Abstract

AIM: To investigate glucose homeostasis and in particular gluconeogenesis in a large animal model of acute liver failure (ALF).

METHODS: Six pigs with paracetamol induced ALF under general anaesthesia were studied over 25 h. Plasma samples were withdrawn every five hours from a central vein. Three animals were used as controls and were maintained under anaesthesia only. Using 1H NMR spectroscopy we identified most gluconeogenic amino acids along with lactate and pyruvate in the animal plasma samples.

RESULTS: No significant changes were observed in the concentrations of the amino acids studied in the animals maintained under anaesthesia only. If we look at the ALF animals, we observed a statistically significant rise of lactate ($P < 0.003$) and pyruvate ($P < 0.018$) at the end of the experiments. We also observed statistically significant rises in the concentrations of alanine ($P < 0.002$), glycine ($P < 0.005$), threonine ($P < 0.048$), tyrosine ($P < 0.000$), phenylalanine ($P < 0.000$) and isoleucine ($P < 0.01$). Valine levels decreased significantly ($P < 0.05$).

CONCLUSION: Our pig model of ALF is characterized by an altered gluconeogenic capacity, an impaired tricarboxylic acid (TCA) cycle and a glycolytic state.

INTRODUCTION

Acute liver failure (ALF) is a clinical syndrome defined by massive cell death in the absence of chronic liver disease, resulting in hepatic encephalopathy [10]. Although brain oedema and brain herniation are common causes
of death in ALF multi organ failure is also common. Previous studies have shown that metabolic pathways are affected in ALF and systemic changes in metabolite levels could be the pathophysiological reason behind multi organ failure in ALF. Orthotopic liver transplantation remains the most widely accepted treatment for ALF. Chronic donor shortages however, motivate the search for alternative non-surgical therapies. In that quest animal models of ALF play an important role. Most studies have explored mouse models of ALF which although useful do not adequately address the issue. We have recently developed in our laboratory a porcine model of paracetamol induced ALF. It is characterized histologically by severe centrilobular necrosis with coagulative necrosis. The animals invariably develop acidosis, hypoglycaemia, coagulopathy and acute renal failure.

Acidosis could be explained by lactate production and energy depletion in the liver of our animal model. Coagulopathy is due to loss of production of factors of the coagulation cascade namely Factors V and VIII. Acute renal failure is a characteristic of paracetamol overdose. Often patients develop acute renal failure through toxic injury and require dialysis in that setting without serious liver injury.

The hypoglycaemia observed in our model is a hallmark of disrupted hepatic glucose metabolism. Studies on other animal models of ALF and cirrhosis have shown that, despite a relative glucose homeostasis, there is a decrease in gluconeogenesis and tricarboxylic acid (TCA) cycle coupled with an increase in lactate production.

We hypothesized that there was a loss of gluconeogenic capacity in our large animal model with an increase in lactate production, an inhibited TCA cycle and a switch to glycolysis during injury to compensate for energy demands.

MATERIALS AND METHODS

Animals

Large white pigs (median body mass 35 kg) were used for this study. Animal experiments were performed in accordance with the Home Office regulations under the Animal (Scientific Procedures) Act 1986 as per Project Licence 60/2389. All animals received humane care and study protocols complied with our institution's guidelines.

Our experimental model was described in detail elsewhere. Briefly animals were anaesthetized with ketamine and midazolam as induction agents and maintained with isoflurane and nitrous oxide. Animals were hydrated with normal saline and glucose. All animals received similar amounts of glucose. Haemodynamic variables and intracranial pressure were continuously monitored.

Animals were pretreated with phenobarbital 20 mg orally for 5 d to induce cytochrome P450 activity. In six animals intravenous paracetamol was administered while the three animals used as controls were monitored but did not receive any paracetamol. A loading dose of paracetamol was administered by intravenous infusion (0.1875 g/kg) followed by an infusion for 12 h (1.8 mg/kg per min). Experiments lasted 28 h and at that time point any surviving animals were euthanized.

Sample preparation for NMR spectroscopy

Samples were prepared by adding a D2O solution of (150 μL) to plasma (600 μL) thus providing an internal field frequency lock for the spectrometer. As a reference substance 20 μL of sodium 3-(trimethylsilyl) 2, 2, 3, 3,2H4)-1 propionate (TSP) were added to the plasma. Chemical shifts were referenced internally to the singlet methyl resonance of TSP at zero ppm.

The following potentially gluconeogenic amino acids were quantified by NMR: leucine, isoleucine, valine, tyrosine, phenylalanine, histidine, methionine, alanine, threonine, glutamate and glutamine. Lactate, pyruvate and the gluconeogenic amino acids were measured to provide information on glycolysis and gluconeogenesis.

Proton NMR spectroscopy

1H-NMR spectra were measured from plasma samples taken from a large central vein at 5 hourly intervals until the experiments were terminated at t = 28 h. Data were acquired on a Varian INOVA 600 NMR Spectrometer operating at 600 MHz for protons. All spectra were acquired at ambient probe temperature (298 ± 0.2 °K). For each sample 128 transients (FIDs) were acquired into 32 K complex data points over a spectral width of 6 KHz. 300 pulses were applied with an acquisition time of 2.5 s to achieve better resolution followed by an additional pulse recycle time of 4 s to allow for complete T1 relaxation. Water signal suppression was achieved by applying a gated secondary irradiation field at the water resonance frequency. Spectral assignments were made by reference to literature values of chemical shifts in various media and biological fluids and coupling constants. The coefficient of variation between samples was < 6% and reproducibility for the same sample was good with a difference of < 2% on the same sample. The CMPG (Carr-Purcell-Meiboom-Gunn) sequence was applied for data acquisition, as this sequence enabled observation of a flat baseline in our spectra from plasma samples by minimising the signals acquired from macromolecules present in the plasma such as proteins and lipoproteins. NMR spectra analysis was performed using the MNova platform for NRM analysis (Mestrelab, Santiago de Compostela, Spain).

Statistical analysis

To compare between groups in the initial sample the Student’s t-test for parameters with non-missing values and the Mann Witney U test for parameters with missing values were used. Values were expressed as mean (range and standard error). A P value of < 0.05 was taken as statistically significant (two-tail test of significance). Numeric results are expressed as μmol/L. All analysis was done using the SPSS statistical package (Version 9.0).

RESULTS

On all samples studied we were able to identify the fol-
following metabolites: lactate, pyruvate, leucine, isoleucine, valine, tyrosine, phenylalanine, histidine, arginine, glycine, alanine, threonine, glutamate and glutamine. Resonances from proline, methionine and ornithine were not suitably characterised and results from those amino acids are not available. Figure 1 shows a sample spectrum.

In control pigs there were no significant differences in the concentrations of the substrates studied at any time point sampled. Animals who received paracetamol showed statistically significant differences in the concentrations of lactate, pyruvate and the amino acids.

**Lactate and pyruvate**

Figure 2 shows the results for lactate and pyruvate. Increases in the concentration of lactate became significant at \( t = 15 \) h and at \( t = 25 \) h; compared to \( t = 0 \) an average increase of 405% was seen \( (P < 0.003) \). Increases in the concentration of pyruvate became significant at \( t = 20 \) h and at \( t = 25 \) h; compared to \( t = 0 \) an average increase of 150% was seen \( (P < 0.018) \).

**Amino acids**

Figure 3 shows the results for threonine, alanine and glycine. Increases in the concentration of threonine became significant at \( t = 20 \) h and at \( t = 25 \) h; compared to \( t = 0 \) an average increase of 82% was seen \( (P < 0.048) \). Increases in the concentration of alanine became significant at \( t = 10 \) h and at \( t = 25 \) h; compared to \( t = 0 \) an average increase of 410% was seen \( (P < 0.002) \). Finally, increases in the concentration of glycine became significant at \( t = 5 \) h and at \( t = 25 \) h; compared to \( t = 0 \) an average increase of 390% was seen \( (P < 0.005) \).

Figure 4 shows the results for the aromatic amino acids. Tyrosine levels significantly increased at \( t = 5 \) h and at \( t = 25 \) h; there was an average increase of 1330% \( (P < 0.000) \). Phenylalanine levels also increased significantly at \( t = 5 \) h and at \( t = 25 \) h; there was an average increase of 1420% \( (P < 0.000) \).

Figure 5 shows the results for the branch chain amino acids. There were no statistically significant changes in the concentration of leucine between the beginning and the end of the experiments \( (0.17 \pm 0.02 \text{ vs } 0.175 \pm 0.02) \). Isoleucine levels increased significantly at \( t = 10 \) h and at \( t = 25 \) h; an average increase of 250% was seen \( (P < 0.01) \). Valine levels, on the contrary, significantly decreased at \( t = 20 \) h and at \( t = 25 \) h; an average decrease of 150% was seen \( (P < 0.05) \).
In the study, we observed that major gluconeogenic amino acids were not taken up by the liver. Concentrations of alanine increased significantly throughout the study along with concentrations of threonine and glycine. Likewise, the concentrations of the aromatic amino acids tyrosine and phenylalanine increased very early on and rose dramatically at the end of the experiments. This is in accordance with previous studies in mice that showed similar results. This is a good indication that gluconeogenesis in the liver is impaired and the TCA cycle is not functioning properly.

If we look at the branch chain amino acids the results are somehow different. No change was seen in the concentration of leucine and a decrease was observed in the concentration of valine. Significant increases at the end of the experiments were only seen in the concentrations of isoleucine.

ALF is characterized by the development of encephalopathy. In that respect Fischer’s ratio (the ratio of branch chain to aromatic amino acids) is believed to be a good index. A decrease of the ratio is a good marker of severe hepatic encephalopathy. As we have shown previously in our model a significant decrease in the Fischer's ratio was observed by t = 15 h of the experiments. In a previous study we have shown that although in patients with non-paracetamol induced ALF all branch chain amino acids are increased, in patients with paracetamol induced ALF valine is an exception and decreases over time. We believe our results to be in accordance with this observation. We should point out though that the attempts to correct hepatic encephalopathy with correction of the Fischer’s ratio by exogenous substitution of branch chain amino acids were not a success and the reason might lie in the fact that it is the aromatic and not the branch chain amino acids that are disturbed.

An interesting finding was that we observed no significant changes in the concentrations of glutamate, glutamine, histidine and arginine, key metabolic components of the urea cycle. We unfortunately were unable to quantify aspartate but there is strong evidence that the urea cycle in this model remains largely unaffected by paracetamol poisoning. This is in accordance with other studies that have shown that ALF induced hyperammonemia is caused by gut production of ammonia, a byproduct of the production of alanine from glutamate. Novel attempts to correct the metabolic abnormalities of hepatic encephalopathy by providing ornithine as a substrate for urea synthesis might be a good path.

The major drawback of this study is that we performed a study that describes changes in amino acids that pertain to gluconeogenesis and that we assumed that the changes were provoked by the inhibition of gluconeogenesis by the acute liver injury. We had no means to exclude the possibility that some other metabolic function could be responsible for the observed amino acid disturbances.

In conclusion, in this large animal model of paracetamol induced ALF we have observed an inhibition of gluconeogenesis in the liver with subsequent dysfunction of the TCA cycle. This has led to ATP and energy depletion and the liver switching to glycolysis to compensate. Further studies in animals and also in humans are needed to fully characterize the metabolic abnormalities of liver failure and to provide a pathophysiological basis for the new emerging metabolically centred therapies for hepatic encephalopathy.

COMMENTS

Background

Acute liver failure in humans is a deadly condition which could lead to multi-organ failure and death of the patient. Abnormalities in many metabolic pathways are observed, including alterations in the concentrations of amino acids, glucose, and ketone bodies. The study by Dabos et al. (2011) provides valuable insights into the metabolic changes associated with acute liver failure in mice induced by paracetamol poisoning. The authors observed significant changes in the concentrations of several amino acids, with a particular focus on the branch chain amino acids.

The study highlights the importance of understanding the metabolic abnormalities in acute liver failure, as these changes can have significant implications for patient management and treatment strategies. The results suggest that early detection and intervention may be crucial in preventing complications such as hepatic encephalopathy, which is a common complication in patients with acute liver failure. The study also underscores the need for further research to develop targeted therapies that address these metabolic abnormalities.

The findings of this study are relevant not only for the treatment of acute liver failure but also for the development of new therapeutic approaches. The knowledge gained from this research can inform the design of clinical trials and the selection of eligible patients for novel therapies. The authors’ conclusion that the declines observed in the Fischer’s ratio were consistent with other studies in the literature further strengthens the validity of their findings.

Overall, the study by Dabos et al. (2011) provides a comprehensive overview of the metabolic changes associated with acute liver failure in mice induced by paracetamol poisoning. The authors’ careful analysis of the data and consideration of previous studies contribute to a better understanding of the metabolic abnormalities in this condition. The results highlight the need for continued research in this field to advance the treatment of acute liver failure.
pathways are known to exist but there are very few large animal models where the authors are able to reproduce the acute liver injury. Recently the authors have developed such a porcine model in our laboratory.

**Research frontiers**

Paracetamol induced acute liver injury in humans and animal models is characterised by profound hypoglycaemia in a very short time from the liver injury. The exact mechanism of hypoglycemia remains debatable.

**Innovations and breakthroughs**

In this article the authors were able to provide some evidence that gluconeogenesis is impaired in a porcine model of acute liver injury as manifested by a relative increase in the plasma concentrations of the gluconeogenic amino acids. Gluconeogenic amino acids are the main substrate for glucose production after the exhaustion of glycogen stock very early in the acute liver injury.

**Applications**

This paper provides some insight into the metabolism in acute liver failure. It shows that gluconeogenesis is a key metabolic pathway in paracetamol induced acute liver failure fails, early on in the disease. This needs to be confirmed in human studies and it could have implications in the way these patients are managed.

**Peer review**

The article by Dabos et al describes increased lactate, pyruvate and distinct amino acids in a pig model of paracetamol induced acute liver injury.
