Effects of Acute Insulin-Induced Hypoglycemia on Indices of Inflammation

Putative mechanism for aggravating vascular disease in diabetes

OBJECTIVE — To examine the effects of acute insulin-induced hypoglycemia on inflammation, endothelial dysfunction, and platelet activation in adults with and without type 1 diabetes.

RESEARCH DESIGN AND METHODS — We studied 16 nondiabetic adults and 16 subjects with type 1 diabetes during euglycemia (blood glucose 4.5 mmol/l) and hypoglycemia (blood glucose 2.5 mmol/l). Markers of inflammation, thrombosis, and endothelial dysfunction (soluble P-selectin, inter leukin-6, von Willebrand factor [vWF], tissue plasminogen activator [tPA], high-sensitivity C-reactive protein [hsCRP], and soluble CD40 ligand [sCD40L]) were measured; platelet-monocyte aggregation and CD40 expression on monocytes were determined using flow cytometry.

RESULTS — In nondiabetic participants, platelet activation occurred after hypoglycemia, with increments in platelet-monocyte aggregation and P-selectin (P ≤ 0.02). Inflammation was triggered with CD40 expression increasing maximally at 24 h (3.13 ± 2.3% vs. 2.06 ± 1.0%; P = 0.009). Both sCD40L and hsCRP (P = 0.02) increased with a nonsignificant rise in vWF and tPA, indicating a possible endothelial effect. A reduction in sCD40L, tPA, and P-selectin occurred during euglycemia (P = 0.03, P ≤ 0.006, and P = 0.006, respectively). In type 1 diabetes, both CD40 expression (5.54 ± 4.4% vs. 3.65 ± 1.8%; P = 0.006) and plasma sCD40L concentrations increased during hypoglycemia (peak 3.41 ± 3.2 vs. 2.85 ± 2.8 ng/ml; P = 0.03). Platelet-monocyte aggregation also increased significantly at 24 h after hypoglycemia (P = 0.03). A decline in vWF and P-selectin occurred during euglycemia (P ≤ 0.04).

CONCLUSIONS — Acute hypoglycemia may provoke upregulation and release of vasoactive substances in adults with and without type 1 diabetes. This may be a putative mechanism for hypoglycemia-induced vascular injury.

Diabetes Care 33:1591–1597, 2010

In people with type 1 diabetes the rapid institution of strict glycemic control aggravates microvascular complications, particularly retinopathy (1). Although attributed to reduced capillary blood flow causing localized ischemia (1), greater exposure to hypoglycemia may have worsened microangiopathy through its putative effects on local vasculature (2). In addition, cardiovascular stress associated with hypoglycemia may precipitate acute macrovascular events in a diseased circulation. While supported by anecdotal reports (3), the increase in cardiovascular mortality in people with type 2 diabetes in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial (4) (and possibly in the Veterans Affairs Diabetes Trial [5]), in which intensive treatment had tripled the frequency of severe hypoglycemia, has caused concern.

Data are median (interquartile range) and means ± SD unless otherwise indicated.

A modified hyperinsulinemic glucose clamp (13) was used to maintain blood glucose at a predetermined level: euglycemia at 4.5 mmol/l and hypoglycemia at 2.5 mmol/l. Each subject underwent two laboratory sessions, separated by at least 2 weeks (mean 7.2 weeks), of a euglycemic study and a hypoglycemic study in a randomized, counterbalanced fashion.

The participants with type 1 diabetes monitored blood glucose intensively during the 48 h preceding each study, which was postponed if any blood glucose value was <3.5 mmol/l or if symptoms suggestive of hypoglycemia were experienced. After fasting overnight, morning insulin was withheld. A retrograde-intravenous cannula for blood-glucose sampling was inserted into the nondominant hand, which was heated to arterialize the venous blood (14). A cannula in the nondominant antecubital fossa was used to infuse 20% dextrose and soluble insulin (Human Acrapid; Novo Nordisk, Crawley, U.K.) at a constant rate of 1.5 μL/kg/min using a Gemini PCI pump (Alaris Medical Systems, San Diego, CA). The dextrose was infused at a variable rate depending on arterialized blood glucose concentrations, which were measured at 5 min intervals using the glucose oxidase method (2300 Stat; Yellow Springs Instruments, Yellow Springs, OH). A third cannula in the other antecubital fossa was dedicated to blood sampling for inflammatory markers.

On each study day, the arterialized blood glucose was stabilized initially at 4.5 mmol/l for 30 min and either maintained at that level (euglycemia) or lowered over 20 min to 2.5 mmol/l for 60 min (hypoglycemia), after which blood glucose was restored to 4.5 mmol/l. Subjects consumed a standardized meal after each study. Blood sample time points were: baseline, during the experimental session (+45 min), during recovery (+105 min), at +6 h, and at +24 h.

**Flow cytometry**

Whole blood samples were collected at the predetermined time points using p-Phenylalanyl-l-propyl-l-arginine chloromethyl ketone, a selective thrombin inhibitor, as an anticoagulant. Samples (100 μL) of whole blood were immediately incubated with 10 μL of each monoclonal antibody (AbD Serotec, Kidlington, U.K.) for 30 min at room temperature, with subsequent red cell lysis by the addition of 1 ml of fluorescent-activated cell sorter (FACS) Lyse solution (Becton Dickinson, Oxford, U.K.). Flow cytometry using the FACS Calibur system (Becton Dickinson, Oxford, U.K.) was performed immediately after the experimental session to assess platelet-monocyte aggregation (CD14/CD42a) and CD40 expression on monocytes (CD14/CD40). Isotype controls were performed in addition to both mono- and dual-stain for each parameter assessed at each time point.

**Soluble marker assays**

Citrated plasma and serum samples were collected at the predetermined time points. These were separated immediately and frozen at −80°C until analysis for the soluble markers:

- Von Willebrand factor (vWF) (enzyme-linked immunosorbent assay [ELISA]; coefficient of variation [CV] 7.3%), tissue plasminogen activator (tPA) antigen (Hyphen Biomed Zymutest; intra-assay CV 3.5%, inter-assay CV 4.4%), soluble CD40 ligand (sCD40L) (high sensitivity ELISA, Bender Medsystems; intra-assay CV 5.5%, inter-assay CV 7.2%), soluble P-selectin (ELISA, R&D Systems; intra-assay CV 5.1%, inter-assay CV 8.8%), IL-6 (High sensitivity ELISA, R&D Systems; intra-assay CV 5.9%, inter-assay CV 9.9%), and high sensitivity CRP (DRG Diagnostics, DRG Instruments, Marburg, Germany; intra-assay CV 4.2%, inter-assay CV 4.1%).

**Catecholamine assays**

Samples for epinephrine quantification were collected in EDTA tubes and immediately separated and frozen at −80°C until analysis by high-performance liquid chromatography and electrochemical detection (intra-assay CV 1.2%, inter-assay CV 3.9%).

**Hypoglycemia symptom score**

The Edinburgh Hypoglycemia Scale (15) was used to assess the symptoms experienced during each experimental session.

**Statistical analyses**

Results were analyzed using SPSS version 15.0 for Windows (SPSS, Chicago, IL). A general linear model (repeated-measures ANOVA) was used, with order of session (euglycemia-hypoglycemia or hypoglycemia-euglycemia) as a between-subjects factor, and condition (euglycemia or hypoglycemia) as a within-subjects factor, to compare hypoglycemia with euglycemia. Additional analysis using paired t tests was performed to assess the change in any given parameter from baseline. A P value <0.05 was considered to be significant. Results are reported as mean ± SD unless otherwise stated.

**RESULTS** — Hypoglycemia provoked a symptomatic response in all subjects with increased scores of autonomic (P ≤ 0.002), neuroglycopenic (P < 0.001), and malaise (P ≤ 0.008) symptoms compared with baseline. Comparison of baseline levels of inflammatory, endothelial and platelet markers in nondiabetic subjects and subjects with type 1 diabetes showed a significantly higher concentration of soluble P-selectin (P = 0.01) and of CD40 expression on monocytes (P = 0.006) in those with diabetes, demonstrating the chronic inflammatory response associated with diabetes.

**Blood glucose**

Target blood glucose concentrations were achieved (Fig. 1). In nondiabetic subjects, blood glucose concentrations were 2.58 ± 0.2 and 4.42 ± 0.5 mmol/l during hypoglycemia and euglycemia, respectively. In those with type 1 diabetes, blood glucose concentrations were 2.46 ± 0.22 and 4.53 ± 0.24 mmol/l, respectively. The blood glucose nadir was similar in both groups.

**Counterregulatory response**

Plasma epinephrine increased during hypoglycemia in participants with and with-
out type 1 diabetes ($P \leq 0.001$; Fig. 1). The epinephrine response occurred only during hypoglycemia and returned rapidly to baseline as anticipated (16).

**Platelet activation**

**Platelet-monocyte aggregation.** In nondiabetic subjects, platelet-monocyte aggregation appeared to rise, from a baseline level of $0.72 \pm 0.8\%$ to $3.09 \pm 8.1\%$ during hypoglycemia, with a peak of $3.49 \pm 10.4\%$ at $24$ h (Fig. 2). Platelet-monocyte aggregation remained unchanged throughout euglycemia. The difference between conditions, and from baseline, did not achieve statistical significance.

In participants with diabetes, there was a late rise in platelet-monocyte aggregation after hypoglycemia at $24$ h compared with baseline ($P = 0.03$).

**Soluble P-selectin.** Soluble plasma P-selectin concentrations increased after hypoglycemia in nondiabetic subjects, exhibiting a late response at $6$ h ($P = 0.01$) and $24$ h ($P = 0.02$; Fig. 2) but decreasing during euglycemia ($P = 0.006$).

P-selectin also decreased during euglycemia in the diabetic group ($P = 0.04$), but did not change during hypoglycemia.

**Endothelial markers**

**tPA.** In nondiabetic subjects, plasma tPA concentrations increased during hypoglycemia, with a higher peak tPA concentration ($12.55 \pm 16.7$ compared with $6.80 \pm 7.9$ ng/ml) (NS between conditions). Plasma tPA decreased significantly between baseline and test phase ($P = 0.004$) and recovery phase ($P = 0.006$), with a paradoxical rise between baseline and $24$ h ($P = 0.06$) after euglycemia (Table 2). However, a diurnal variation in tPA concentration is recognized to occur, which may account for the decline observed during euglycemia (17). No significant differences occurred in the diabetic group (Table 2).

**Inflammation**

**CD40 expression.** CD40 expression on monocytes increased after hypoglycemia in nondiabetic subjects, from a baseline of $1.92 \pm 2.2\%$ to a maximum of $3.13 \pm 2.3\%$ at $24$ h ($P = 0.009$). A significant difference between hypoglycemia and euglycemia conditions was present at $6$ h ($P = 0.05$) and at $24$ h ($P = 0.04$) (Table 2).

In participants with type 1 diabetes, monocyte CD40 expression increased from $3.69 \pm 3.4\%$ to $5.34 \pm 4.4\%$ during hypoglycemia ($P = 0.006$), compared with no change during euglycemia ($3.64 \pm 2.0\%$ to $3.65 \pm 1.8\%$, respectively; $P = $ NS). The increment during
Hypoglycemia had dissipated by the time of the recovery phase and remained unchanged thereafter (Table 2).

sCD40L. In nondiabetic subjects, plasma sCD40L concentrations were higher during hypoglycemia than during euglycemia (2.80 ± 3.2 vs. 2.41 ± 2.8 ng/ml), with a trend toward significance (P = 0.09). A significant reduction in sCD40L concentration occurred during euglycemia between baseline and recovery phase (P = 0.03) (Table 2).

In those with diabetes, a significant difference was observed between the baseline levels on each study day: 3.36 ± 2.9 ng/ml on the hypoglycemia day compared with 2.86 ± 2.8 ng/ml on euglycemia day (P = 0.03), rendering subsequent measurements difficult to compare. A significant difference was again observed between the experimental condition levels, with a level of 3.41 ± 3.2 ng/ml during hypoglycemia and 2.85 ± 2.8 ng/ml during euglycemia (P = 0.03) (Table 2). Changes from baseline did not achieve significance.

IL-6. IL-6 levels rose in all experiments, maximally at 6 h, irrespective of condition, with no clear differences identifiable in either group between the study conditions (Table 2).

hsCRP. Test phase hsCRP was higher in all subjects during hypoglycemia (1.81 ± 1.9 vs. 1.22 ± 1.9 ng/ml in nondiabetic participants [P = 0.02]; 2.72 ± 3.1 vs. 2.20 ± 2.9 ng/ml in subjects with diabetes [P = ns]) (Table 2). A significant difference was observed in the baseline concentrations in the nondiabetic participants (P = 0.01), frustrating interpretation of subsequent responses.

CONCLUSIONS — Previous studies have demonstrated that hypercoagulability, platelet and neutrophil activation, C-reactive protein, IL-6, and Endothelin-1 are upregulated after acute hypoglycemia (3,6–11), while a euglycemic insulin infusion (for at least 2 h) was shown to reduce inflammatory markers, consistent with an anti-inflammatory effect of insulin (18). The present study sought to replicate these effects, while investigating other underlying mechanisms of vascular disease, and tests were selected to investigate the effect of acute hypoglycemia on important cellular processes (platelet activation, endothelial dysfunction and inflammation) underlying the development of acute and chronic vascular complications in type 1 diabetes.

The present study showed that hypoglycemia generated a response in some of these markers, suggesting that hypoglycemia-induced metabolic stress may have adverse pathophysiological consequences while the euglycemic insulin infusion caused a potentially beneficial decrement in some parameters. However, the magnitude of most observed changes was small, and not all markers changed significantly.

The present study confirmed that platelet activation is promoted by hypoglycemia (8), with increments both in platelet-monocyte aggregation and soluble P-selectin. Conversely, P-selectin decreased during euglycemia. Endothelial function, using vWF and tPA Ag as surrogate markers, may have been disrupted, as shown by the increase in vWF after hypoglycemia in nondiabetic volunteers, but this change was not replicated in those with diabetes. However, a reduc-
The need to lower blood glucose to a hypoglycemic level was achieved through the use of an insulin clamp, which induced a more controlled glucose clamp (blood glucose 2.2 mmol/l) was induced (21). The more rapid reduction was achieved by using euglycemia (39 mg/dl) as observed in the present study. A further limitation was the need to increase hypoglycemia, while declining during euglycemia, with an elevation of hsCRP being observed in nondiabetic subjects during hypoglycemia, whereas in diabetic subjects, an increase in hsCRP was higher during hypoglycemia in nondiabetic subjects and in diabetic subjects with a significant change. The responses, compared with the more prolonged, and still present at 24 h. The persistence of these vascular changes for 24 h, long after blood glucose recovery, suggests that the period of risk after hypoglycemia may be longer.

A positive trend after hypoglycemia was evident, or the only measurable difference between the groups was observed in all subjects. Unfortunately, baseline differences in hsCRP in nondiabetic subjects, with an elevation in hsCRP in the diabetic subjects, were higher during hypoglycemia in nondiabetic subjects and in diabetic subjects. Surprisingly, CD40L was associated with the increase in hsCRP, whereas in diabetic subjects, a significant change occurred in the diabetic patients. This increase in hsCRP, while declining during hypoglycemia, was higher during hypoglycemia in the diabetic patients.

Table 2—Endothelial Function and Inflammation in Nondiabetic Subjects and Subjects With Type 1 Diabetes
amine the experimental conditions on two separate days in a counterbalanced fashion. Because the baseline levels of many inflammatory markers can differ on separate days, as was observed with sCD40L and hsCRP, this biological variability hinders the interpretation and comparison of subsequent results. However, the present study design was necessary to allow comparison of the euglycemia and hypoglycemia conditions in individual subjects, as both time and insulin infusion per se may exert effects on biomarker levels. This study design cannot control for other day-to-day factors that could influence baseline levels of inflammatory markers. However, the effects of hypoglycemia could be evaluated, as each participant acted as their own control. This produces less variability than a comparison of results among individuals, as more interindividual variation in inflammatory marker levels is present than intraindividual variation. In addition, it was possible to analyze each study separately, by examining changes in parameters from baseline on that particular day, enabling the detection of significant effects exerted by hypoglycemia compared with euglycemia. Baseline levels of all markers (except IL-6) were higher in the diabetic group (significant for P-selectin and CD40 expression). This could affect the magnitude of response induced by the experimental procedures. However, an analysis of the percentage change from baseline was consistent with the trends identified in the absolute results (shown as in the online appendix available at http://care.diabetesjournals.org/cgi/content/full/dc10-0013/DC1).

As anticipated, epinephrine secretion was stimulated by hypoglycemia. It is likely that hormonal changes underlie the activation and upregulation of the vascular biomarkers. Catecholamines promote platelet activation (22), while adrenoreceptor blockade attenuates these effects (23,24). The participants with type 1 diabetes exhibited attenuated plasma epinephrine responses to hypoglycemia compared with the nondiabetic subjects, who were naive to such a hypoglycemic stimulus, this being consistent with the recognized decline in the magnitude of counterregulatory hormonal responses with increasing duration of type 1 diabetes (25). This attenuated epinephrine response may explain the lower responses of vascular biomarkers to hypoglycemia.

In summary, the effects of hypoglycemia on several vascular biomarkers that are implicated in the pathogenesis of vascular disease, would support the premise that acute hypoglycemia may be detrimental to an already diseased vasculature (2). Euglycemia may have a protective, anti-inflammatory effect. In the present study, the participants had no overt vascular disease and were unlikely to develop any demonstrable effects from a short period of exposure to hypoglycemia. However, in people with diabetes of long duration, who are likely to have underlying vascular disease, these responses may not be benign. The release of potent vasoactive substances could potentially aggravate chronic vasculopathy, and contribute to the precipitation of acute macrovascular events. This may aggravate established diabetic micro- and macrovascular disease in those who are exposed to recurrent hypoglycemia.
