and above 40 km.

For SMR CO observations, we used the data (CTSO, version 225) as described in Barret et al. (2006), with the following coincidence criteria: ±10 h, ±9° latitude and ±10° longitude. A quality filter to select the most reliable data (good convergence and measurement response over 75%) led to 99 coincidences, with a vertical sensitivity from ~20 to 95–100 km, and an average vertical resolution of ~3 km.

The largest set of validation data is provided by the MLS/Aura instrument. More than 2100 coincidences were found using the following criteria: same day, ±0.75° latitude, ±12° longitude. Following the recommendations from Pumphrey et al. (2007), the MLS data (version 2.2) were filtered using the following values for internal checks: L2gpPrecision >0; and Quality >0.2; and Status <126; and Convergence <1.8. The vertical sensitivity of MLS ranges from 10 to 85 km, with 3–4 km vertical resolution over most of this range.

Typical CO profiles for each limb-viewing instrument are compared with the corresponding ACE-FTS CO data in Fig. 17. In general, the agreement per set of profiles is reasonable, depending on the altitude level considered. The ACE-FTS CO profiles are usually smoother than SMR and MLS (see Pumphrey et al., 2007 for further discussion), but the ACE-FTS v2.2 sometimes show oscillations (with even negative values) around 40–50 km, which might lead to large discrepancies when comparing with the other limb instruments at these altitudes.

Figure 18 provides the averaged profiles, the relative differences, the standard deviations and the number of coincidences per altitude, over the whole data set for each instrument. When looking at the relative difference plots, for MIPAS (Fig. 18, bottom left plot) the agreement is very good. After smoothing with the averaging kernel, the differences between the convolved ACE-FTS and MIPAS profiles (red line) are within ±26% at all altitudes, except between 38 and 41 km where it reaches ~50%. These differences are linked to the very unusual situation of strong CO-downward transport in the Arctic polar vortex in 2004, where most of the coincidences between ACE-FTS and MIPAS are located. When all the data above 70° N are filtered out, the differences were found to be further reduced (not shown here), but the number of coincident data decreased from 99 to 27.

SMR CO mixing ratios (Fig. 18, bottom middle plot) are considerably larger than those of ACE-FTS (by more than 50%) below ~22 km. Between 25 and 68 km, we found a very good agreement as the difference does not exceed 25%. Above 60 km, the ACE-FTS mixing ratios become larger than the SMR values.

For MLS, we found a negative bias below 20 km, large oscillating discrepancies between 20 and 35 km, a good agreement between 38 and 42 km, a negative bias ranging from −25% to −100% from 42 to 65 km, and a strong positive bias between 65 and 80 km.

Several studies comparing CO measured by the ACE-FTS, SMR and MLS limb sounders have already been published (Froidevaux et al., 2006; Barret et al., 2006; Pumphrey et al., 2007). Our results are broadly consistent with those studies however the plots might look different because we used 1/2 (COACE + COlimb) to calculate the relative values, instead of (COlimb) as was used in the above-mentioned papers. In the upper troposphere (below 20 km), we found that ACE-FTS CO profiles are much lower than those of MLS and SMR, in agreement with the results from Pumphrey et al. (2007) who have compared MLS version 2.2 and ACE-FTS CO. Livesey et al. (2008) also show that MLS CO is a factor of 2 too high at the 215 hPa retrieval level by comparison with MOZART airborne in situ data. In the lower stratosphere (below 30 km) ACE-FTS exhibits an underestimation of CO relative to MLS which is consistent with Pumphrey et al. (2007) and Froidevaux et al. (2006). Barret et al. (2006) reported an underestimation of MLS CO relative to SMR, especially in the tropics, at these altitudes.

Two dimensional latitude/altitude comparison plots for ACE-FTS and MLS are provided in Fig. 19, similar to what was reported in (Pumphrey et al., 2007). We display the ACE-FTS and coincident MLS data by taking a series of ACE-FTS measurements over latitudes moving from south to north between 2 September and 13 October, and plotting the mean daily profiles. To reduce noise, we averaged the closest MLS profiles to each ACE-FTS profile. Although the MLS data are more noisy and ragged, particularly near 45–60 km, it is clear that there are many similarities between the two datasets. We note in particular the high volume mixing ratios in the southern polar vortex. The biases between the two instruments can also be seen.

5 Summary and conclusions

This paper provides an assessment of the CO atmospheric profiles obtained during the first three years of the ACE mission, in order to quantify the level of agreement obtained with other available instruments. The ACE-FTS CO version 2.2 products are derived from solar occultation measurements, using two CO absorption bands located around 2100 cm\(^{-1}\) and 4250 cm\(^{-1}\), which allows sounding the atmosphere from about 5 km up to 100 km. The vertical sampling ranges from 2 to 6 km, depending on the altitude and on the beta angle of the measurement. Although the horizontal coverage of ACE-FTS is limited by the solar occultation mode, when accumulating several months of measurements we show that interesting features can be studied in the mid-troposphere (transport of pollution plumes associated with pollution and biomass burning events), in the UTLS (convection over tropical regions) and in the stratosphere-mesosphere (descent of CO-rich air masses over the winter poles).

A comprehensive validation exercise was undertaken that involved the simultaneous analysis of partial column data derived from the routine profile observations from eleven ground-based stations, of profiles derived from balloon borne and aircraft observations, and of vertical distributions as measured by the available nadir and limb-looking satellites. For each instrument, we carefully selected the coincident and most reliable data products to intercompare (partial columns or part of vertical profiles). When required, an additional data processing step or constraint was added such as convolution with the averaging kernel functions, or sorting based on PV for high latitude ground-based stations.

The intercomparison of the ACE-FTS CO profiles at all altitude levels proved to be difficult as none of the correlating instruments provide measurements that cover the full range of the ACE measurements. A summary of the averaged percent differences, as a function of altitude, for all the instruments included in this validation paper, is provided in Table 5. In the mid to upper troposphere, we were able to compare the ACE-FTS CO data with partial columns provided by ground-based data, with the highly resolved profiles provided by MOZAIc (aircraft), and with the nadir observations from the MOPITT and TES nadir-looking instruments. For the latter, the agreement is excellent when the averaging kernel information is taken into account, although these results should be tempered by the fact that there is not much more than one piece of information available from the nadir-viewing satellite observations. As the maximum sensitivity of both TES and MOPITT are around the altitude of the first levels of the ACE-FTS CO observation, we can conclude that the ACE-FTS CO products are reliable between 6 and 10 km, with an agreement reaching 2.5% at these altitudes. We report a good agreement with the MOZAIc (15% on average between 6 and 12 km) and SPIRALE (around 25% or better below 20 km) measurements, despite the loose coincidence criteria. The comparison of partial columns retrieved by ACE-FTS with partial columns retrieved from ground-based FTIR data at several locations revealed differences ranging between 13 and 34% when adequate smoothing is applied, with no systematic bias and standard deviations between 7 and 28%. The causes of the disagreement could be linked to atmospheric variability. In the stratosphere, from about 12 to 50 km, where the CO levels are usually very low, large discrepancies were found with SPIRALE balloon observation but it relies on one single coincident measurement in polar vortex conditions. From 20 to 100 km, comparisons performed with limb sounders show an agreement better than 10%, except for MLS. For the latter, individual profiles were found to be much noisier than the ACE-FTS data, but when averaged over longer time period and latitudes the CO atmospheric features agree well (Fig. 19). From these findings, combined with our initial estimation of the ACE-FTS retrieval errors, we assigned the following uncertainties to the ACE-FTS measurement data: better than 15% in the upper troposphere (8–12 km), than 30% in the lower stratosphere (12–30 km), and than 25% from 30 to 100 km.

Acknowledgements. The Atmospheric Chemistry Experiment (ACE), also known as SCISAT-1, is a Canadian-led mission mainly supported by the Canadian Space Agency (CSA) and the Natural Sciences and Engineering Research Council of Canada. Odin is a Swedish-led satellite project funded jointly by Sweden (SNSB), Canada (CSA), and France (Centre National d’Etudes Spatiales, CNES) and Finland (Tekes). C. Clerbaux and S. Turquety are grateful to CNES for financial support. We thank Matthieu Pommier and Catherine Wespes for their contributions. The research in Belgium was funded by the F.R.S.-FNRS (M.I.S. n°F.4511.08), the Belgian State Federal Office for Scientific, Technical and Cultural Affairs and the European Space Agency (ESA-Prodex arrangements n°C90-219). Financial support by the "Actions de Recherche Concertées" (Communauté Française de Belgique) is also acknowledged. ULg group members acknowledge that the International Foundation High Altitude Research Stations Jungfraujoch and Gornergrat (HFSJG), 3012 Bern, Switzerland, made it possible for us to carry out our experiments at the High Altitude Research Station at Jungfraujoch. The ground-based FTIR (and MW) data used in this publication were obtained as part of the Network for the Detection of Atmospheric Composition Change (NDACC). Data from these stations is publicly available from http://www.ndacc.org. SMR/Odin and MOZAIc data are stored in the Ether French atmospheric data base (http://ether.ipsl.jussieu.fr). Work at the Toronto Atmospheric Observatory was supported by NSERC, CFCAS, ABB Bomem, ORDCF, PREA, the University of Toronto, and a grant from the Canadian Space Agency. The SPIRALE balloon measurements could only be performed thanks to the technical team (L. Pomathiod, B. Gauhbercher, G. Jannet); the flight was funded by ESA and CNES for the Envisat validation project; the CNES balloon launching team is greatly acknowledged for successful operations. The IAA team was supported by the Spanish project ESP2004-01556 and EC FEDER funds. The elements of the research described in this publication carried out at the Jet Propulsion Laboratory, California Institute of Technology, were under a contract with the National Aeronautics and Space Administration.
