Abnormal uterine bleeding is the leading indication for discontinuation of long-term progestin-only contraceptives (LTPOCs). Histological sections of endometria from LTPOC-treated patients display abnormally enlarged blood vessels at bleeding sites. Paradoxically, a trend toward reduced endometrial perfusion in LTPOC users has been reported in these patients. We hypothesized that hypoxia/reperfusion-induced free radical production inhibits the expression of angiopoietin-1 (Ang-1), a vessel stabilizing factor, leaving unopposed the effects of endothelial Ang-2, a vessel-branching and permeability factor. Immunohistochemical studies confirmed selective decreases in stromal cell Ang-1 in LTPOC-exposed endometrium. To indirectly assess whether LTPOC enhances endometrial free radical production, immunostaining was conducted for the phosphorylated form of the stress-activated kinases SAPK/JNK and p38. These kinases were greatly increased in endometrium from LTPOC-treated patients. Interestingly, the endothelial cells but not the stromal cells displayed enhanced immunostaining for the phosphorylated mitogen-activated kinase (pMAPK) after LTPOC treatment. To further examine the effects of progestin, hypoxia, and reactive oxygen species (ROS) on the regulation of Ang-1 and Ang-2 as well as the activation of MAPK, SAPK/JNK, and p38 by the relevant cell types, we conducted in vitro studies with cultured normal human endometrial stromal cells (HESCs) and human endometrial endothelial cells (HEECs). Cultures of HESCs were treated with vehicle control, estradiol (E₂), or with medroxyprogesterone acetate ± E₂ under hypoxic and normoxic conditions. Although medroxyprogesterone acetate but not E₂ increased Ang-1 expression, hypoxia greatly decreased Ang-1 protein and mRNA expression. In contrast, HESCs did not appear to express Ang-2 protein or mRNA. Conversely, cultured HEECs did not appear to express Ang-1, but expressed Ang-2, the levels of which were significantly increased by hypoxia. Hypoxia also induced the phosphorylation of SAPK/JNK and p38 in both cultured HESCs and HEECs. Moreover, ROS such as that observed after hypoxia/reperfusion resulted in the activation of SAPK/JNK and p38 in HESCs and HEECs and inhibited Ang-1 in cultured HESCs. These effects could be blocked by oxygen radical scavengers. Consistent with the in vivo studies, MAPK was activated after ROS treatment in HEECs but not in HESCs. Our findings suggest that LTPOC-induced endometrial bleeding occurs as a result of hypoxia/reperfusion-induced free radicals that directly damage vessels and alter the balance of Ang-1 and Ang-2 to produce the characteristic enlarged and permeable vessels that are prone to bleeding. (Am J Pathol 2002, 161:979–986)

Long-term progestin-only contraceptives (LTPOC) provide a highly practical solution to family-planning needs in developed and developing countries. Unfortunately, bleeding in the early months of treatment often results in the discontinuation of these otherwise safe and efficacious contraceptive methods. Several studies have shown that levonorgestrel (LNG) administered either locally to the uterine cavity or systemically results in very significant morphological changes in the endometrium including gland atrophy, extensive decidual transformation of the stroma, and increased endometrial vasculature density.1–3 With long-term LNG contraception, the vessels are enlarged, dilated, thin-walled, and fragile, suggesting they are the product of aberrant angiogenesis.4,5 Indeed, a number of investigators have found a link between LTPOC-associated bleeding and aberrant expression of the angiogenic agent vascular endothelial growth factor (VEGF).6–8 Immunostaining for

VEGF in endometrial glands and stroma was significantly increased after LTPOC therapy, however, no correlation was found between the VEGF-staining index and endometrial microvascular density.7

Although VEGF initiates angiogenesis, it is now known that another family of proteins, the angiopoietins acting via the Tie-2 receptor, are key regulators of the subsequent angiogenic steps including vessel branching, maturation, and stabilization. Angiopoietin-1 (Ang-1) promotes vascular integrity by optimizing the integration of the endothelial cells with the surrounding supporting cells. Recently it was reported that Ang-1 protects the adult vasculature from bleeding by countering the permeability effects observed after excess exposure to VEGF.9,10 In contrast, Ang-2 is a partial antagonist of Ang-1/Tie-2 interactions and is generally expressed in areas undergoing vascular remodeling.11 Like VEGF, Ang-2 enhances vascular permeability and branching. Both hypoxia and VEGF up-regulate Ang-2 expression in bovine microvascular endothelial cells.12,13 Thus, Ang-1 and Ang-2 have complementary roles in vascular development and maintenance. Therefore, it is plausible that altered regulation of Ang-1 and Ang-2 is responsible for the pathological endometrial angiogenesis observed after LTPOC treatment.

In a recent pilot study, Hickey and colleagues14 demonstrated a trend toward reduced endometrial perfusion in long-term progestogen users. We hypothesized that this trend could reflect changes in the autoregulation of endometrial blood flow that likely induce focal areas of hypoxia. Recently, our laboratory has shown that Ang-2 is expressed by endometrial endothelial cells and it is strongly up-regulated by hypoxia and the inflammatory agent phorbol myristate acetate.15 In addition, a number of investigators have demonstrated that hypoxia also up-regulates VEGF expression in endometrial stromal cells and glands.16,17 Hypoxia is frequently followed by reperfusion and results in oxidative damage in the surrounding tissues.18–20 Such oxidative stress has been shown to induce SAPK/JNK and p38 kinases in a number of different cell types.21–24 In addition, increased circulating levels of lipid peroxides with concomitant depression of the antioxidant vitamin E have been reported in users of LTPOCs experiencing breakthrough bleeding.25 Thus, we posit that LTPOC-induced hypoxia/reperfusion and/or oxidative stress promotes the dysregulation of Ang-1 and Ang-2 and gene activation resulting from the phosphorylation of stress-activated kinases in endometrial stromal and endothelial cells leading to fragile vessel formation and ultimately breakthrough bleeding. The aim of this study was to test this hypothesis by evaluating the effect of progestins, hypoxia, and oxidative stress on the expression of the angiopoietins, MAPK, SAPK/JNK, and p38 kinases in vivo and in vitro.

Materials and Methods

Tissues

Endometrial specimens for immunohistochemical studies were obtained from women with normal menstrual cycles before and 3 months after starting LTPOC with either Norplant implants (n = 6) or a LNG-releasing intrauterine system (LNG-IUS; n = 10). Pretreatment samples were obtained from either the proliferative or secretory phases of the cycle by blind pipelle biopsy (Unimar, Willon, CT). In addition, endometrial specimens were obtained from patients undergoing hysterectomies for myomas, and transported on ice to a sterile laminar flow hood for endometrial cell isolation and culture. Small portions were formalin-fixed for dating by the histological criteria of Noyes and colleagues.26 The use of endometrial tissue for study was approved by the respective centers’ Institutional and Ethical Review Boards and written informed consent was obtained before endometrial sampling.

Immunohistochemistry

Endometrial specimens from control and LTPOC-treated patients were fixed in 4% paraformaldehyde and embedded in paraffin. Peroxidase staining was conducted with the ABC elite kit from Vector Laboratories (Burlingame, CA) as described.15 Goat polyclonal antibodies to Ang-2 were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Rabbit polyclonal antibody to Ang-1 was obtained from Alpha Diagnostic (San Antonio, TX). Rabbit polyclonal antibodies to phosphorylated SAPK/JNK, p38, and to total or phosphorylated MAPK were obtained from Cell Signaling Technology (Beverly, MA).

Preparation of Primary Endometrial Stromal Cells (HESCs)

Human Endometrial Stromal Cells (HESCs)

HESCs were isolated and grown to confluence in a 37°C incubator using a basal medium as previously described.27 For hormone treatment of HESCs, the experimental period was initiated by the addition of vehicle control or 10−8 mol/L estradiol (E2) ± 10−7 mol/L me-droxyprogesterone acetate (MPA). The cells were treated for 10 days, changing the medium every 3 to 4 days. Cultures were then exposed to either normoxic or hypoxic conditions for an additional 48 hours in a serum-free, defined medium as previously described.27 The latter was achieved by placing select cultures in sealed chambers containing a portable gas oxygen analyzer and a beaker of water to maintain humidity. The chambers were then purged with 5% CO2 and 95% N2 until the oxygen analyzers read 0 to 1% O2 (12 to 14 mm Hg) and returned to the incubator for 48 hours. No changes in O2 levels were observed throughout the duration of the incubations. Experimental incubations were terminated by removing the conditioned media and extracting the cell lysate directly with either sodium dodecyl sulfate gel-loading buffer for protein studies or with Tri-reagent (Sigma, St. Louis, MO) for total RNA as previously described.28
land, WA) in CS-C Complete Medium supplemented with 15% stripped fetal calf serum as described. The cells were harvested by trypsin/ethylenediaminetetraacetic acid (EDTA) and split 1:6 for four to six passages. The experimental conditions were performed in a serum-free defined medium as described. Select cultures were treated with hypoxia and harvested for protein or total RNA in the same manner as that described for the HESCs (see above).

**Reactive Oxygen Species (ROS) Generation**

ROS were generated either by the addition of H$_2$O$_2$ (50 μmol/L), FeCl$_2$ (50 μmol/L), or both for the indicated times in defined media. Desferrioxamine (250 μmol/L), or dimethyl sulfoxide (DMSO) (28 mmol/L) were used to block oxygen radical production. All reagents for ROS were obtained from Sigma-Aldrich (St. Louis, MO).

**Western Blotting**

Western blotting was conducted on 5 to 15% gradient gels (Bio-Rad, Hercules, CA) as previously described. Antibodies to phosphorylated SAPK/JNK, p38, and total or phosphorylated MAPK were obtained from Cell Signaling Technology. Antibodies to Ang-1 were from Alpha Diagnostic and to Ang-2 from Santa Cruz Biotechnology.

**Northern Blotting**

Northern blots for Ang-1 and Ang-2 were conducted as previously described.

**Reverse Transcriptase-Polymerase Chain Reaction (RT-PCR)**

RT-PCR for Ang-1 and Ang-2 was conducted as follows: reverse transcription, first strand synthesis was performed with Superscript First Strand Synthesis Systems for RT-PCR (Life Technologies, Inc., Grand Island, NY) using 1 to 5 μg of total RNA and oligo(dT) (0.5 μg/μl) as recommended by the manufacturer. The reaction was terminated by incubating at 70°C for 15 minutes and followed by treatment with RNase H for 20 minutes before proceeding to the PCR step. PCR was then conducted with Platinum PCR SuperMIX (Life Technologies, Inc.) and 5 μl of template DNA derived from the first strand synthesis plus 200 mmol/L of sense and antisense primers for Ang-1 or Ang-2. The PCR primer pair for Ang-1 used is commercially available from R&D Systems (Minneapolis, MN). The product yields a fragment 582 bp long. The primer pair for Ang-2 was synthesized by Life Technologies, Inc. using the sequence published by Kim and colleagues. The product yields a fragment 1535 bp long. Thirty-five cycles were performed for the PCR reaction.

RT-PCR for Tie-2 and GAPDH. Reverse transcription was conducted in the same manner as that for Ang-1 and Ang-2. The PCR step was conducted with the MPCR Kit from Maxim Biotech Inc. (San Francisco, CA) that contains primers for Tie-2 and GAPDH according to the manufacturer’s instructions. The PCR product for Tie-2 results in a 212-bp fragment and the product for GAPDH results in a 750-bp fragment.

**Results**

**Immunohistochemical Studies**

**Ang-1 and Ang-2**

Fixed endometrial specimens obtained before and after 3 months of LTPOC treatment were stained for Ang-1 and Ang-2. Figure 1 indicates that both secretory and proliferative endometrium stained for Ang-1 in an even manner. The highest degree of staining occurred in the endometrium with low-level staining in the stroma and in the glands. In contrast, high-dose local intrauterine progestin (LNG-IUS)-exposed endometrium displayed patchy
staining for Ang-1 with some areas of high staining and some areas of low to no staining. The percentage of high versus low staining is \( \approx 80\% \) versus \( 20\% \) (GK). In contrast to that observed in cycling endometrium, most of the staining for Ang-1 after LTPOC was observed in the stromal cells (Figure 1). Unlike results observed with Ang-1, immunostaining for Ang-2 was mainly confined to endothelial cells in both control and LTPOC-exposed endometria (Figure 2). Because of the high levels of Ang-2 expressed in normal cycling endometrium as well as that expressed after LTPOC, it was difficult to ascertain whether LTPOC resulted in a significant increase in endothelial cell Ang-2 expression in the endometria of LNG-treated patients compared to controls.

**SAPK/JNK and p38**

To assess whether stress pathways were activated after LTPOC treatment, sections were stained for phosphorylated SAPK/JNK and p38. As can be seen in Figure 3, both p38 and SAPK/JNK were greatly activated after LTPOC in the stromal, endothelial, and glandular epithelial cells (\( n = 5 \)). MAPK was activated specifically in the endothelial cells after LTPOC. In contrast, there was no difference in immunostaining for total MAPK in LTPOC-treated versus controls (not shown).

**Effects of Progestin, Hypoxia, and Oxidative Stress on the Expression of Ang-1 and Ang-2 in Cultured HESCs**

As can be seen in Figure 4A, MPA greatly enhanced the expression of Ang-1 mRNA by cultured HESCs compared to those treated with vehicle control or E\(_2\). The effects of progestin were similar in the presence or absence of E\(_2\). The expression of Ang-1 protein mimicked the results observed for mRNA (Figure 4B, Western blot).

We next studied the effects of hypoxia after steroid hormone treatment of cultured HESCs. As can be seen in Figure 5, A and B, hypoxia abolished the MPA-induced expression of Ang-1 mRNA and protein expression. Because hypoxia is generally followed by reperfusion leading to free radical generation, we investigated whether oxidative stress may be involved in the generation of the fragile vessels and bleeding associated with LTPOC treatment. To test this hypothesis, HESCs were incubated under control or oxygen radical-generating conditions as described in Materials and Methods. Figure 6A indicates that the production of ROS decreased the
expression of Ang-1 mRNA. The addition of the antioxidant desferrioxamine, a potent Fe-chelating agent, blocked the reduction in Ang-1 mRNA consistent with the agent's ability to block ROS production31 and inhibit oxidative damage. Similar results to those observed for mRNA were also observed for Ang-1 protein by Western blotting (Figure 6B).

In contrast, there was no discernable level of Ang-2 mRNA as assessed by either Northern blotting or by RT-PCR in either control or steroid-treated HESC cultures with or without hypoxia or oxidative stress (Figure 7).

Effects of Hypoxia and Oxidative Stress on HEEC Ang-1 and Ang-2 Expression

Although a recent study reported the presence of steroid receptors in human endometrial endothelial cells (HEECs),32 we and others have not been able to demonstrate these findings.33,34 The lack of receptors was observed in either early passaged33 or unpassaged endometrial endothelial cells (unpublished results). Hence, given their apparent lack of steroid receptors, HEECs were not treated with ovarian steroids. In contrast to the HESC cultures, HEECs failed to express detectable levels of Ang-1 mRNA after conducting RT-PCR. Conversely, they expressed Ang-2 mRNA whereas HESCs did not (Figure 7). No signal was observed when the reaction was performed with primers for Ang-1, Ang-2, or Tie-2 (not shown).

In addition, we demonstrate that as expected, HEECs but not HESCs display a band for the Tie-2 receptor. As a control, we show that GAPDH was expressed by all cells (Figure 7).

Effects on the Activation of SAPK/JNK and p38 by Oxygen Radicals on Cultured Endometrial Cells

Cultured HESCs were incubated under control or oxygen radical-generating conditions. As can be seen in Figure...
8. Western blot analysis showed that SAPK/JNK and p38 were greatly activated (ie, phosphorylated) under these conditions whereas MAPK was not. The addition of the oxygen radical scavenger DMSO greatly decreased the activation of these kinases. Parallel blots were probed for total MAPK (unphosphorylated) demonstrating equal levels of protein in all samples.

Similarly, Western blot analysis of cultured HEECs incubated under control or oxygen radical-generating conditions demonstrated that both SAPK/JNK and p38 were greatly activated by oxidative stress and DMSO decreased their activation (Figure 9). In contrast to the effect on HESCs, oxidative stress resulted in the activation of MAPK in HEECs. The levels of total MAPK however, demonstrated similar loading levels.

Discussion

LTPOC treatment is often associated with vascular changes that result in increased numbers of abnormally enlarged fragile vessels and breakthrough bleeding. However, the exact mechanism(s) regulating this aberrant angiogenesis are not clearly understood. The finding of a trend toward reduced perfusion in short-term progestogen users suggests that LTPOC treatment results in hypoxia. Tissue hypoxia is almost invariably followed by reperfusion-induced free radical damage. It is now known that oxidative damage is involved in the pathogenesis of several human diseases. The classic example of organ damage related to ischemia reperfusion is represented by injury to the myocardium. Indeed, reperfusion not only causes a rapid degeneration of endothelial cell function in the heart but also in the lung, gut, and kidney and has been linked to systemic sclerosis, Parkinson’s disease, and atherosclerosis. Thus, ischemia/reperfusion are two critical events that may result from LTPOC treatment leading to the generation of oxidative stress, aberrant angiogenesis, and breakthrough bleeding. Importantly, it is now known that ROS play a major role in the activation of cell signaling pathways leading to vascular pathologies.

Indeed, SAPK/JNK activation has been shown in rat cardiac myocytes after hypoxia/reperfusion. In cultured hepatocytes, hypoxia alone was able to induce JNK/SAPK activity, but not to the extent of that observed when hypoxia was followed by reperfusion. Similarly, p38, another stress-activated kinase, has been shown to be activated in response to hypoxia in pulmonary microvascular endothelial cells and by hypoxia/reperfusion in cultured cardiac myocytes. Thus, the up-regulation of these pathways may represent a tool to identify free radical generation in affected tissues.

Our current findings demonstrated that proliferative and secretory endometrium display immunohistochemical staining for Ang-1. Although staining was observed in the vessels, RT-PCR conducted on total RNA isolated from cultured HEECs did not produce the Ang-1 fragment whereas the fragment was produced by HESCs. In contrast, HEECs expressed Ang-2 and Tie-2 mRNA. Thus, it is possible that the staining pattern reflects binding of Ang-1 to its endothelial cell receptor, Tie-2. In contrast to the pattern of Ang-1 expression in cycling endometrium, an uneven pattern of immunostaining for Ang-1 was observed in endometrial tissue exposed to long-term LNG (local intrauterine or systemic delivery). It is important to note, that because of the difficulty in obtaining large numbers of tissues from LTPOC users, the immunohistochemical studies in the present report combined samples from patients treated with LNG deliv-
ered either as Norplant implants or as a LNG-releasing intrauterine system (LNG-IUS) and is limited to a total number of 16 specimens.

Consistent with the hypothesis that localized areas of hypoxia-reperfusion and the resultant formation of active oxygen species impair Ang-1 production after LTPOC, we show that both hypoxia and oxygen radical production decrease expression of Ang-1 mRNA and protein in cultured HESCs (Figures 5 and 6). Thus, we posit that although progestin enhances cultured HESC Ang-1 expression in a normoxic, nonoxidative milieu, the inhibitory effects of LTPOC observed in vivo result from decreased endometrial perfusion, hypoxia/reperfusion, and paraadoxically decreased expression of Ang-1. Furthermore, previous studies have shown hypoxia induced HEEC Ang-2 expression. Increased Ang-2 promotes capillary branching and increased permeability, and decreased Ang-1 augments these effects and results in reduced vessel stabilization via the Tie-2 receptor that is expressed by the endothelial cells (Figure 7). Thus, hypoxia/reperfusion and induction of free radicals could reduce the local endometrial Ang-1:Ang-2 ratio leading to aberrant angiogenesis and the observed abnormal vessels found in LTPOC-exposed endometria. This altered Ang-1:Ang-2 ratio would occur within the context of a simultaneous induction in VEGF expression, exacerbating the aberrant angiogenic stimulus and predisposition toward leaky vessels.

Further supporting our hypothesis that focal areas of hypoxia-reperfusion lead to the formation of active oxygen species after LTPOC treatment, is our finding of preferential activation of SAPK/JNK and p38, in LTPOC-exposed endometria (Figure 3). In addition, the generation of oxygen radicals in vitro greatly activated SAPK/JNK and p38 in HESC and HEEC cultures (Figures 8 and 9). Interestingly, MAPK was activated only in the endothelial but not the stromal cells after LTPOC treatment, consistent with results observed in cultured HEECs (Figure 9).

Our present findings together with a previous study demonstrating increased circulating levels of lipid peroxides, concomitant depression of the antioxidant vitamin E, and a suggestion that vitamin E supplementation may counteract these unwanted side-effects in LTPOC users experiencing breakthrough bleeding have clinical implications and suggest that antioxidant therapy may reduce the degree and extent of LTPOC-associated abnormal uterine bleeding.
