ABSTRACT
Spatial fluctuations in ultraviolet backgrounds can subtly modulate the distribution of extragalactic sources, a potential signal and systematic for large-scale structure surveys. While this modulation has been shown to be significant for 3D Lyα forest surveys, its relevance for other large-scale structure probes has been hardly explored, despite being the only astrophysical process that likely can affect clustering measurements on scales $\gtrsim$Mpc. We estimate that background fluctuations, modulating the amount of H I, have a fractional effect of $(0.03 - 0.3) \times (k/[10^{-2}\text{Mpc}^{-1}])^{-1}$ on the power spectrum of 21cm intensity maps at $z = 1 - 3$. We find a smaller effect for Hα and Lyα intensity mapping surveys of $(0.001 - 0.1) \times (k/[10^{-2}\text{Mpc}^{-1}])^{-1}$ and even smaller effect for more traditional surveys that correlate the positions of individual Hα or Lyα emitters. We also estimate the effect of backgrounds on low-redshift galaxy surveys in general based on a simple model in which background fluctuations modulate the rate halo gas cools, modulating star formation: We estimate a maximum fractional effect on the power of $\sim 0.01(k/[10^{-2}\text{Mpc}^{-1}])^{-1}$ at $z = 1$. We compare sizes of these imprints to cosmological parameter benchmarks for the next generation of redshift surveys: We find ionizing backgrounds could result in a bias on the squeezed triangle non-Gaussianity parameter $f_{NL}$, that can be larger than unity for power spectrum measurements with a SPHEREx-like galaxy survey, and typical values of intensity bias. Marginalizing over a shape of the form $k^{-1}P_{L}$, where $P_{L}$ is the linear matter power spectrum, removes much of this bias at the cost of $\approx 40\%$ larger statistical errors.

Key words: cosmology: theory — large-scale structure of universe

1 INTRODUCTION
Radiation backgrounds, especially of the ionizing sort, have the potential to impact structure in the Universe on larger scales than any other non-gravitational, astrophysical process. The photons in these backgrounds can travel significant fractions of the Hubble length (Meiksin & Madau 1993a; Haardt & Madau 1996, 2012), and, with their ability to ionize neutral hydrogen and alter the cooling rates of ions, they can modulate the properties of extragalactic sources (Benson et al. 2002; Hambrick et al. 2009). Despite this large-scale impact, the effect of background fluctuations on various large-scale tracers has only been investigated for 21cm intensity mapping surveys (Wyithe & Loeb 2009). This paper attempts to estimate how ionizing background fluctuations impact post-reionization 21cm intensity mapping surveys, Lyα and Hα emitter surveys, and galaxy surveys in general.

Detecting the imprint of these fluctuations on large-scale structure (LSS) surveys would constrain the properties of the sources, such as the fraction of the ionizing background that owes to quasars versus galactic emissions (e.g., Madau & Haardt 2015). In addition, an imprint from background fluctuations in LSS surveys could complicate cosmological parameter constraints on, e.g., neutrino masses, the scalar spectral tilt plus its running, or primordial non-Gaussianity – meeting motivated benchmarks for all of these parameters requires sub-percent precision on clustering measurements if not much better (Baldauf et al. 2016). Ionizing backgrounds have already been shown to be an important systematic for extracting cosmological parameters from 3D Lyα forest observations (McQuinn et al. 2011a; Pontzen 2014; Gontcho et al. 2014; Meiksin & McQuinn 2018). We investigate here whether ionizing background fluctuations could also be relevant for other LSS measurements.1

1 We note that the shapes imparted by ionizing background fluctuations are only captured by standard biasing expansions (e.g. Desjacques et al. 2018) on scales larger than the mean free path (and produce non-local biasing terms). Additionally, arguments that certain large-scale correlations must owe to primordial non-Gaussianity or equivalence principle violations, and
A related effect that is not considered here is the effect of reionization on dwarf galaxies (Thoul & Weinberg 1996; Gnedin 2000; Noh & McQuinn 2014), an effect that can potentially cascade up to more massive galaxies as the affected dwarfs merge and grow. This could affect the clustering of galaxies, especially small galaxies at high redshifts (Babich & Loeb 2006; Pritchard et al. 2007; Wyithe & Loeb 2007). The spectral shape of the effect of reionization is more difficult to predict than the shape imparted by the post-reionization background as considered here. We suspect that the effects studied here are larger than the imprint of reionization, especially for the redshifts we consider ($z < 3$).

This paper is organized as follows. Section 2 describes how the ionizing background affects linear scales in LSS measurements, and Section 3 outlines the formalism used to calculate the spectrum of ionizing background fluctuations and presents the fluctuation models this study employs. Section 4 estimates the impact of background fluctuations on post-reionization 21cm intensity mapping surveys. Section 5 presents similar estimates but for surveys that ground fluctuations on post-reionization 21cm intensity mapping models this study employs. Section 4 estimates the impact of back-reionization fluctuations and presents the fluctuation and Section 3 outlines the formalism used to calculate the spectrum, especially for the redshifts we consider ($z < 3$). Section 7 compares the requirements for constraining targeted cosmological parameters to benchmark values, a particularly relevant one (owing to its similar shape to that imparted by ionizing background fluctuations) being squeezed triangle primordial non-Gaussianity.

## 2 THE IMPACT OF INTENSITY FLUCTUATIONS ON GALAXY CLUSTERING

Metagalactic fluctuations angle-averaged ionizing intensity, $J$, have a component that traces the cosmic matter field with transfer function $T_J(k, w_o)$ and an effective source number density $n_J(k, w_o)$, where $w_o$ indicates some frequency-weighting of the radiation background and the $k$-dependence of both $T_J$ and $n_J$ account for the propagation of radiation. Thus, the linear power spectrum of intensity fluctuations is given by

$$P_J(k) = T_J(k, w_o)^2 P_{b_J}(k) + n_J(k, w_o)^{-1},$$

where $P_{b_J}(k)$ is the linear power spectrum. In Section 3 we discuss how $T_J$ and $n_J$ are computed. For much larger wavenumbers than that set by the mean free path (and that set by the quasar lifetime for the “shot” $n_J^{-1}$ component), $T_J^2$ and $n_J^{-1}$ decrease as $k^{-2}$, resulting in the impact of ionizing backgrounds being largest at low wavenumbers.

Our concentration is not the nature of fluctuations, $P_J$ itself. For $P_J$, we follow the calculations of Meiksin & McQuinn (2018), whose calculation we briefly summarize below. Instead, our focus is the imprint that $J$ fluctuations have on LSS surveys. When including intensity fluctuations, the standard expression for the linear power spectrum of some galaxy population is extended to

$$P_g(k) = (b_g + b_J T_J + f n_J)^2 P_{b_g} + b_g^2 n_J^{-1},$$

where $g = n - k \cdot \hat{n}$, $n$ is the line-of-sight unit vector, $f \approx \Omega_m(z)^{0.6}$ and the associated term arises from redshift space distortions (Kaiser 1987), and $b_g$ ($b_J$) are the linear density bias (intensity bias) of the particular galaxy population. Equation (2) ignored that the $b_J$ coefficient could be different between the stochastic and density-tracing terms if the property that shapes galaxy observability is averaged over a longer time than the lifetime of sources, which would act to decrease the shot noise bias coefficient. Similarly, there should be a separate bias coefficient for the ionizing background at every previous redshift (Cabass & Schmidt 2018).

Equation (2) made the simplification that the clustering is shaped by the background at the observed redshift, which should largely hold for the processes that couple the galaxy distribution to the radiation background considered here.

Since $b_J$ sets the magnitude of intensity fluctuations, much of the focus of this study is on estimating this bias for different types of galaxy survey. To preview our results, our estimates of $b_J$ from Sections 4-6 are summarized in Table 1, in addition to our estimates for the fractional effect of intensity fluctuations on $P_g$.

## 3 THE LINEAR THEORY OF IONIZING RADIATION BACKGROUND

On megaparsec scales and greater, fluctuations in the $z \lesssim 5$ ionizing background are small and, hence, well described by perturbation theory. While the fluctuations are small, they may still be a relevant driver of inhomogeneity for large-scale structure (LSS) surveys. Aside from the Lyα forest, this source of inhomogeneity has not been previously considered.

This section discusses our calculation of the linear power spectrum of intensity fluctuations, with our approach following the spirit of earlier calculations for intensity fluctuations (Meiksin & White 2004; Croft 2004; McDonald et al. 2005; McQuinn et al. 2011a; Pontzen 2014; Gontcho et al. 2014; Pontzen et al. 2014; Suarez & Pontzen 2017; Meiksin & McQuinn 2018). Our calculations especially follow the formalism presented in Meiksin & McQuinn (2018), which builds most closely off the approach in Pontzen (2014) but instead solves the fully time-dependent rather than the steady state solution. Future sections use these calculations to estimate the imprint on various LSS surveys.

To proceed, we linearize and then solve the cosmological radiative transfer equation, given by

$$\frac{\partial I_{\nu_0}}{\partial t} + 2 \frac{a}{c} I_{\nu_0} + a^{-1} \hat{n} \cdot \nabla I_{\nu_0} = -\kappa_{\nu_0} I_{\nu_0} + j_{\nu_0},$$

where $\nu_0 \equiv \nu/(1+z)$, $I_\nu$ is the specific photon number intensity [photons $Hz^{-1}s^{-1}cm^{-2}sr^{-1}$] — noting that $J_\nu = (4\pi)^{-1} \int d\Omega I_\nu$ — $a$ the cosmic scale factor, $\kappa_\nu$ and $j_\nu$ the absorption and emission coefficients, and we have set the speed of light to unity for simplicity.

Linearizing this equation in the intensity fluctuation $\delta I_{\nu_0}$ and going to Fourier space yields

$$\frac{\delta I_{\nu_0}}{I_{\nu_0}} \approx i a^{-1} \hat{n} \cdot k \delta I_{\nu_0} + (\bar{\kappa}_{\nu_0} + 2H) \delta I_{\nu_0},$$

where

$$\beta_\delta(\nu, t) \equiv \bar{\kappa}_{\nu} - \kappa_{\nu_0} c_n \delta_n, \quad \beta_\delta(\nu, t) \equiv \bar{\kappa}_{\nu} c_n \delta_n,$$

where tildes indicate the field’s Fourier dual and we also have

2 Time dependence is even more important to include for our calculations than those in Meiksin & McQuinn (2018), which only considered $z > 2$, as at low redshifts much of the background is comprised of photons that traveled a significant fraction of the horizon.
Impact of UVB fluctuations on galaxy clustering

Table 1. The impact of ionizing background fluctuations on different redshift surveys. Here $b_J$ is our estimated response of the overdensity in the specified LSS observable to a fraction fluctuation in the background intensity. We also list rough numbers for the fractional change in the specified LSS tracer’s power spectrum from background fluctuations that use our models for $P_f$.

* Like in the other rows, these values are used for calculating the third column; however, unlike in the other rows, there is a large range of possible values, with our estimates in § 6 finding $b_J = (−0.01 − 0.1)$. These estimates should be taken with caution, assuming simplistically that the star formation rate of $L_*$ galaxies is tied to the cooling rate of circumgalactic gas.

The impact of ionizing background fluctuations on galaxy clustering

We further assume that quasars dominate the ultraviolet background, consistent with the findings of most background models at $z \lesssim 3$ (Meiksin & Madau 1993b; Haardt & Madau 2012; McQuinn & Wosreck 2014; Upton Sanderbeck et al. 2018), although a dominant galactic contribution would only have an effect on our estimates for the imprint on $P_f$. To model quasars, we use the 1 Ry quasar emissivity of Haardt & Madau (2012), and we assume that their spectral index in specific intensity is $\alpha_Q = 1.7$. For the quasar bias, we linearly interpolate between $c_{\gamma, \delta} = \{0.5, 1.1, 1.5, 1.6, 2.2\}$ at $z = \{1, 1.4, 1.8, 2.1, 2.6, 3.0\}$, numbers based on quasar SDSS clustering measurements (Ross et al. 2009; Laurent et al. 2017). (Note that our ionizing source biases are denoted as $c_{\gamma, \delta}$ to not confuse with the weights of the measured clustering signal $b_0$ and $b_J$; c.f. Eqn. 2.) We further assume that $c_{\gamma, \delta} \propto (1 + z)$ to extrapolate to $z > 3$. While these bias measurements are for the $L_*$ quasars observable with BOSS, we note in that many models for quasar clustering the luminosity dependence is weak (Lidz et al. 2006). We further take the shot noise to be dominated by quasars for which the effective number density is given by $\bar{\eta} = \int \frac{dL\phi(L)L^2}{\int \frac{dL\phi(L)L^2}}$, where $\phi(L)$ is the full redshift evolution quasar luminosity function of Hopkins et al. (2007). The effective number densities and source biases enter in the cross power spectrum of the ionizing source spatial overdensity between times $t_I$ and $t_m$ (see Meiksin & McQuinn 2018):

$$P_f(k|t_I, t_m) = c_{\gamma, \delta}(t_I)c_{\gamma, \delta}(t_m)P_f(k|t_I, t_m) + \bar{n}^{-1}L(t_I - t_m),$$

where $P_f(k|t_I, t_m)$ is the linear matter power at times $t_I$ and $t_m$, and $\mathcal{L}$ is the convolution of the source light curve with itself normalized so that $\mathcal{L}(0) = 1$. For simplicity, we assume quasars sources with top hat light curves with widths of 10, 100, and $\infty$ Myr, with the former two values reflecting the range of estimates based on direct and indirect probes (Martini & Weinberg 2001).

For the mean opacity coefficient, we use $\kappa_{\nu} = 0.027[(1 + z)/5]^{1.5}[(\nu/\nu_{I_{Rs}})^{−1.5}$ physical Mpc$^{-1}$, for which the inverse of $\kappa_{\nu=I_{Rs}}$ (which yields the mean free path at the Lyman-limit) uses the measurement of Wosreck et al. (2016) to $z = 2.3 – 5.5$, and we have assumed the expected scaling with $\nu$ for an H I column density distribution with slope of $\beta = 1.5$. At lower redshifts than $z \approx 2$, opacity effects become unimportant as the propagation of radiation backgrounds becomes limited by the Horizon allowing us to use this fit even beyond its intended redshift range. We take the response of the opacity to the ionizing background to be $c_{\gamma, \delta} = 0.5$. This value is consistent with an analytic model based on Miralda-Escudé et al. (2000) for $\beta = 1.5$ and with what is directly measured from simulations at $z \sim 2 – 4$ (McQuinn et al. 2011a).

The remaining bias coefficients $c_{\gamma, \delta}$ and $c_{\gamma, \delta}$, are set to zero. Setting $c_{\gamma, \delta}$ to zero is justified because the sources are more biased than the absorbers. The limit $c_{\gamma, \delta} = 0$ is applicable if the photoionization rate does not have a significant effect on modulating the emission: models find associated recombinations contribute at the $10 – 20\%$ level to $L_*(z)$ (Faucher-Giguère et al. 2009).

To solve for $\delta_f$, we can average Equation 4 over frequency with weighting $\nu_\nu = \delta_\nu$, and angle, using the solution to the homogeneous equation for $I_f$.

Solving this simpler frequency-averaged equation is found to be very accurate (Meiksin & McQuinn 2018). We indicate the $\sigma_f$, $I_f$-weighted average of coefficients with a subscript $\sigma$, noting that the angular-averaged Green’s function for the right hand side of the resulting equation is $j_0(k_{\nu_\sigma}r_{\nu_\sigma})\exp[-\int_{t}^{t'} dt'' \kappa_{\eta_\sigma,\sigma}(t'')]$, where $j_0$ and $\kappa_{\eta_\sigma,\sigma} \equiv \{2 + \alpha \kappa\}H + \Gamma^{-1}\int \frac{d\nu}{\sigma f_{\sigma} I_f}$, and ignoring fluctuations in the spectral index of the background on $\delta_f$, the solution to the spatial Fourier transform of this equation can be written in terms of the following transcendental equation

$$\tilde{\delta_f}(t) = \int_{0}^{t} dt'' j_0(k_{\eta_\sigma,\sigma})\exp[-\int_{t}^{t'} dt'' \kappa_{\eta_\sigma,\sigma}(t'')] \times \hat{\delta_0}_{\sigma_\sigma} + \beta_{\sigma_\sigma} \delta_{\gamma_\sigma} \tilde{\delta_\gamma}_{\sigma_\sigma}.$$
This equation can be solved for $\delta_1$ by discretizing the first integral in Equation 6 and some matrix algebra (Meiksin & McQuinn 2018).

Figure 1 shows the results of the power spectrum of photoionization rate overdensity, $\delta_2$, fluctuations at $z = 0.5$, 1, 2, and 3 for the different lifetime models. The solid black curves are the matter density power spectrum, whose value (to order-unity density bias factors) indicates the level of fluctuations in LSS surveys. The dashed blue curves are the density-tracing component of the photionization rate fluctuations and the matter density, the ionizing background term that often makes the largest imprint on galaxy clustering. The amplitude of fluctuations in the radiation background increases with redshift. Even at low redshifts, the fluctuations can be larger than the density fluctuations at the radiation background increases with redshift. Even at low redshifts, the fluctuations can be larger than the density fluctuations at the lowest, horizon-scale wavenumbers that are of much interest for primordial non-Gaussianity searches. The importance of ionizing background fluctuations for LSS surveys depends on the bias with which these surveys trace the background fluctuations, $b_f$. The ensuing sections estimate $b_f$ for several surveys.

4 21CM INTENSITY MAPPING SURVEYS

Many efforts are coming online that aim to detect the post-reionization redshifted 21cm emission from the residual H I gas that is trapped in and around galaxies. These efforts generally do not have sufficient collecting area to detect individual sources, but instead will map the diffuse intensity of many sources (a mode referred to as 'line intensity mapping'). Namely, the CHIME and HI-RAX experiments are targeting 21cm emission from $z = 0.8 - 2.5$ (Bandura et al. 2014; Newburgh et al. 2016a), and MEERKAT is targeting this signal from $z = 0.4 - 1.1$. BINGO and FAST could extend the range of redshifts probed to $z = 0$ (Battye et al. 2012; Bigot-Sazy et al. 2016), and mapping all the way to reionization is possible, perhaps with the Square Kilometer Array (Carilli & Rawlings 2004; Kovetz et al. 2017) or with the instruments envisioned in Cosmic Visions 21 cm Collaboration et al. (2018).

Fluctuations in the ionizing background will modulate the distribution of H I: Regions exposed to a larger ionizing background will show higher densities and, hence, retain less H I. Cosmological simulations post-processed with ionizing radiative transfer have been found to reproduce the broad features of the observed H I column density distribution (Altay et al. 2011; McQuinn et al. 2011a; Rahmati et al. 2013a). Such simulations can be used to estimate the response of H I to the background by post-processing simulations with different backgrounds and observing the change in H I. We can in-effect do such a calculation by using the physically-motivated fitting formulae in Rahmati et al. (2013a) that describe the density and photoionization rate dependences of the H I fraction in their radiative transfer simulations. Using these formulae, we find a factor of $\delta_1$ fractional change in the background results in a surprisingly large factor of $-0.25\delta_1$ change in the global amount of neutral hydrogen for $\delta_1 \leq 1$. This estimated response does not depend on redshift to good approximation (being invariant to the extent that the column density distribution is invariant). The details of the Rahmati et al. (2013a) formula and this calculation are presented in Appendix A. This large response translates to the intensity bias of $b_f = -0.25$ (see Eqn. 2).

In addition to deriving $b_f$ from the relations in Rahmati et al. (2013a), we have pursued two other methods for estimating $b_f$ for 21cm intensity mapping surveys that result in similar values. Each of these methods make different assumptions. In one such method, we perform radiative transfer on a slab of a given H I column with width corresponding to the Jeans scale at a specified density for $10^3$ K gas (see Appendix A2). This Jeans-scale ansatz is motivated by the arguments in Schaye et al. (2000) and by the densities of absorbers in cosmological simulations (Altay et al. 2011; McQuinn et al. 2011b), and this ansatz results in a one-to-one relation between H I column density and density. The motivation for this slab calculation is that it more explicitly tracks the ionization physics that is hidden in the Rahmati et al. (2013a) fitting formulae (at the expense of the simplified geometry). We find that a factor of $\delta_1$ fractional change in the ionizing background results in a factor of $-0.20\delta_1$ change in the global amount of neutral hydrogen, consistent with our previous estimate. Finally, one can do a simple estimate assuming that all absorbers have the same power-law profile and self shield at a critical density (Miralda-Escudé et al. 2000; McQuinn et al. 2011b; see Appendix A3). This model has been found to have some success at reproducing the shape of the observed column density distribution (Zheng & Miralda-Escudé 2002). For a power-law profile that results in an H I column density distribution with a power-law index of $\beta = 1.3(1.5)$ that is consistent with observations, this cruder model results in an even somewhat larger response of $-0.45 \pm 0.75$. While we trust this model the least, the assumptions it makes are much different than the other model, and it still results in a large response. The estimated value of $b_f$ is also redshift independent in both the slab and power-law absorber models. All three models of $b_f$ ignore the effect on local radiation on the H I ionization state, which could act to decrease the sensitivity to the ultraviolet background. Simulations that include local radiation suggest that it is a minor factor in setting the ionization state (Rahmati et al. 2013b).

Wyithe & Loeb (2009) estimated a considerably smaller response of $(b_f \sim 10^{-2} - 10^{-3})$ of mean H I density to the ionizing background. Their estimate approximated DLAs as an exponential disks and ignored optically thin gas, leading to a smaller response than our estimates. Wyithe & Loeb (2009) commented that $b_f$ would be of the order of unity if the density profile of self shielding systems was isothermal (i.e. $n_H \propto r^{-2}$). Indeed, the H I column density distribution suggests an underlying profile closer to isothermal (Miralda-Escudé et al. 2000; Zheng & Miralda-Escudé 2002; McQuinn et al. 2011b), and an isothermal-like profile was the basis of our third estimation method.

In addition to the intensity bias, $b_f$, to compute the amplitude of fluctuations also requires an estimate of the H I density bias, $b_g$. At $z = 0.8$, the Switzer et al. (2013) 21cm-galaxy cross-correlation measurement of $\Omega_M n_H b_g = (0.62^{+0.23}_{-0.22}) \times 10^{-3}$ combined with the quasar absorption line measurements of $\Omega_M n_H = 0.5 \times 10^{-3}$ yield $b_g = 1.0 \pm 0.3$. At $z = 2.1$, DLA clustering measurements find $b_g = 2.0 \pm 0.1$ (Font-Ribera et al. 2012; Pérez-Rafols et al. 2018). There are currently no measurements of $b_g$ at higher redshift; our calculations at $z = 3$ assume $b_g = 2$.

We note that DLA bias measurements are number density-weighted, as opposed to 21cm intensity mapping measurements, which weight by
Figure 1. Models for the power spectrum of the photoionization rate overdensity, $P_J$, at the specified redshifts. The solid colored curves show the shot noise contribution to $P_J$ for different quasar lifetime models. The dashed blue curve is the clustered component of $P_J$, which does not depend on the quasar lifetime. For reference, the solid black curve is the linear matter overdensity power spectrum. The dotted curve is the cross power between the density tracing (clustered) component of the $J$ fluctuations and the linear matter overdensity; we find the dominant contribution from $J$ fluctuations to galaxy clustering owes to this cross correlation.

Figure 2. Predictions for the fractional impact of ionizing background fluctuations on the angularly-averaged power spectrum of the diffuse 21cm intensity, computed using $b_J = -0.25$, as motivated by the estimates discussed in the text. The solid curves are the negative of the total fractional contribution to the power from intensity fluctuations, and the dashed are the same but dropping the shot noise contribution to $\delta^2 I$. The shot noise component becomes increasingly important with increasing redshift and increasing quasar lifetime. The dotted lines show the negative of the solid curves to show their behavior below zero.

Figure 2 shows the fractional effect of intensity fluctuations on the 21cm power spectrum at $z = 1$, $z = 2$, and $z = 3$ for models with quasar lifetimes of $t_Q = 100$ Myr and $t_Q = \infty$. For the intensity bias, we use our most detailed estimate based on Rahmati et al. (2013a) that yields $b_J = -0.25$. The solid curves are the total contribution to the $\mathrm{H\, I}$ power spectrum from intensity fluctuations, whereas the dashed curves are the contribution excluding shot noise (which depends on quasar lifetimes). The fractional effect of background fluctuations on the 21 cm power spectrum at $z = [1, 2, 3]$ is $b_J^2/k^2$. The fractional effect of intensity fluctuations of the models that exclude shot noise scale as approximately $k^{-1}$, as the largest contribution from $J$ fluctuations owes to the $2T_J \rho_\delta$ term with $T_J \sim k^{-1}$ at $k \gg \kappa_{\mathrm{eff}, \sigma}$. This clustering component is comparable to the shot noise at the lowest and highest wavenumbers shown, most notably for the $z = 3$ case. As quasars become more numerous toward $z \sim 3$, the shot noise decreases, but the shot noise term is most prominent in our $z = 3$ model because $b_J$ is larger as $z \to 3$ and this term goes as $b_J^2$.

We note that the lowest wavenumbers shown are difficult to measure by 21cm efforts due to foreground removal; foreground removal limits HIRAX to measurements to $k \gtrsim 0.03$ Mpc$^{-1}$ where the fractional imprint of intensity fluctuations is less than $10^{-3}$, $10^{-2}$ and $0.05$ at $z = 1$, 2 and 3 (Newburgh et al. 2016b).

neutral hydrogen density, and so the biases probed by these techniques should differ slightly.
However, the projections for the Cosmic Visions 21 cm Collaboration et al. (2018) are more optimistic, anticipating measurements to $k \approx 0.005 h \text{ Mpc}^{-1}$, a wavenumber where we predict fractional imprints of $\sim 0.1, 0.3$ and 1 at these redshifts (and the effects of intensity fluctuations would be even larger at the higher redshifts that Cosmic Visions 21 cm Collaboration et al. (2018) is also targeting).

5 RECOMBINATION LINE SURVEYS

Most recombination-line emissions originate from recombinations in the ISM of galaxies that result from the absorption of ionizing photons from nearby stars. However, at $1 \lesssim z \lesssim 3$ Type I AGN produce $\sim 10\%$ of all ionizing photons, with stars producing the rest (e.g. Haardt & Madau 2012). Because most if not all of the ionizing photons from Type I AGN escape their host galaxies, but those of stellar origin likely do not, this suggests that $\sim 10\%$ of recombinations are tied to the ionizing background in the steady state limit in which recombinations are in global balance with emissions (which holds at $z \gtrsim 3$). As much of ten percent of photons of large-scale structure surveys that probe recombination lines, such as H$\alpha$ H$\delta$ and H$\gamma$ Ly$\alpha$, could be from recombinations that trace the ionizing background.

There are several upcoming Ly$\alpha$ and H$\alpha$ surveys whose cosmological determinations could be biased by these fluctuation-tracing recombinations. HETDEX aims to constrain the Cosmology from the clustering of Ly$\alpha$ emitters at $1 < z < 3$ (Hill et al. 2008), and SPHEREx – a proposed NASA Medium-class explorer satellite that is funded for concept studies – aims to detect H$\delta$ emission from galaxies from much of the Cosmic Volume (Doré et al. 2016). HETDEX and SPHEREx will undertake both ‘traditional’ galaxy surveys and intensity mapping campaigns (with the latter defined as surveys that map all the emissions and do not locate individual sources). The effect of ionizing backgrounds is largest for intensity mapping surveys as we find below that traditional galaxy surveys likely do not detect the majority of the (diffuse) background-sourced recombination photons.

To estimate the size of the background-tracing emissions in these lines, let us decompose the recombination radiation emission into an internal-to-galaxies component – driven by ionizing photons absorbed before they escape their host ISM and the subsequent recombination – and an external component – driven by ionizing photons in the extragalactic ionizing background:

$$j_{\text{rec}} = j_{\text{rec, int}} + j_{\text{rec, ext}}, \tag{7}$$

In the first line, $j_{\text{rec, int}}$ and $j_{\text{rec, ext}}$ are the internal emission coefficient and external (background-sourced) emission coefficient for the desired recombination line. The second line expands the two emission sources into an overdensity that traces the sample galaxies, $\delta_{\text{g}} \equiv (b_{g} + f\mu^{2})\delta$ and, for the external coefficient, also an overdensity that traces the ionizing background $\delta_{\text{g}}$ with bias $c_{\text{rec, g}}$. To the extent that the cross sections of absorbers are unchanged by the ionizing background and that every photoionization is balanced with a recombination – approximations that are likely to hold – $c_{\text{rec, g}} = 1$.

From Equation 7, we can compute the galaxy power spectrum for a luminosity-weighted galaxy clustering measurement or an intensity mapping survey:

$$P_{\text{rec}}(k) = \left( b_{g} + f\mu^{2} + f_{\text{ext}}c_{\text{rec, g}}T_{\mu} \right)^{2} P_{\delta_{\text{g}}}(k),$$

where, to connect to our previous notation (c.f. Eqn. 2), $b_{\mu} = f_{\text{ext}}c_{\text{rec, g}}T_{\mu}$ and we have defined $f_{\text{ext}} \equiv j_{\text{rec, ext}}/(j_{\text{rec, int}} + j_{\text{rec, ext}}) \approx j_{\text{rec, ext}}/j_{\text{rec, int}}$. We note that at $z \gtrsim 3$, when photons that make it into the background are quickly absorbed and, thus, sourcing recombinations, $f_{\text{ext}}$ is given by the fraction of ionizing photons that escape galaxies – including ones hosting AGN – $(f_{\text{ext}})$ times the fraction of these ionizing photons that will be absorbed ($\approx \kappa_{e}/\kappa_{\text{ext}}$) times the fraction of these recombinations the survey picks up ($f_{n,g}$):

$$f_{\text{ext}} \approx \frac{\overline{\kappa}_{\text{ext}}}{\overline{\kappa}_{\text{rec}}/\kappa_{\text{ext}}} f_{n,g} \times \frac{\bar{\kappa}_{g}}{\bar{\kappa}_{\text{ext}}} \times f_{\text{esc}}.$$ 

Our calculations use the quasar emissivity function of (Khair & Srianand 2015) and the UV-only star formation rate from Haardt & Madau (2012) to calculate $f_{\text{ext}}$, making the assumption that all ionizing photons escape from quasars, and approximately none make it out of galaxies. We find $f_{\text{esc}} = [0.06, 0.07, 0.04]$ and $\bar{\kappa}_{g}/\bar{\kappa}_{\text{ext}} = [0.12, 0.42, 0.70]$ at $z = [1, 2, 3]$, values we adopt for subsequent calculations.

5.1 Intensity mapping surveys

Figure 3 shows our estimates for the recombination-line flux power spectrum at $z = 1, z = 2$, and $z = 3$ for ionizing background fluctuation models with quasar lifetimes of $t_{Q} = 100 \text{ Myr}$ and $t_{Q} = \infty$. These estimates are for the intensity mapping mode in which $f_{n,g} = 1$ so that all recombination photons (emitted towards the observer) contribute to the survey. This applies, for example, to the intensity mapping surveys of SPHEREx in H$\alpha$ and HETDEX.
impact of UVB fluctuations on galaxy clustering

7

in Lyα. For these calculations, we use the estimated Lyα intensity density bias of $b_R = [1.16, 1.19, 1.40]$ for $z = [1, 2, 3]$ of Pullen et al. (2014), and if we assume the same $b_R$ values should apply for Hα in intensity mapping then our calculations also hold for this line (an assumption which should hold up to preferential dust destruction of Lyα photons in more massive galaxies). We further assume that the sizes of absorbers are not affected by $f$ so that $b_R = 1$, and, since $b_J = f_{\alpha} b_R$ and using the previously quoted $f_{\alpha}$, we find $b_J = [0.007, 0.03, 0.03]$ at $z = [1, 2, 3]$. The uncertainty in our estimate of $b_J$ comes primarily from $f_{\alpha}$. Though measurements of photoionization rates in the Lyα forest constrain the total number of ionizing photons, the number of ionizing photons per unit star formation is still unknown to a factor of ~2 (Shull et al. 2012), as is the star formation rate density and the fraction of recombination photons that are not absorbed by dust, leading to an uncertainty in our estimates of the order of unity.

The solid curves are the total fractional effect to the power spectrum from intensity fluctuations, and the dashed curves show the fractional effect without shot noise. Note that the intensity bias for recombination radiation is positive, in contrast to our 21cm intensity bias, so the effect of intensity fluctuations is to enhance the power. The clustering component of intensity fluctuations (and really its cross with the survey galaxy overdensity) is so small, for the shot noise in the galaxy-selecting campaigns of HETDEX, using $b_J$ is smaller (Sharma et al. 2012; McQuinn & Werk 2018; Fielding et al. 2017). In addition, the gas that actually cools and condenses, and condensation in the halo (e.g. Sharma et al. 2012; Voit et al. 2017; McQuinn & Werk 2018; Tumlinson et al. 2017). This approach fails to capture the nonlinearity of the physics governing star formation, but serves as an illustrative first-order estimate.

Processes such as stellar feedback, metal enrichment, and changes in gas temperature from an increased background intensity make the relation between background intensity and star formation potentially very complex. However, in the picture where galaxies are relatively closed systems with minimal energy escape (which is a reasonable assumption at low redshift) and each galactic system is an approximate steady state, any additional cooling would be balanced by additional star formation in its associated feedback to reheat the gas and balance cooling. A more detailed picture might be found by running simulations of individual galaxies exposed to different ionizing backgrounds and measuring the resulting change in brightness. This approach would come with its own set of caveats – the CGM in such simulations is often unable to reproduce observed properties, such as commonly observed ions, with the simulated CGM depending sensitively on how feedback is prescribed.

With our simple model, we investigate the cases of galaxies with virial temperatures of $5 \times 10^5$, $5 \times 10^6$ and $5 \times 10^7$ K. Such temperatures correspond to halos of approximately $10^{11.5}$ – $10^{12} M_\odot$ at $z \sim 0$, for which abundance matching techniques find host stellar masses of $\sim 10^{10} – 10^{11} M_\odot$ (Behroozi et al. 2010; Li & White 2009) – typical star-forming galaxy masses. To calculate cooling rates, we assume that gas in these halos is likely to have densities near the ‘virial density’ or mean halo gas density ($\rho_{halo} = 200 \rho$, where $\rho$ is the cosmic mean gas density). Models suggest typical densities of halo gas at $\sim 100$ kpc from the galaxy that range from roughly the mean halo density to a factor of ten smaller (Sharma et al. 2012; McQuinn & Werk 2018; Fielding et al. 2017). In addition, the gas that actually cools and condenses, sourcing star formation, might be the denser gas that lies closer to galaxies. Thus, we discuss a range of densities centered around the virial density.

To understand how the ionizing background can shape halo cooling, we have run a grid of CLOUDY ionization models for virialized halo gas. The cooling rate of gas depends on its temperature $T$, spectral shape, and ionization parameter, $U$, where $U = \Phi/n_{\text{HIC}}$. In these estimates, $n_{\text{HIC}}$ is the density of hydrogen nuclei, and $\Phi$ is the ionizing photon flux, which is proportional to the photoionization rate, $\Gamma$. We use the rates from the Haardt & Madau (2012) model; the metagalactic ionizing background should
Figure 4. The fractional change in the cooling rate with respect to a fractional change in the ionization parameter, which is equal to our intensity bias parameter $b_J$. The purple, green, and blue curves show this change for gas temperatures of $5 \times 10^5$, $10^6$ and $5 \times 10^6$K, respectively. The grey band brackets the ionization parameters, corresponding to a factor of three less and more than the mean halo gas density of $z = 0.5 - 2$ halos ($\log U \approx -1.5$ for the mean halo gas density at all of these redshifts).

Figure 5. Predictions for the fractional change from ionizing background fluctuations on the $z = 0.5$, $z = 1$ and $z = 2$ galaxy power spectrum for $b_J = 0.05$. Unlike in the previous plots, these estimates apply to galaxy surveys of 'typical' galaxies with $T_{\text{vir}} \sim 10^6$K and not just to intensity mapping surveys. However, the values are more uncertain as these calculations require assumptions for how galaxy formation is affected by ionizing backgrounds. Our model that connects observability to halo cooling suggests $b_J = [2 \times 10^{-3} - 0.2]$, the amplitude of the fractional change in the power spectrum scales linearly with $b_J$. The solid curves are the total contribution to the power spectrum from intensity fluctuations, and the dashed curves with corresponding colors are the contribution excluding shot noise.

for $b_J$ is a factor of several larger or smaller if we vary the virial temperature or density by factors of a few, and our results for the fractional impact on the power spectrum depend linearly on $b_J$.

The galaxy density bias, $b_g$, is calculated using a Sheth-Tormen halo mass function (Sheth et al. 2001), where $b_g$ is $[1.24, 1.47, 2.12]$ for $z = [0.5, 1.0, 2.0]$ at a virial temperature of $10^6$K corresponding to halo masses of $[1.5 \times 10^{12}, 1.1 \times 10^{12}, 6.2 \times 10^{11}] M_\odot$.⁹

Figure 5 shows the effect of fluctuations on the galaxy flux power spectrum under these choices for $b_g$ and $b_J$. Because the intensity bias is small, the effect of fluctuations is no more than a couple percent at $k < 10^{-2}$ Mpc⁻¹. However, precision measurements in future surveys (such as searches for primordial non-Gaussianity at the sub-percent level) may still be biased by this small modulation. We estimate by how much this level of contamination could bias cosmology constraints in the following section.

A galaxy’s star formation rate could also be modulated by metagalactic Lyman-Werner ($\sim 11\text{eV}$) background, which can dissociate molecular hydrogen and hence prevent star formation. The effective mean free path of such backgrounds is smaller than this for ionizing backgrounds ($\sim 0.1 H^{-1}$ compared to $\sim H^{-1}$ at low redshift) so that fluctuations in the Lyman-Werner background are larger. However, the Lyman-Werner background inside a molecular cloud is likely to be dominated by galactic star formation at kpc-scale separation (Gnedin 2010), unlike the background that sets the ionization of the much more extended circumgalactic medium at

---

⁹ For $5 \times 10^5$ K gas, $b_g = [1.06, 1.23, 1.72]$ at $z = [0.5, 1.0, 2.0]$, corresponding to halo masses of $[5.2 \times 10^{11}, 3.6 \times 10^{11}, 2.1 \times 10^{11}] M_\odot$.
100 kpc. Thus, the modulation of total galactic star formation rates from Lyman-Werner backgrounds is likely to be smaller than from ionizing backgrounds, which can affect gas accretion onto a galaxy.

6.2 Galaxies selected by stellar mass

The previous subsection’s estimates were for galaxy selection that is sensitive to star formation rate. If the selection is more sensitive to stellar mass, the background that shapes the cooling is more weighted towards the past, when the fluctuations were larger, predicting a larger imprint of the background. Additionally, in the past, background fluctuations could have a larger effect on cooling because of the lower virial temperatures of the progenitor system. One could also imagine that if the background were larger in a region, then there would be less cooling at earlier times leading to larger densities and more cooling at later times, reducing the response we have estimated.

We note that clustering measurements based on number density weighting of galaxies will be affected by the number of galaxies around the detection threshold. If the magnitude of the ionizing background were increased, a galaxy that may otherwise have been above this threshold could be undetectable due to a slight modulation in luminosity and conversely, an otherwise fainter galaxy may be slightly more luminous in the presence of a diminished background. The magnitude of this effect depends on the slope of the cumulative luminosity function at the detection threshold as this determines the number density of galaxies that would come into or out of the survey. The effect of number density weighting results in $b_j \rightarrow 2.5a b_{fNL}$, where $b_{fNL}$ is our previously calculated $b_j$ but evaluated at the survey detection threshold, $\alpha \equiv d \log_{10} n(> m_b)/dn$ where $n(> m)$ is the cumulative distribution above some apparent magnitude $m$ with $m_{th}$ being the threshold. Values of $\alpha$ are typically quoted at $\alpha \sim 0.5 \pm 2$ (Liu et al. 2014; Ménard et al. 2010), although likely the enhancement is modest for a deep survey like SPHEREx. For our case where $b_{fNL} = 0.05$, number weighting would result in somewhat larger values of $b_j \approx 0.06 - 0.25$ if $\alpha = 0.5 - 2$.

7 COSMOLOGICAL PARAMETER BIASES

Finally, we investigate the robustness with which certain cosmological parameters can be constrained from galaxy redshift surveys in the face of the contamination from ionizing background fluctuations. Figure 6 shows the $z = 1$ galaxy fractional effect on the power spectrum of the fluctuation models from the previous section. The dark green curve shows the full model with $t_{Q} = \infty$ and the dark blue dashed curves show just the clustering component only. For the latter, we show models with three different galaxy biases, $b_g = 1.1, 1.5, 1.9$, with this range motivated in the calculations below. We want to compare these to motivated benchmarks for some of the most interesting cosmological parameters. In particular, also shown is the fractional effect of neutrino mass of 0.1 eV on the $z = 1$ galaxy power spectrum relative to the massless case (computed with CAMB; Lewis & Bridle 2002), of a change in the spectral index of scalar potential fluctuations with $n_s \pm 0.01$, and of the squeezed triangle non-Gaussianity parameter with $f_{NL} = 1$ for a comb of bias models again with $b_g = 1.1, 1.5, 1.9$ relative to the gas with $f_{NL} = 0$. We use the expression in Dalal et al. (2008) for the scale dependent bias (see also Matarrese & Verde 2008; Slosar et al. 2008). The values of these parameters are motivated by being comparable or better than current CMB limits (Planck Collaboration 2018) and being at the level achievable with future galaxy redshift surveys (Baldauf et al. 2016).

The shape of the residual fractional imprint from massive neutrinos and $n_s$ variations are different than background fluctuations, and, therefore, we expect the effect of background fluctuations are unlikely to be confused with these effects, though could still introduce bias if not modeled. However, the shape induced by a finite $f_{NL}$ is qualitatively similar to background fluctuations. A survey that aims to estimate the value of $f_{NL}$ may be biased if background fluctuations are not included and marginalized over.

To estimate this bias (and the cost of such marginalization) we use a Fisher Matrix approach (Tegmark 1997), which provides a quick way to estimate the inverse covariance matrix (the Fisher Matrix) of parameter constraints from a measurement (in our case a measurement of $P_g$). This formalism assumes that second-order terms of the Taylor expanded log likelihood ($\mathcal{L}$) of the survey power are sufficient to estimate the errors. The Fisher Matrix of the parameters $p_i$ for a galaxy survey measurement of the power spectrum $P_g(k, z)$ is

$$F_{ij} \equiv -\frac{2}{\sigma^2_p} \frac{\partial^2 \mathcal{L}}{\partial p_i \partial p_j} = \sum_k \frac{1}{\sigma^2_p} \frac{\partial P_p}{\partial p_i} \frac{\partial P_p}{\partial p_j}, \quad (10)$$

where the sum in wavenumber goes over all power spectrum wavenumber bins (also known as “band powers”). The error on a band power owes to a combination of cosmic variance and shot noise:

$$\sigma^2_p = \frac{4\pi^2}{k^3 \Delta \log k} V(z) \left( P_g(k, z) + \frac{1}{n_g(z)} \right)^2, \quad (11)$$

where $V(z)$ is the survey volume, $\Delta \log k$ is the width of the band power bin, and $n_g$ is the galaxy number density. We evaluate the comoving volume for a given redshift as $4\pi \chi(z)^3/3$, where $\chi(z)$ is the comoving distance to redshift $z$. This enables us to explore how the estimated values of $f_{NL}$ change for a survey that would observe the entire comoving volume at a given redshift, but performing the parameter estimation on $k > k_{min}$. Where the minimum wavenumber depends on the survey’s geometry and also can be shaped by survey systematics (like diffuse light from the galaxy).

We want to estimate the bias on $f_{NL}$ for a survey that ignores the effect of background fluctuations. The Fisher matrix allows us to estimate the bias on each parameter $p_i$ via

$$\Delta p_i = \sum_j F_{ij}^{-1} \left( \sum_k \frac{1}{\sigma^2_p} \frac{\partial P_p}{\partial p_j} \Delta P_p \right), \quad (12)$$

where $\Delta P_p$ is the unaccounted effect of intensity fluctuations on the measured galaxy clustering power spectrum. This expression for the bias follows from the optimal quadratic estimator (Bond et al. 1998; Seljak 1998; Bond et al. 2000).

In the simplified analysis presented here to understand the bias for measuring $f_{NL}$, we consider a two-parameter model where $P_g$ is parameterized by the galaxy density bias, $b_g$, at each redshift and by $f_{NL}$ (i.e. the set of the $p_i$ is comprised of only these two parameters). We fix all of the standard cosmological parameters to fiducial values – given by (Planck Collaboration et al. 2016) – as we do not expect that including these in the calculation would change the estimated bias since these parameters have a smaller effect on low wavenumbers affected by intensity fluctuations and $f_{NL}$.

Figure 7 shows how the bias in $f_{NL}$ parameter, $\Delta f_{NL}$, depends on the largest mode probed by a given survey ($k_{min}$). A value of $b_g = -0.05$ was used for the calculation, but this value can be smaller if the response of the cooling rate to photoionizing background is suppressed. However, in the more likely case of number
density weighting or if the halo gas is colder or lower density we found it could be larger. Different colors show the value of $\Delta f_{NL}$ for different values of the halo mass: $5 \times 10^{11} M_\odot$ (blue), $10^{12} M_\odot$ (green) and $5 \times 10^{12} M_\odot$ (red). Using a Sheth-Tormen halo mass function (Sheth et al. 2001), we can match halo mass to both the number density of galaxies and galaxy bias. Moreover, such a formalism predicts a redshift evolution of the galaxy bias and number density. For redshifts $[0.5, 1.0, 2.0]$, as considered in this paper, the biases and number densities are: $b_g(z) = [1.05, 1.29, 2.02]$ and $n_g(z) = [3.9, 3.7, 2.6] \times 10^{-3}$ (h/Mpc)$^3$ for the halo mass of $5 \times 10^{11} M_\odot$; $b_g(z) = [1.16, 1.45, 2.33]$ and $n_g(z) = [2.1, 1.8, 1.1] \times 10^{-3}$ (h/Mpc)$^3$ for the halo mass of $10^{12} M_\odot$; and, $b_g(z) = [1.52, 2.00, 3.39]$ and $n_g(z) = [0.41, 0.51, 0.11] \times 10^{-3}$ (h/Mpc)$^3$ for the halo mass of $5 \times 10^{12} M_\odot$. These estimates depend on the smallest wavenumber used to constrain $f_{NL}$, with its bias $\Delta f_{NL}$ increasing with increasing $k_{\text{max}}$. In Figure 7, and unless otherwise stated, we have assumed $k_{\text{max}} = 0.2$ h/Mpc.

Here we discuss the trends and dependencies in the $f_{NL}$ bias, $\Delta f_{NL}$. The smaller the survey $-$ and hence the larger the value of $k_{\text{min}}$ $-$ the larger $\Delta f_{NL}$, a trend which owes to the relative effect of intensity fluctuations becoming larger towards smaller scales compared to the signal from $f_{NL}$. Moreover, the smaller the halo mass, the larger the effect on $\Delta f_{NL}$. This trend arises from the larger bias of more massive halos and because the effect of $f_{NL}$ is via an additive contribution to the galaxy bias that scales as $f_{NL}(b_g - 1)$. Since bias enhances the signal from non-Gaussianity with respect to intensity fluctuations, the net result is a linear bias that $\Delta f_{NL} \propto (b_g - 1)^{-1}$ and that depends on wavenumber. When the density bias approaches unity, the non-Gaussianity signal vanishes, and $\Delta f_{NL}$ approaches infinity. (In the same regime, however, the estimated error on the $f_{NL}$ parameter $(\sigma_{f_{NL}})$ increases towards infinity. Since both signals depend on the value of this scale-dependent bias contribution to $b_g$, their dependence on $(b_g - 1)$ largely cancels out, and the ratio of $\Delta f_{NL}/\sigma_{f_{NL}}$ remains finite across the transition of $b_g = 1$.) The value of $\Delta f_{NL}$ in our calculations also mildly depends on the number density of galaxies, $n_g$. However, as long as the number density is high enough that the shot-noise contribution in Equation 11 does not dominate on large scales, then the value of $\Delta f_{NL}$ does not vary with $n_g$. Finally, as long as the amplitude of intensity fluctuations is small, i.e. $b_J \ll 1$, then $\Delta f_{NL} \propto b_J$ and so the bias increases linearly with $b_J$.

This bias can be mitigated by marginalizing over possible intensity fluctuation models. When marginalizing over the amplitude $b_J$ assuming the shape of the intensity fluctuation imprint is known, we find that the errors on $f_{NL}$ increase by $53, 42$ and $26\%$ at $z = [0.5, 1, 2]$ respectively. While the shape of $T_f$ is mostly determined by the clustered component of intensity fluctuations, whose wavenumber scaling is known on scales smaller than the mean free path. However, the shape is somewhat affected by the stochastic nature of the sources. To test how the exact shape of $T_f$ influences the results, we have replaced the shape of $T_f$ with a simple $k^{-1}$ scaling for the residuals that is matched to our fiducial model at a wavenumber of $k_p = 0.002$ h Mpc$^{-1}$ (see Figure 6). In this model, the transfer function $T_f$ becomes $T_f(k_p)(k/k_p)^{-1}$.) Using this simple approximation for $T_f$, we recomputed $\Delta f_{NL}$. We find that this approximation reduces the bias $\Delta f_{NL}$ considerably, by a factor of $0.1, 0.2$ and $0.3$ at redshifts of $0.5, 1.0$ and $2.0$ respectively. In conclusion, while ignoring the effect of UV fluctuations can potentially bias the estimated value of $f_{NL}$, including the suggested simple template and marginalizing over $b_J$ considerably reduces bias at the cost of a $\sim 40\%$ larger error on $f_{NL}$.

Figure 6. Residuals of different cosmological effects on the galaxy power spectrum at $z = 1$. The dark green curve shows the absolute value of the fractional change in the power spectrum of our model from Section 6 with background fluctuations sourced by quasars with infinite lifetimes. The thin blue curve shows the result of different line style models, excluding shot noise with $b_g = [1.1, 1.5, 1.9]$ (dotted, solid, dashed). The thin turquoise curve shows our background fluctuations model excluding shot noise with a modified transfer function that scales as $k^{-1}$. The fractional effect on power from neutrinos with a total mass over all flavor eigenstates of 0.1 eV is shown in purple, $\Delta n_\nu = 0.01$ is shown as the pink band, and $f_{NL} = 1$ is shown in orange with $b_g = [1.1, 1.5, 1.9]$ (dotted, solid, dashed).

Figure 7. Bias in the estimate of $f_{NL}$ from a survey which neglects intensity fluctuations as a function of the largest scale probed by the survey, $k_{\text{min}}$. The dashed, solid and dotted curves are $z = 0.5, 1.0,$ and $2.0$, respectively. Different colours correspond to the values for this bias, $\Delta f_{NL}$, when assuming different halo masses (and thus different galaxy biases and number densities $-$ see text for details). The vertical dashed line shows the typical $k_{\text{min}} = 10^{-3}$/h Mpc$^{-1}$ that is assumed in the forecasts of Doré et al. (2014). The bias of intensity fluctuations used is $b_J = -0.05$. The resulting $\Delta f_{NL}$ depends linearly on the assumed $b_J$.

8 CONCLUSIONS

Motivated by the principle that the ionizing background is the only non-gravitational astrophysical process that can affect $\gg 1$ Mpc large-scale structure (LSS) correlations, this paper made estimates for the impact of ultraviolet background fluctuations for various galaxy surveys. In particular, we have focused on efforts that map the diffuse post-reionization 21cm intensity, that select millions of Ly$\alpha$ and H$\alpha$ emitters, and that survey Milky Way-like galaxies.

For the diffuse 21cm radiation from all galaxies, a larger ionizing background results in less H I. While most cosmic H I resides in damped Lyman-$\alpha$ systems that are self shielded to the ionizing background (and, hence, seemingly well protected from fluctuations), we developed three different estimates that suggest that the response of the H I fraction is not insignificant, with our two most realistic estimates finding a $0.25\Delta T/T$ change, where $\Delta T$ is the infinitesimal change in the background photoionization rate. We further find that this response is relatively constant with redshift. We also developed a model for fluctuations in the ionizing background, which, in combination with the response estimates, were used to predict the effect of background fluctuations on galaxy clustering. We estimated a fractional change in the 21cm power spectrum of $\sim [0.03, 0.1, 0.3] (k/10^{-3} \text{Mpc}^{-1})^{-1}$ at $z = [1, 2, 3]$ relative to the case without UV background fluctuations.

We next investigated surveys that target recombination lines, such as Ly$\alpha$ and H$\alpha$ emitter surveys. A larger ionizing background results in an increase in recombination emission, as the number of recombinations is tied to the number of photoionizations. When surveying in intensity mapping mode (to capture recombinations that may occur far from a galaxy), the intensity bias is roughly the ratio of ionizing photons that make it into the background to those that are produced in total. For $z = [1, 3]$, we find a fractional response of $[0.008, 0.03] \times \Delta T/T$. With our model for fluctuations in the ionizing background, we estimated a fractional change in power of $\sim [0.001, 0.1] (k/10^{-2} \text{Mpc}^{-1})^{-1}$ at $z = [1, 3]$ relative to the case without UV background fluctuations. However, for the campaigns that correlate individual galaxy positions (rather than intensity mapping the diffuse background), we find the imprint of intensity fluctuations is likely to be negligibly small.

Finally, we considered how a standard galaxy survey could be affected by ionizing backgrounds. Following work that connects the cooling rate in galactic halos to their star formation rate, we adopted the ansatz that the star formation rate is proportional to the cooling rate of halo gas. Considering motivated ranges for the density of the relevant cooling gas in halos (centered around 200 times the mean density), for gas at $10^6$ K we found a fractional response in the star formation rate of $\sim 0.01 - 0.16 \Delta T/T$, and a resulting fractional change in the galaxy clustering power spectrum of $\sim [10^{-3}, 10^{-2}] (k/10^{-2} \text{Mpc}^{-1})^{-1}$ for luminosity weighting. Number weighting can increase the effects by a factor of a few as well as somewhat smaller temperatures, and the fractional impact increases with redshift owing to the ionizing background fluctuations being larger. Because these calculations relied on the simple ansatz that galaxy observability scales with the cooling of halo gas (and the properties of diffuse halo gas are also poorly constrained), this estimate is more uncertain than our estimates for 21cm and recombination radiation surveys.

For typical responses, the modulation from ionizing backgrounds is generally dominated by the cross correlation between the traditional galaxy clustering signal and the density-tracing component of intensity fluctuations, resulting in a fractional imprint that typical scales as $k^{-1}$ on wavenumbers larger than the inverse of the photon mean free path. We also considered the stochastic contribution to intensity fluctuations from the rareness of the sources. We found that the stochastic term can matter if (1) $b_J \gtrsim 0.1$ resulting in a large coupling to intensity fluctuations and (2) quasars with $> 100$ Myr lifetimes are the dominant contributor to the ionizing background. The former condition was only satisfied for our estimates for 21cm intensity mapping surveys.

The effect of ionizing backgrounds is the only astrophysical contaminant of cosmological correlations on greater than megaparsec scales (as winds from galaxies only travel a limited distance). We compared the spectrum and amplitude of the predicted effects to benchmark cosmological parameter constraints targeted by forthcoming large-scale structure surveys, finding that varying neutrino mass or the scalar spectral index, $n_s$, effect the galaxy clustering power spectrum with a much different spectral imprint than intensity fluctuations. However, the effects of intensity fluctuations are more similar to local primordial non-Gaussianity. We find that measurements of the squeezed-triangle primordial non-Gaussianity parameter $f_{NL}$ using the galaxy power spectrum could be biased by fluctuations in the ionizing background at the level of $\Delta f_{NL} \sim (1 - 3) \times (b_J/0.05)$, near benchmark values for surveys such as SPHEx. However, the value of $b_J$ can be smaller than 0.05 if the response of the cooling rates in galaxies to the intensity fluctuations is suppressed, or larger when considering the selection bias from the number density weighted surveys. This would reflect in smaller, or larger, value of $\Delta f_{NL}$. Our calculations find that marginalizing over a template that scales as $k^{-1}P_s(k)$, almost completely removes this bias, but comes with a cost of 40% larger error bars on $f_{NL}$.

In conclusion, as long as they are not ignored, intensity fluctuations are unlikely to substantially hamper precision cosmology even with futuristic galaxy redshift surveys.

ACKNOWLEDGMENTS

We would like to thank the anonymous referee for their thoughtful comments. We would like to thank Anson D’Aloisio, Andrew Pontzen, and Simeon Bird for detailed comments on an earlier draft. We also thank Sarah Tuttle for helpful discussions. **APPENDIX A: A. MODELS FOR THE RESPONSE OF H I TO A CHANGE IN THE IONIZING BACKGROUND**

In this appendix, we describe our three methods for computing the response of H I to a change in the ionizing background as described in § 4.

### A1 Model based on results of Rahmati et al. (2013a)

This method uses the H I column density distribution from cosmological simulations post-processed with ionizing radiative transfer presented in Rahmati et al. (2013a). The calculations simulate the
LSS, the properties of halo gas, feedback processes, as well as ionizing transfer with complicated geometries. Rahmati et al. (2013a) calculated how the H I in these simulations correlates with the incident ionizing background, finding that the photoionization rate as a function of density is given by the physically-motivated fitting formula

\[
\frac{\Gamma_{\text{HI}}}{\Gamma_{\text{bk}}} = 0.98 \left[ 1 + \left( \frac{n_{\text{HI}}}{n_{\text{HI},\text{SS}}} \right) \right]^{-2.28} + 0.02 \left[ 1 + \left( \frac{n_{\text{HI}}}{n_{\text{HI},\text{SS}}} \right) \right]^{-0.84},
\]

(A1)

where \(\Gamma_{\text{bk}}\) is the background photoionization rate incident upon the absorber, \(\Gamma_{\text{HI}}\) is the photoionization rate which it self shields to, and \(n_{\text{HI},\text{SS}}\) is an estimate for the density of the IGM that starts to self-shield. This density threshold is given by setting \(\Gamma_{\text{HI}} = 1\) and using the following relation from Schaye (2001):

\[
N_{\text{HI}} = 2.3 \times 10^{13} \text{cm}^{-2} \left( \frac{n_{\text{HI}}}{10^{-5} \text{cm}^{-3}} \right)^{3/2} \left( \frac{T}{10^{4} \text{K}} \right)^{-0.26} \times \left( \frac{\Gamma_{\text{bk}}}{10^{-12} \text{s}^{-1}} \right)^{-1} \left( \frac{f_{\mu}}{0.16} \right)^{1/2},
\]

(A2)

which is derived by relating the size and density of absorbers by assuming they have size equal to the Jeans length. Evaluating for \(N_{\text{HI}} = 4 \times 10^{17}\), this gives

\[
n_{\text{HI},\text{SS}} = 6.7 \times 10^{-3} \frac{\sigma_{\text{eff}}}{2.49 \times 10^{-18} \text{cm}^{-2}} \left( \frac{T}{10^{4} \text{K}} \right)^{0.17} \times \left( \frac{\Gamma_{\text{bk}}}{10^{-12} \text{s}^{-1}} \right)^{2/3} \text{cm}^{-3}.
\]

(A3)

These formulae allow one to relate the H I fraction of a system to its density and the ionizing background intensity.

In addition to these formulae, our model requires as input the column density distribution in simulations in the case where the systems’ H I fraction is computed assuming the background is unattenuated, which we take from Rahmati et al. (2013a). (This unattenuated column density distribution is more power-law like, not showing the “break” at \(N_{\text{HI}} \sim 10^{18} \text{cm}^{-2}\) that owes to self shielding. We also use that this column density distribution does not change substantially with redshift (Prochaska et al. 2010), though simulations suggest a mild steepening at \(N_{\text{HI}} \leq 10^{19} \text{cm}^{-2}\) and higher redshifts than considered here.

We utilize equation (A1) to calculate the photoionization rate, \(\Gamma_{\text{HI}}\), which then allows us to calculate the neutral fraction. Using the ratio of the self-shielded to the optically thin neutral fraction, we determine how changes in the background alter the self-shielding threshold and, subsequently, how changes in the photoionization rate affect the neutral fraction. Figure A1 shows the \(z = 3\) background-unattenuated column density distribution function from Rahmati et al. (2013a) (dotted curve) as well as our calculation for the self-shielding column density distribution function using the Rahmati et al. (2013a) fitting formulae (green curve). The magenta dotted curve is the full 3D self-shielding calculation in a cosmological simulation, from Rahmati et al. (2013a). Note that qualitatively the change is similar to our approximate calculation, suggesting that our estimate should be reasonably accurate. The red curve shows how the column density distribution function changes when the global photoionization rate is doubled.

Using the optically thin column density distribution in Rahmati et al. (2013a), a gas temperature of \(10^{4} \text{K}\), and ionizing background photoionization rate of , we calculate the bias as the change in mean cosmic number density of H I dictated by the magnitude of the ionizing background as a function of the photoionization rate and redshift,

\[
b_{J} = \frac{d \log f_{\text{HI}}}{d \log \Gamma} \left( \int dN_{\text{HI}}^{\text{NSS}} f_{\text{NSS}}^{\text{NSS}}(N_{\text{HI}})N_{\text{HI}}(N_{\text{HI}}^{\text{NSS}} | \Gamma, z) \right),
\]

(A4)

where \(f_{\text{NSS}}^{\text{NSS}}\) is the column density distribution with no self-shielding.

### A2 Photoionized slab model

Our second method to calculate how H I responds to the ionizing background models absorbers as semi-infinite slabs. This method lacks the complex 3D geometry of self-shielding systems that is encoded into the Rahmati et al. (2013a) fitting formulae, but makes the ionization physics (which is enfolded in the Rahmati et al. (2013a) fitting formulae) more transparent. These slabs are modeled as infinite in extent and their width is set by the Jeans length. We set the density \(n_{\text{HI}}\) as given by Equation A2 for a given column, and we take the temperature to be \(T = 10^{4} \text{K}\). We perform 1D radiative transfer calculations with the incident radiation oriented perpendicular to the slab, with one ray incident from both sides and the two rays summing to a total incident photoionization rate of \(\Gamma_{\text{bk}}\). The incident background spectrum is modeled as a simple power law of the form \(J_{\nu} \propto (\nu/\nu_{0})^{-\alpha}\), where \(\alpha = 1\) with a cut-off at 4 Ry, motivated by the shape of ionizing background models above 1 Ry (Haardt & Madau 2012). The radiative transfer divides the slab into cells, attenuating the rays as they traverse cells by their neutral fraction during the previous iteration, casting one ray after the other. In each cell, we assume the gas within the cell is in photoionization equilibrium to calculate the neutral fraction that will

![Figure A1](image-url)
be used for subsequent iterations. This calculation is then iterated until the neutral fraction has converged.

This calculation yields a mapping between our initial “no self-shielding” $N_{\text{HI}}^{\text{NSS}}$ and $N_{\text{HI}}^{\text{SS}}$, just as in our calculation based on Rahmati et al. (2013a). Again using the optically thin column density distribution of Rahmati et al. (2013a) we can transform to the optically thick using this calculation, and estimate the response of the H I abundance. The final results of this slab model calculation yields a $0.20\delta\Gamma$ change in the amount of H I when the photoionization rate is increased by a factor of $\delta\Gamma$ for $\delta\Gamma \ll 1$.

This model and that in § A1 assumed the size of the absorber is the Jeans length (Schaye et al. 2000). The Jeans length is only an approximate scale and so, even to the extent this assumption holds, it should only hold to an order unity factor. To understand the sensitivity of our models to this ansatz, we varried the slab width and find that the H I bias changes negligibly ($\sim 1\%$) when varying the assumed width within a factor of two around the Jeans scale.

### A3 Model based on a critical density for self shielding and power-law profiles

Finally, a rough estimate for the impact of ionizing background fluctuations on the amount of H I can be obtained from modeling the self-shielding absorbers as having a single power-law profile and a specific density $\Delta_{\text{SS}}$ above which the gas self shields (Miralda-Escudé et al. 2000; Furlanetto & Oh 2005; McQuinn et al. 2011b). Unlike the previous two approaches, this method does not rely on numerical simulations or the Schaye (2001) model for the density of absorbers. In addition, the approximation that self-shielding occurs at a critical density reasonably agrees with what is found in simulations (McQuinn et al. 2011b), and this power-law model has some success at reproducing the column density distribution of Lyman-limit systems and DLAs (Zheng & Miralda-Escudé 2002).

In this model, the photoionization rate sets the value of $\Delta_{\text{SS}}$ via the relation $\Gamma \propto \Delta_{\text{SS}}^{(7-\gamma)/3}$, where $\gamma$ is the power-law index of the gas density distribution $P(\Delta)$ at $\Delta \gg 1$, where $\Delta$ is in units of the cosmic mean density (see McQuinn et al. 2011b). The mass in HI is proportional to $\int_{\Delta_{\text{SS}}}^{\infty} d\Delta P(\Delta) \sim \Delta_{\text{SS}}^{(7-\gamma)/3} \sim \Gamma_{2}^{(7-\gamma)/9} \sim \Gamma_{2}^{-3/2(1-\beta)}$, where $\beta$ is the spectral index of the column density distribution at optically thin columns ($\gamma$ and $\beta$ are easily related in this model). Thus, the overdensity in H I is related to the overdensity in $\Gamma$ via $\delta_{\text{HI}} = -3/2(1-\beta)\delta\Gamma$ meaning that $b_{f} = 3/2(1-\beta)$ in Equation 2. For $\beta = \{1.3, 1.5, 1.7\}$, the range consistent with observations at $N_{\text{HI}} \sim 10^{17}$ cm$^{-2}$, we find $\{-0.45, -0.75, -1.05\}$. This somewhat larger response than the $[-0.2 - 0.3]$ yielded by our other methods, again suggests that the response is large. The response is likely somewhat weaker than this model predicts because this model does not capture the self-shielding transition well, showing a more abrupt break in the column density distribution (Zheng & Miralda-Escudé 2002).

This paper has been typeset from a T\textsc{eX}e\textsc{l}P\textsc{X} file prepared by the author.
