Forest plots: trying to see the wood and the trees
Steff Lewis, Mike Clarke

Few systematic reviews containing meta-analyses are complete without a forest plot. But what are forest plots, and where did they come from?

What is a forest plot?
In a typical forest plot, the results of component studies are shown as squares centred on the point estimate of the result of each study. A horizontal line runs through the square to show its confidence interval—usually, but not always, a 95% confidence interval. The overall estimate from the meta-analysis and its confidence interval are put at the bottom, represented as a diamond. The centre of the diamond represents the pooled point estimate, and its horizontal tips represent the confidence interval. Significance is achieved at the set level if the diamond is clear of the line of no effect.

The plot allows readers to see the information from the individual studies that went into the meta-analysis at a glance. It provides a simple visual representation of the amount of variation between the results of the studies, as well as an estimate of the overall result of all the studies together. Forest plots increasingly feature in medical journals, and the growth of the Cochrane Collaboration has seen the publication of thousands in recent years.

History
The origin of forest plots goes back at least to the 1970s. Freiman et al displayed the results of several studies with horizontal lines showing the confidence interval for each study and a mark to show the point estimate. This study was not a meta-analysis, and the results of the individual studies were therefore not combined into an overall result. In 1982, Lewis and Ellis produced a similar plot but this time for a meta-analysis, and they put the overall effect on the bottom of the plot (fig 1). They based the idea on modified box plots.

The first meta-analyses to include squares of different sizes to show the positions of the point estimates were probably those produced by the Clinical Trial Service Unit in Oxford in the 1998 overview of the prevention of vascular disease by antiplatelet therapy. The area of each square was proportional to the weight that the individual study contributed to the meta-analysis.

Summary points
Forest plots show the information from the individual studies that went into the meta-analysis at a glance

They show the amount of variation between the studies and an estimate of the overall result

Forest plots, in various forms, have been published for about 20 years

During this time, they have been improved, but it is still not easy to draw them in most standard computer packages.
We have updated the original Lewis and Ellis plot\(^1\) to show how it might look in the modern style (fig 2). We obtained data for most of the component studies from a subsequent paper.\(^3\) In the 1980s, no standard computer packages could easily produce these plots, and they came from specially produced computer programs. Even now, most standard statistical packages cannot easily produce such a plot.

**Why a forest plot?**

The plot was not called a “forest plot” in print for some time, and the origins of this title are obscured by history and myth. At the September 1990 meeting of the breast cancer overview, Richard Peto jokingly mentioned that the plot was named after the breast cancer researcher Pat Forrest, and, at times, the name has been spelt “forest plot.” However, the phrase actually originates from the idea that the typical plot appears as a forest of lines. A contender for the first use of the name “forest plot” in print is a review of nursing interventions for pain that was published in 1996.\(^4\) An abstract at the Cochrane colloquium later that year also used this name.\(^5\) We would welcome suggestions of precedents to these uses or any other versions of this brief history of the plot.

We thank Jon Godwin for preparing figure 2.

**A memorable patient**

**A chandelier and a vat of custard**

It was a busy Friday night in casualty. We were one senior house officer down and there had been a major accident on a nearby main road. All of us had been looking after seriously injured patients for the preceding couple of hours—not all of them had survived, and emotions were running high. During that time, the backlog of minor injuries had built up to a six hour wait, and tempers were fraying in the waiting room. The nurses were fielding angry patients, often with trivial injuries, and were desperate for one of us to come and help.

I returned to the minor side to start clearing the backlog as soon as possible. I was in a superefficient and slightly short-tempered mood—didn’t they realise that we had to deal with far more important things than cut fingers or drums? I picked the next card out of the box and went to the cubicle.

With barely a glance at the patient I said brusquely, “Well, what’s the matter there?” A middle aged man looked back at me and said, in a nonchalant tone, “I was preparing for my usual Friday night sexual activity when the chandelier broke, and I fell into the vat of custard.”

It took a second or two for me to realise what he’d said. I looked up at him in disbelief. “Really?” I asked. “No,” he said, “but I’ve been sitting in the waiting room for two hours trying to pluck up the courage to say that.”

As a grin broke over my face, I asked what had really happened, and he told me what he had done. As I treated him, I relaxed and chatted to him as a real person, not a patient.

I spent the rest of the shift smiling. It inspired me to think that someone faced with a long wait had thought up something like that, and kept it in his mind, without getting annoyed or impatient. He changed my perspective, brightened up my evening, and reminded me of the fact that people, not patients, were in the waiting room.

I have long since forgotten his name, but I still think about him when I’m having a bad day.

Katherine Whybrey GP registrar, 19 Beaumont Street Surgery, Oxford
