Impaired gluconeogenesis in a porcine model of paracetamol induced acute liver failure

Konstantinos J Dabos, Henry R Whalen, Philip N Newsome, John A Parkinson, Neil C Henderson, Ian H Sadler, Peter C Hayes, John N Plevris

RESULTS: No significant changes were observed in the concentrations of the amino acids studied in the animals maintained under anaesthesia only. If we look at the ALF animals, we observed a statistically significant rise of lactate \( (P < 0.003) \) and pyruvate \( (P < 0.018) \) at the end of the experiments. We also observed statistically significant rises in the concentrations of alanine \( (P < 0.002) \), glycine \( (P < 0.005) \), threonine \( (P < 0.048) \), tyrosine \( (P < 0.000) \), phenylalanine \( (P < 0.048) \) and isoleucine \( (P < 0.01) \). Valine levels decreased significantly \( (P < 0.05) \).

CONCLUSION: Our pig model of ALF is characterized by an altered gluconeogenetic capacity, an impaired tricarboxylic acid (TCA) cycle and a glycolytic state.

INTRODUCTION

Acute liver failure (ALF) is a clinical syndrome defined by massive cell death in the absence of chronic liver disease, resulting in hepatic encephalopathy. Although brain oedema and brain herniation are common causes...
followed by an infusion for 12 h (1.8 mg/kg per min). Ex-
was administered by intravenous infusion (0.1875 g/kg)

osecretion in our large animal model with an increase in
 cycle coupled with an increase in lactate production
mark of disrupted hepatic glucose metabolism. Studies
require dialysis in that setting without serious liver injury
patients develop acute renal failure through toxic injury and
failure is a characteristic of paracetamol overdose. Often
agulation cascade namely Factors V and VIII[8]. Acute renal
is due to loss of production of factors of the co-
agulation cascade namely Factors V and VIII[8]. Acute renal
failure is a characteristic of paracetamol overdose. Often
patients develop acute renal failure through toxic injury and
require dialysis in that setting without serious liver injury[9].

The hypoglycaemia observed in our model is a hallmark
of death in ALF multi organ failure is also common[2,3].
Previous studies have shown that metabolic pathways
are affected in ALF and systemic changes in metabolite
levels could be the pathophysiological reason behind
multi organ failure in ALF[4,5].

Orthotopic liver transplantation remains the most
widely accepted treatment for ALF[1,2,7]. Chronic donor
shortages however, motivate the search for alternative
non-surgical therapies. In that quest animal models of
ALF play an important role. Most studies have explored
mouse models of ALF which although useful do not ade-
ately address the issue[4,6]. We have recently de-
veloped in our laboratory a porcine model of paracetamol
induced ALF[5]. It is characterized histologically by se-
vere centrilobular necrosis with coagulative necrosis.
The animals invariably develop acidosis, hypoglycaemia,
coagulopathy and acute renal failure.

Acidosis could be explained by lactate production and
energy depletion in the liver of our animal model[6]. Coagu-
lopathy is due to loss of production of factors of the co-
agulation cascade namely Factors V and VIII[8]. Acute renal
failure is a characteristic of paracetamol overdose. Often
patients develop acute renal failure through toxic injury and
require dialysis in that setting without serious liver injury[9].

The hypoglycaemia observed in our model is a hallmark
of ALF and cirrhosis have shown that, despite a relative glucose homeostasis, there is a de-
crease in gluconeogenesis and tricarboxylic acid (TCA)
cycle coupled with an increase in lactate production[6,10-12].

We hypothesized that there was a loss of gluconeoge-
netic capacity in our large animal model with an increase in
lactate production, an inhibited TCA cycle and a switch to
glycolysis during injury to compensate for energy demands.

MATERIALS AND METHODS

Animals

Large white pigs (median body mass 35 kg) were used for
this study. Animal experiments were performed in accordance
with the Home Office regulations under the Animal (Scientific
Procedures) Act 1986 as per Project Licence 60/2389. All animals received humane care and study protocols complied with our institution’s guidelines.

Our experimental model was described in detail else-
where[7]. Briefly animals were anaesthetized with ketamine
and midazolam as induction agents and maintained with
isoflurane and nitrous oxide. Animals were hydrated with
normal saline and glucose. All animals received similar
amounts of glucose. Haemodynamic variables and intra-
cranial pressure were continuously monitored.

Animals were pretreated with phenobarbital 20 mg
orally for 5 d to induce cytochrome P450 activity. In six an-
imals intravenous paracetamol was administered while the
three animals used as controls were monitored but did not
receive any paracetamol. A loading dose of paracetamol
was administered by intravenous infusion (0.1875 g/kg)
followed by an infusion for 12 h (1.8 mg/kg per min). Ex-
periments lasted 28 h and at that time point any surviving
animals were euthanized.

Sample preparation for NMR spectroscopy

Samples were prepared by adding a D2O solution of
(150 μL) to plasma (600 μL) thus providing an internal
field frequency lock for the spectrometer. As a refer-
ence substance 20 μL of sodium 3-(trimethylsilyl) 2, 2, 3,
3-2H4)-1 propionate (TSP) were added to the plasma. Chemical shifts were referenced internally to the singlet
methyl resonance of TSP at zero ppm.

The following potentially gluconeogenic amino acids
were quantified by NMR: leucine, isoleucine, valine, tyro-
sine, phenylalanine, histidine, methionine, alanine, thero-
nine, glutamate and glutamine. Lactate, pyruvate and the
 gluconeogenic amino acids were measured to provide
information on glycolysis and gluconeogenesis.

Proton NMR spectroscopy

1H-NMR spectra were measured from plasma samples
 taken from a large central vein at 5 hourly intervals until
the experiments were terminated at t = 28 h. Data were
acquired on a Varian INOVA 600 NMR Spectrometer
operating at 600 MHz for protons. All spectra were ac-
quired at ambient probe temperature (298 ± 0.2 °K). For
each sample 128 transients (FIDs) were acquired into 32
K complex data points over a spectral width of 6 KHz.
300 pulses were applied with an acquisition time of 2.5
s to achieve better resolution followed by an additional
pulse recycle time of 4 s to allow for complete T1 relax-
atation. Water signal suppression was achieved by applying
a gated secondary irradiation field at the water resonance
frequency. Spectral assignments were made by reference
to literature values of chemical shifts in various media and
biological fluids and coupling constants[13]. The coeffi-
cient of variation between samples was < 6% and reproduc-
ibility for the same sample was good with a difference of
< 2% on the same sample. The CMPG (Carr-Purcell-Mei-
boom-Gunn) sequence was applied for data acquisition, as
this sequence enabled observation of a flat baseline in our
spectra from plasma samples by minimising the signals
acquired from macromolecules present in the plasma such
as proteins and lipoproteins[14]. NMR spectra analysis was
performed using the MNova platform for NMR analysis
(Mestrelab, Santiago de Compostela, Spain).

Statistical analysis

To compare between groups in the initial sample the
Student’s t-test for parameters with non-missing values
and the Mann Whitney U test for parameters with missing
values were used. Values were expressed as mean (range
and standard error). A P value of < 0.05 was taken as
statistically significant (two-tail test of significance). Nu-
meric results are expressed as μmol/L. All analysis was
done using the SPSS statistical package (Version 9.0).

RESULTS

On all samples studied we were able to identify the fol-
Following metabolites: lactate, pyruvate, leucine, isoleucine, valine, tyrosine, phenylalanine, histidine, arginine, glycine, alanine, threonine, glutamate and glutamine. Resonances from proline, methionine and ornithine were not suitably characterised and results from those amino acids are not available. Figure 1 shows a sample spectrum.

In control pigs there were no significant differences in the concentrations of the substrates studied at any time point sampled. Animals who received paracetamol showed statistically significant differences in the concentrations of lactate, pyruvate and the amino acids.

### Lactate and pyruvate

Figure 2 shows the results for lactate and pyruvate. Increases in the concentration of lactate became significant at $t = 15$ h and at $t = 25$ h; compared to $t = 0$ an average increase of 405% was seen ($P < 0.003$). Increases in the concentration of pyruvate became significant at $t = 20$ h and at $t = 25$ h; compared to $t = 0$ an average increase of 150% was seen ($P < 0.018$).

### Amino acids

Figure 3 shows the results for threonine, alanine and glycine. Increases in the concentration of threonine became significant at $t = 20$ h and at $t = 25$ h; compared to $t = 0$ an average increase of 82% was seen ($P < 0.048$). Increases in the concentration of alanine became significant at $t = 10$ h and at $t = 25$ h; compared to $t = 0$ an average increase of 410% was seen ($P < 0.002$). Finally, increases in the concentration of glycine became significant at $t = 5$ h and at $t = 25$ h; compared to $t = 0$ an average increase of 390% was seen ($P < 0.005$).

Figure 4 shows the results for the aromatic amino acids. Tyrosine levels significantly increased at $t = 5$ h and at $t = 25$ h; there was an average increase of 1330% ($P < 0.000)$. Phenylalanine levels also increased significantly at $t = 5$ h and at $t = 25$ h; there was an average increase of 1420% ($P < 0.000$).

Figure 5 shows the results for the branch chain amino acids. There were no statistically significant changes in the concentration of leucine between the beginning and the end of the experiments ($0.17 \pm 0.02$ vs $0.175 \pm 0.02$). Isoleucine levels increased significantly at $t = 10$ h and at $t = 25$ h; an average increase of 250% was seen ($P < 0.01$). Valine levels, on the contrary, significantly decreased at $t = 20$ h and at $t = 25$ h; an average decrease of 150% was seen ($P < 0.05$).
DISCUSSION

In this study in a large animal model of paracetamol induced acute liver failure we have shown that glucose homeostasis is impaired with hypoglycaemia, increased concentrations of lactate and pyruvate and increased concentrations of most gluconeogenic amino acids.

It is common knowledge that patients with severe acute liver injury due to paracetamol overdose quickly develop hypoglycaemia. In contrast, most animal models of ALF do not develop hypoglycaemia. In ALF the hepatic production of glucose is inhibited but there is compensation by kidney gluconeogenesis\[4,5,14,15\].

In our model the concentration of lactate, despite a temporary decline at the beginning of the experiments, increased quickly and was significantly increased at \( t = 15 \) h. Likewise, pyruvate concentration increased and that increase became significant at \( t = 20 \) h. This suggests that early on glycolysis is switched on in the liver. As paracetamol also affects the kidney and an early kidney toxic injury is usually seen in cases of paracetamol induced ALF\[16\], attempted compensatory gluconeogenesis maybe occurring in the kidney but it is not sufficient to maintain normal glucose levels in this model of ALF.

We have also observed that major gluconeogenic amino acids were not taken up by the liver. Concentrations of alanine increased significantly throughout the study along with concentrations of threonine and glycine. Likewise the concentrations of the aromatic amino acids tyrosine and phenylalanine increased very early on and rose dramatically at the end of the experiments. This is in accordance with previous studies in mice that showed similar results\[3,4,17\]. This is a good indication that gluconeogenesis in the liver is impaired and the TCA cycle is not functioning properly.

If we look at the branch chain amino acids the results are somehow different. No change was seen in the concentration of leucine and a decrease was observed in the concentration of valine. Significant increases at the end of the experiments were only seen in the concentrations of isoleucine.

ALF is characterized by the development of encephalopathy. In that respect Fischer’s ratio (the ratio of branch chain to aromatic amino acids) is believed to be a good index\[18\]. A decrease of the ratio is a good marker of severe hepatic encephalopathy. As we have shown previously in our model a significant decrease in the Fischer’s ratio was observed by \( t = 15 \) h of the experiments\[7\]. In a previous study we have shown that although in patients with non-paracetamol induced ALF all branch chain amino acids are increased, in patients with paracetamol induced ALF valine is an exception and decreases over time\[9\]. We believe our results to be in accordance with this observation.

We should point out though that the attempts to correct hepatic encephalopathy with correction of the Fischer’s ratio by exogenous substation of branch chain amino acids were not a success and the reason might lie in the fact that it is the aromatic and not the branch chain amino acids that are disturbed\[20\].

An interesting finding was that we observed no significant changes in the concentrations of glutamate, glutamine, histidine and arginine, key metabolic components of the urea cycle. We unfortunately were unable to quantify aspartate but there is strong evidence that the urea cycle in this model remains largely unaffected by paracetamol poisoning. This is in accordance with other studies that have shown that ALF induced hyperammonemia is caused by gut production of ammonia, a by-product of the production of alanine from glutamate\[21\]. Novel attempts to correct the metabolic abnormalities of hepatic encephalopathy by providing ornithine as a substrate for urea synthesis might be a good path\[22-25\].

The major drawback of this study is that we performed a study that describes changes in amino acids that pertain to gluconeogenesis and that we assumed that the changes were provoked by the inhibition of gluconeogenesis by the acute liver injury. We had no means to exclude the possibility that some other metabolic function could be responsible for the observed amino acid disturbances.

In conclusion, in this large animal model of paracetamol induced ALF we have observed an inhibition of gluconeogenesis in the liver with subsequent dysfunction of the TCA cycle. This has led to ATP and energy depletion and the liver switching to glycolysis to compensate. Further studies in animals and also in humans are needed to fully characterize the metabolic abnormalities of liver failure and to provide a pathophysiological basis for the new emerging metabolically centred therapies for hepatic encephalopathy\[26\].

COMMENTS

Background

Acute liver failure in humans is a deadly condition which could lead to multi-organ failure and death of the patient. Abnormalities in many metabolic...
Pathways are known to exist but there are very few large animal models where the authors are able to reproduce the acute liver injury. Recently the authors have developed such a porcine model in our laboratory.

**Research frontiers**

Paracetamol-induced acute liver injury in humans and animal models is characterised by profound hypoglycaemia in a very short time from the liver injury. The exact mechanism of hypoglycaemia remains debatable.

**Innovations and breakthroughs**

In this article the authors were able to provide some evidence that gluconeogenesis is impaired in a porcine model of acute liver injury as manifested by a relative increase in the plasma concentrations of the gluconeogenic amino acids. Gluconeogenic amino acids are the main substrate for glucose production after the exhaustion of glycogen stock very early in the acute liver injury.

**Applications**

This paper provides some insight into the metabolism in acute liver failure. It shows that gluconeogenesis is a key metabolic pathway in paracetamol-induced acute liver failure, early on in the disease. This needs to be confirmed in human studies and could have implications in the way these patients are managed.

**Peer review**

The article by Dabos et al describes increased lactate, pyruvate and distinct amino acids in a pig model of paracetamol-induced acute liver injury.
