Waste not, want not: CO₂ (Re)cycling into Block Polymers

A new way to combine two different polymerisation reactions, using a single catalyst, results in efficient block polymer synthesis. The selective polymerisation of mixtures of L-lactide-O-carboxylic anhydride and cyclohexene oxide, using a di-zinc catalyst in a one-pot procedure, allows the preparation of poly(L-lactide-b-cyclohexene carbonate). The catalysis quantitatively recycles the carbon dioxide released during polyester formation into the subsequent polycarbonate block.

Aliphatic polycarbonates (PC) and polyesters (PE) are attracting attention as sustainable alternatives to petrochemicals.¹⁻³ Many are biodegradable, recyclable and biocompatible and some are sourced from renewable resources.⁴⁻⁶ Here, block polymers comprising polylactide (PLA) and poly(cyclohexene carbonate) (PCHC) are targeted as they allow combination of two of the most widely studied materials in each class.²,⁶,⁷ PLA is a commercially produced biodegradable plastic, which is sourced from biomass and at end-life can be recycled or biodegraded.⁴ It serves as a replacement for petroleum derived plastics in sectors including packaging, house-hold goods, automotive and biomedicine.⁴,⁵ One limitation is its poor temperature stability, for example semi-crystalline PLA has a moderate glass transition temperature (Tg) (~60 °C), which prevents applications at higher temperatures.⁸ PCHC is a widely investigated amorphous polymer produced by CO₂/cyclohexene oxide copolymerisation and, because of its rigid carbonate and ring structures, shows a higher Tg value (110-120 °C).⁶ Here, a new catalysis concept is explored as a means to deliver block polymers which in future may result in improved polymer thermal and mechanical properties. In this vein, several groups have already demonstrated the enhanced performances for PLA-b-PCHC but almost all these block polymers were prepared by sequential addition methods or by tandem catalysis.⁹,¹⁴ Inspired by the enhanced properties of these block polymers, we investigate an alternative method to prepare them which couples together two different polymerisation cycles (Scheme 1). Our one-pot synthetic strategy targets PLA synthesis using the controlled ring opening polymerization (ROP) of O-carboxylic anhydride (L-LA-OCA). The ROP is driven by release of ring-strain and results in the release of a molecule of CO₂ per polymer repeat unit.¹⁵,¹⁶ We reasoned that it might be possible to recycle the emitted carbon dioxide using controlled epoxide/CO₂ ring opening copolymerisation (ROCOP) to produce PCHC.

ROCOP is thermodynamically driven by epoxide ring-strain and several catalysts are reported showing rapid CO₂ insertion rates.⁶,⁷,¹⁷ Indeed, some of us have already reported high activity di-nuclear ROCOP catalysts which are effective at low pressures (1 bar) of CO₂.¹⁸⁻²¹ Here, a di-zinc catalyst is targeted that is straightforward to prepare and which shows a zeroth order in CO₂ pressure over the range 1-40 bar.²²,²³

Scheme 1. Proposed polymerisation pathway whereby the di-zinc catalyst bridges two catalytic cycles: LLAOCA ROP and CO₂/CHO ROCOP. Where [Zn] represents [LZn(OAc)₂] during catalysis; R = initiating group and P = growing polymer chain.

Thomas and co-workers had previously reported N-carboxy anhydride ROP that produces polypeptides in a tandem catalytic process and the released CO₂ was used to make cyclic carbonates.²⁴

Inspired by this intriguing recycling opportunity and with polymerisation catalysts in hand known to operate under low CO₂ pressures, we proposed a single catalyst could be used in a switchable process to deliver block polymer product (Scheme 1).

Firstly, [LZn(OAc)] was assessed for the ROP of L-lactide-ocarbonyloxane (OCA) in THF as model for subsequent processes in neat epoxide (Table 1). The OCA ROP was successful resulting in the formation of PLLA polymer over 16 h (Fig. S1, S2). The 1H NMR spectrum of the crude showed ~97% conversion to PLLA (Figure S1, S2). The isolated PLLA was analysed by 1H{[1]H} and 13C{[1]H} NMR spectroscopy, the former showed a single resonance at 5.16 ppm corresponding to PLLA and confirming there was no significant epimerisation (Fig. S3, S4). The isolated polymer showed a molar mass of 4300 g mol⁻¹ and narrow dispersity (D = 1.15) (Fig. S5 (a)). Having established the success of the di-zinc catalyst for OCA ROP, its potential to recycle the liberated CO₂ was tested using an equimolar mixture of THF and CHO (Table 1).

[a] All the polymerisations were conducted in a 15 mL Schlenk tube in THF, THF-CHO mixture or neat CHO, [LZn(OAc)₂][LLAOCA] = 500, [LLAOCA] = 1.25 M, [LZn(OAc)₂] = 0.2 mol%, at 80 °C. [b] Determined by 1H NMR spectroscopy from the normalized integrals for resonances from LLAOCA (1.76 ppm) and PLLA (1.56 ppm). [c] Determined by 1H NMR spectroscopy of the crude polymer from the normalized integrals for resonance from PLLA (1.56 ppm) and PCHC (4.92-4.18 ppm). [d] Determined by 1H NMR spectroscopy, Mₘ₉₀₀ = [(LLAOCA Conv x 72)÷(PCHC Conv x 142)]/2, [e] Determined by SEC in THF, calibrated with narrow polydispersity polystyrene standards. [f] Polymerisation conducted in THF, [LZn(OAc)₂][LLAOCA] = 500, [LLAOCA] = 1.25 M. [g] Polymerisation conducted in THF-CHO mixture with [LZn(OAc)₂][LLAOCA][CHO] = 1/500/500, [LLAOCA] = 1.25 M in THF-CHO mixture. [h] Molar mass values are corrected by multiplying by 0.58.

A reaction at relative molar loadings of 1:500:500 ([Zn]:CHO:LLAOCA) was stopped after 16 h and showed complete OCA consumption. Both the rate of formation and the molar mass of the PLLA formation were similar to the reaction conducted in neat THF, confirming that the epoxide did not interfere with the OCA ring-opening polymerisation. Nonetheless, there was no evidence for any polycarbonate formation and we reasoned this was likely due to the low overall epoxide concentration. For this di-zinc catalyst, the epoxide/CO₂ rate law is first-order in epoxide concentration and thus rates should increase at higher epoxide concentrations.

All subsequent experiments were conducted using the same catalyst: monomer loadings but in neat epoxide. In order to systematically study the reaction, a series of experiments were conducted at different reaction times (Table 1). Over the first hour, the reaction proceeds only with OCA ROP as clear from the reaction stopped after ~10 mins which showed 23% conversion to PLLA but no resonances for PCHC or any other by-product (e.g. cyclic carbonate). After an hour, the complete OCA conversion to PLLA had occurred and there was ~8% conversion to PCHC as apparent from a growing resonance at 4.65 ppm in the 1H NMR spectrum. Reactions were quenched from 1 - 48 h and showed progressively increased conversion to PCHC, with the final reaction delivering ~91% CO₂ conversion (Table 1). The reaction analysis indicated that there was a high catalytic selectivity, with OCA ROP occurring prior to CO₂/epoxide ROCOP.

To establish that block polymers rather than mixtures of homopolymers formed, the polymer products were analysed by GPC. The reactions showed progressively increasing molar mass with conversion to PCHC and of the final polymer sample showed a molar mass of 13,500 g mol⁻¹ with the corresponding highest CO₂ incorporation. The 1H NMR spectra shows resonances at 5.10-4.95 ppm and 4.93-4.76 ppm which correspond to junction units between the ester and carbonate blocks (Fig. S6). Low intensity resonances at 74.67 ppm and 71.81 ppm, in 13C{[1]H} NMR spectrum of isolated PLLA-b-PCHC, are also attributed to methine junctions (Fig. S7). The block polymer structure was further indicated by HMBC NMR spectroscopy which confirmed junction unit assignments and was consistent with previous reports of PLLA-b-PCHC copolymer prepared by the sequential addition routes (Fig. S8). The polymer DOSY NMR spectrum showed a single diffusion coefficient for all resonances, as expected for a block polymer, whereas a physical mixture of the two homopolymers shows two different diffusion coefficients (Fig. S9, S10).

Overall, the analyses indicated that the catalytic process proceeded in a sequential manner and delivered a block polymer product. To improve understanding and allow kinetic analysis, reactions were repeated using both in situ 1H NMR and in situ ATR-IR spectroscopies. For these experiments, known concentrations of monomers and catalyst, with mesitylene as an internal standard, were reacted in a Y Young NMR tube in an NMR spectrometer at 80 °C. The NMR spectra were acquired at regular intervals over 53 h. Monomer conversions were determined by analysing the normalized integrals of selected signals. The monomer conversion/time plot shows clearly that OCA ROP occurs fastest and is complete in around 3.5 h (Fig. 1). At this stage of the reaction there is no evidence for any formation of PCHC or cyclic carbonate. Furthermore, there is a linear fit to the data which indicates an apparent zero order in OCA concentration (kobs = 1.08 x 10⁻⁴ s⁻¹) (Fig. S11). After the OCA has been completely consumed, there is a steady increase in the concentration of polycarbonate and low quantities (~3%) of trans-cyclohexene carbonate (CHC) by-product. The formation of trans-CHC occurs by back-biting of the growing
polymer chain, and, in this case, becomes more prominent at the later reaction stages. This increasing by-product formation is attributed to progressive depletion of CO\(_2\) resulting in the catalytic cycle resting at the metal-alkoxide intermediate (which is the precursor to trans-CHC). It should be emphasised that overall the reaction is highly selective, yielding up to 91% of CO\(_2\) to block polymer and only 9% of cyclic by-product.

One limitation of NMR analysis is that the system cannot be stirred and this raised concerns that the block selectivity might arise from CO\(_2\) diffusion limitations. To test the relevance of this factor, the reaction was also monitored using \textit{in situ} ATR-IR spectroscopy in a Schlenk tube equipped with an ATR-IR probe and with magnetic stirring. Changes in intensity of characteristic IR absorptions were monitored including for CO\(_2\) (2340 cm\(^{-1}\)), LLAOCA (1184 cm\(^{-1}\)), PLLA (1191 cm\(^{-1}\)) and PCHC (1237 cm\(^{-1}\)) (Fig. 2). Initially, the LLAOCA resonance showed a decrease in intensity and there were concomitant increases to the resonances assigned to PLLA and CO\(_2\). Over these time periods, there was no intensity for the resonance attributed to PCHC, substantiating the selectivity observed by NMR spectroscopy. Only after the complete consumption of the LLAOCA resonance was there any intensity for the signals attributed to PCHC.

Both findings are fully consistent with the \textit{in situ} \(^1\)H NMR studies and suggest that the selectivity is independent of CO\(_2\) diffusion since rates are broadly the same with or without stirring.

In terms of reaction pathway, the process is proposed to operate via two distinct catalytic cycles which are bridged by a common zinc-alkoxide intermediate (Scheme 1). MALDI-ToF analysis of the PLLA homopolymer showed chains were end-capped with a cyclohexyl acetate end group (Fig. S14). This finding is consistent with initiation occurring via ring-opening of a cyclohexene oxide molecule to produce the key zinc-alkoxide intermediate. This intermediate can propagate LLAOCA ring opening polymerisation. Polymerisation of the LLAOCA is proposed to proceed by elimination of a CO\(_2\) molecule and re-generation of a zinc-alkoxide with each monomer insertion. At this stage it is unclear precisely why the high selectivity for block polymer formation arises. It could be that a minimum pressure (concentration) of CO\(_2\) is required to allow the ROCOP process to occur, a notion which is consistent with previous studies that at pressures below 1 bar CO\(_2\) the ROCOP reaction shuts down. On the other hand, it could be that the LLA zinc-alkoxide intermediate is stabilized by formation of a 5-membered chelate, a finding in line with other ROP catalysts. It is clear that the CHO/CO\(_2\) ROCOP does not occur until the complete consumption of the LLAOCA. It is also apparent that nearly all the
released CO$_2$ can be recycled to yield the PLLA-b-PCHC block polymer.

Differential Scanning Calorimetry (DSC) was used to determine the thermal properties of PLLA-b-PCHC polymers (Table S3, Fig. S15). All materials showed higher glass transition temperatures ($T_g$) (61-78 °C) than PLLA and values which correlate with the wt. % of PCHC in the polymer. Switchable catalysis using vinyl-CHO and LLAOCA yielded a related block polymer: PLA-b-PVCHC as did the reaction between L-phenyl lactic acid O-carboxyanhydride (LpheLAOCA) and CHO (Table S2). These polymerizations indicate that the selective catalysis may be more generally applicable and could deliver other block polyester-carbonates in future.

In summary, a new catalytic process starting from mixtures of OCA and epoxide selectively produced poly(L-lactide-b-cyclohexene carbonate). The CO$_2$ emitted in one polymerisation reaction (OCA ROP) is efficiently recycled into the second polycarbonate block. The catalysis is highly selective and permits near quantitative consumption of the carbon dioxide. Although at an early stage, the process appears promising both from the point of view of CO$_2$ utilization and as means to modify properties of oxygenated polymers. Further research to investigate the detailed polymerisation mechanism, to expand the range of catalysts and to apply it to other monomers is recommended.
